The *urine* in chronic nephritis varies in its characteristics depending upon the degree of activity of the disease In the latent phase, albuminuria may be minimal or marked and cylindruria is variable and by arbitrary definition red blood cells in the urinary sediment if present at all are few in number When the nephritis is active red blood cells are numerous and the urine has the characteristics of that seen in acute nephritis it may be smoky in appearance or even grossly bloody Microscopic hematuria may be recurrent and transient in nature or it may persist over a period of years In general cases in which red blood cells persist in large numbers run a relatively rapid course However the writer has seen one patient who under almost constant observation showed persistent and marked microscopic and at times macroscopic hematuria for twelve years before she succumbed to her disease In the nephrotic phase of chronic nephritis the urine contains large amounts of albumin whereas red cells while frequently numerous are at times present in only small numbers thus making it difficult in the latter case to distinguish it from true nephrosis As nephritis progresses and usually when the kidneys have become reduced in size through extensive fibrosis the specific gravity becomes fixed between 1 008 and 1 012 In this advanced stage albuminuria cylindruria and microscopic hematuria frequently decrease strikingly The late changes in renal function receive their physiologic explanation through the fact that few glomerular units are capable of function and tubular degeneration prevents normal reabsorption and secretion

As the ability of the kidneys to concentrate gradually diminishes the patient compensates for this physiologic defect by increased thirst and increased ingestion of fluid *Nocturia* i e nocturnal polyuria ensues and occasionally constitutes the pre-

senting symptom in patients whose disease has progressed silently to an advanced degree

Renal function may decrease rapidly and a patient may die in uremia in the course of a few months following the onset of the disease On the other hand in many cases of chronic glomerulonephritis there may be normal renal function for many years as measured by the usual tests Thus the ability to concentrate is gradually impaired and the urea clearance decreases as does the excretion of phenolsulfonphthalein or other dyes As impairment of function advances particularly if the fluid intake of the patient be restricted accumulation of the end products of nitrogen metabolism gradually takes place over a period of many months In other patients the specific gravity of the urine may remain fixed for months or years without associated nitrogen retention and then either with or without the development of cardiac insufficiency or in the presence of infection or after an operation renal decompensation may occur rapidly and the patient dies in uremia in the course of a few weeks In exceptional cases severe renal decompensation as indicated by nitrogen retention may be present for years For example the author had a patient who after six years of active glomerulonephritis proved postmortem reached a point where her excretion of phenolsulfonphthalein in two hours was nil her blood urea was 90 mg per 100 cc and her creatinine was 6 mg per 100 cc She worked most of the time during the next six years and annual observations showed persistence of her markedly impaired renal function with further accumulation of urea in the blood Late in her disease she had also an acidosis which is common terminally These cases of prolonged renal insufficiency when they occur early in childhood produce *dwarfism* associated with osteoporosis and are inappropriately described as *renal rickets* The nature of the chemical disturbances occurring in advanced nephritis is discussed in the section on uremia

Diagnosis —The diagnosis of chronic glomerulonephritis is usually simple and is based on the continued presence of albuminuria cylindruria and varying degrees of microscopic hematuria either with or without extrarenal manifestations of the disease Under a number of circumstances however the diagnosis is difficult and yet it is important from a practical standpoint as prognosis and therapeutic indications may depend upon it It has already been pointed out that the differential diagnosis between acute nephritis and an exacerbation of chronic nephritis is at times impossible Nevertheless marked enlargement of the heart extreme degrees of hypertension thickened and tortuous arteries changes in the eyegrounds severe anemia marked lowering of the serum proteins and fixations of the specific gravity of the urine point definitely to a chronic process although they do not in rare instances preclude the possibility of the acute form with a subsequent favorable outcome The differentiation of the nephrotic phase of chronic glomerulonephritis and true nephrosis is also difficult In both of these depression of the basal metabolic rate lipemia hypoproteinemia with inversion of the albumin globulin ratio and heavy albuminuria occur Marked elevation of the blood pressure enlargement of the heart gross or marked microscopic hematuria and changes in the eyegrounds make chronic glomerulonephritis the more likely diagnosis The age of the patient also lends some significance as true nephrosis among adults is extremely rare That even these criteria at times fail is apparent from the fact that among the writer s patients was a boy of fifteen who was proved at autopsy to have pure nephrosis despite the elevation of blood urea to 100 mg per 100 cc the fact that his blood pressure reached a level of 160/100 and that occasional red cells were present in the urinary sediment The differentiation between orthostatic albuminuria and nephritis has been discussed in conjunction with acute nephritis

In all patients presenting the picture of advanced renal insufficiency the possibility of renal disease other than nephritis must be borne in mind Bilateral pyelonephritis with or without stones bilateral renal tuberculosis hydronephrosis due to ureteral or prostatic obstruction and advanced polycystic disease of the kidneys may all terminate in uremia Hence when confronted with advanced renal disease in which the etiology is not certain it is often impossible to characterize the renal lesion without

knowledge of the natural history of the dis ease and the application of the appropriate urologic techniques

Prognosis—The prognosis in chronic glomerulonephritis is ultimately bad but the speed with which the disease reaches its fatal termination is extremely variable It is practically impossible to estimate the probable life span of a patient on the basis of a single set of clinical observations and tests of renal function and it is not infrequently difficult to estimate it even with the aid of repeated observations over a period of months or years For example a patient may be seen in an acute exacerbation of the disease and then may enter the latent phase and lead a normal and useful existence for many years before his disease reaches the uremic state On the other hand another patient may have nephritis of apparently identical severity and yet his disease may progress to its termination in a few weeks or months Despite these discouraging comments there are features of the disease which distinctly facilitate prognosis When the disease is ac companied by persistent and marked micro scopic hematuria it usually ends fatally in months or at best in a few years If the dis ease is accompanied by progressive elevation of the blood pressure the outlook for more than a few years is poor When progressive cardiac insufficiency develops a return to a more benign course is distinctly unusual The presence of choked disks arterial changes hemorrhages and exudate in the eyegrounds offers as a rule a prognosis of less than two years The progressive devel opment of anemia likewise indicates that an advanced stage of the disease has been reached Pericarditis when it occurs devel ops terminally Single tests of renal function except relatively late in the course of chronic glomerulonephritis offer little of prognostic value but repeated observations made in the course of the disease may reveal a curve indicating the velocity of its progression When the urea clearance is reduced to minimal values when the excretion of phenolsulfonphthalein is virtually zero and nitrogen retention increases progressively the prog nosis can usually be measured in months instead of years It must be recognized how ever that there are exceptions to the general statements as is shown by the writer s patient who was able to continue work for six years after her excretion of phenolsulfon phthalein and the level of blood urea and creatinine suggested a prompt demise An other patient whose blood urea was 500 mg per cent and who had profound anemia left the hospital after treatment with trans fusions and infusions and worked for eight months before death occurred

Treatment—In the latent stage of chronic nephritis there are no therapeutic indications other than warning the patient against overfatigue and ridding him of ob vious foci of infection particularly in the upper respiratory tract Certainly dietary restriction is not indicated when the only pathologic manifestations consist of albu minuria and cylindruria Patients in this phase of the disease should be instructed to seek medical aid if symptoms or signs de velop and they should be seen by their phys ician routinely at perhaps yearly intervals in order to have the status of their disease appraised This annual survey should in clude examination of the urine a blood count blood urea and serum protein deter minations as well as a physical examination with emphasis laid on the heart blood pres sure eyegrounds and presence of edema Abnormalities found in the course of these studies may necessitate the instigation of active therapeutic measures If activity develops as determined by hematuria par ticularly if associated with edema and hypertension bed rest is indicated and the treatment is that of acute nephritis The patient should be urged to remain in bed at least until the generalized signs have dis appeared and if possible until microscopic hematuria becomes minimal

In the nephrotic phase also bed rest is indicated as this tends to inhibit the devel opment of edema It is in this phase of chronic glomerulonephritis that the most definite indication for dietary regulation is encountered Rigid salt restriction and the incorporation of enough protein in the diet to maintain nitrogen equilibrium constitute the basic principles involved The custom of forcing the protein intake beyond the body requirements in the writer s experience has failed to attain its theoretical end namely that of raising the serum protein level Addis believes that it is of vital importance to

keep the protein of the diet at the lowest possible level compatible with nitrogen equilibrium In the opinion of the writer the evidence presented does not warrant this rigid restriction of protein Details of this aspect of therapy are discussed in conjunction with the nephroses Patients in the nephrotic state are especially susceptible to infection of the respiratory tract and should be protected from exposure

The symptomatology associated with hypertension is particularly distressing to patients The *headaches* sleeplessness nervousness and irritability are trying Sedatives particularly chloral hydrate and bromide in small doses are useful in the treatment of these symptoms Daily periods of rest and the avoidance of unnecessary physical exertion which may add further cardiac strain are also of great importance as is the prevention of obesity through dietary restriction Regulation of the bowels and even free catharsis in addition to the use of analgesics should be resorted to in the treatment of hypertensive headaches The treatment of hypertensive encephalopathy has been discussed in the section on acute nephritis

Cardiac insufficiency whether incipient or outspoken demands bed rest and the principles involved in its treatment are those which apply to cardiac decompensation in general The problem of fluid regulation is difficult because rigid limitation is indicated in congestive heart failure whereas with renal insufficiency enhanced by the inability to concentrate the liberal ingestion of fluid should be maintained to curb nitrogen retention In such a situation the treatment of the cardiac insufficiency deserves first consideration and moderate restriction of fluid perhaps to 1500 cc a day may be tried Salt restriction and a cardiac diet with an allowance of about 50 Gm of protein a day should be employed Digitalis and sedatives are indicated as in other congestive disorders of the heart In the presence of an elevated venous pressure and especially when associated with pulmonary edema phlebotomy may afford relief This procedure naturally has no place when anemia is present The use of diuretics particularly the mercurials is contraindicated in the presence of renal insufficiency as these substances not infrequently induce hematuria or anuria While cardiac insufficiency causes some depression of the excretion of phenolsulfonphthalein as well as of urea its effect on renal function is not extreme For example if the phthalein' excretion in two hours is less than 30 per cent and if the blood urea is higher than about 75 mg per 100 cc it is probable that nephritis is present in addition to congestive heart failure In these cases of cardiac decompensation where the integrity of the kidney is in doubt the employment of diuretics should be undertaken only with extreme caution

The treatment of the *anemia* of chronic nephritis is both important and difficult Profound anemia contributes to weakness cardiac insufficiency edema and probably to the degree of renal failure The effects of large doses of iron and of liver extract are notoriously disappointing as might be anticipated from the fact that the anemia is essentially aplastic in type Where the anemia is hypochromic perhaps due to hemorrhage some benefit may be expected from iron therapy Transfusions offer the best results but these should be given slowly If hypertension or cardiac insufficiency be present it is desirable to have venous pressure determinations made during transfusions in order that pulmonary edema may be avoided

Pregnancy as a rule and for reasons unknown intensifies chronic glomerulonephritis If pregnancy is not interrupted many patients either abort or develop a toxemia after the fifth month On the other hand a certain number of women are able to reach term and are delivered of healthy babies despite the presence of chronic glomerulonephritis In deciding whether or not pregnancy should be terminated each case should be considered individually If the patient s desire to continue pregnancy is great her request should be granted with the understanding that premature labor may have to be induced promptly if the blood pressure rises edema increases or other signs of toxemia begin to appear

The problems concerned with the management of advanced nephritis are discussed in the section on uremia

ROBERT F LOEB

ARTERIOLAR NEPHROSCLEROSIS

Hypertensive vascular disease terminates in cerebral hemorrhage cardiac insufficiency or uremia In this section we are concerned with that 10 per cent of patients whose disease leads to renal insufficiency The term 'arteriolar nephrosclerosis is applied to involvement of the renal area by hypertensive vascular disease giving rise to disturbances in renal function associated with the development of a clinical picture identical with chronic glomerulonephritis

Etiology and Mechanism —The etiology and mechanism of hypertensive vascular disease are unknown Consequently it is not surprising to find innumerable theories concerning this subject Thus the endocrine glands have been implicated because hypertension constitutes an important part of the clinical picture in the Cushing syndrome due to basophilic adenoma of the pituitary gland as well as in certain cases of tumor of the adrenal glands Pressor substances derived from kidneys rendered ischemic by means of Goldblatt clamps have been isolated in the dog by Braun Menendez and by Page The importance of the elaboration of hypertensin from renin in human hypertensive disease has, however not been definitely established Reflexes associated with mechanical obstruction of the cerebral and renal circulations have also been considered as initiating factors in the disease Direct toxic action of unknown substances derived from unknown sources has been assumed to injure the arterioles and hypertension has been considered secondary to these changes The importance of any or all of these factors in the development of the clinical and histologic picture of hypertensive vascular disease either with or without involvement of the renal area is still obscure

It is probable that the clinical pattern seen in arteriolar nephrosclerosis represents a syndrome rather than a disease entity because of the diverse nature of disorders with which it may be associated For example in one instance it represents the aftermath of pyelonephritis in childhood in another it may develop with lead intoxication in still another it may appear in the course of chronic glomerulonephritis or secondary to pregnancy In the majority of cases it begins insidiously and apparently as a vasospastic phenomenon without a recognized relation to other disease processes

Predisposing Factors —*Arteriolar* nephrosclerosis occurs most frequently in middle age, although it may occur at any age after the first decade When it develops in the second and third decades it is more apt to be acute in its nature and to run a fulminating course The distribution among the sexes shows a slight preponderance among females perhaps because pregnancy frequently appears to play a role in the disease Lead and arsenic poisoning and pyelonephritis are at times either predisposing or inciting factors There is a strong familial tendency toward hypertensive vascular disease and the so called "sthenic type' appears to be particularly susceptible

Pathology —Two general types of lesions are encountered in the kidneys in nephrosclerosis The differences in these types are related to the velocity with which the disease has progressed to its termination, but whether they are due solely to the speed of the morbid process or whether two different mechanisms are involved is not known When the progression of hypertensive vascular disease is slow and the patient dies of renal insufficiency after many years the term benign nephrosclerosis is employed in contradistinction to malignant nephrosclerosis In the latter form the patient succumbs in a few months or perhaps in a year or two In dogs Goldblatt has been able to produce the exact prototype of benign and "malignant' hypertensive disease by applying lesser or greater constriction to the renal arteries by means of special clamps

Postmortem the kidneys from a patient with slowly progressive arteriolar nephrosclerosis are usually smaller than normal the surface is roughly granular brownish red in color and adherent to the capsule On section the cortex is irregularly narrowed Histologic examination reveals extensive thickening of the arterioles with narrowing of their lumina The intima shows marked widening and there is reduplication of the elastic lamellae The glomeruli may show striking changes The basement membrane

of the tufts is first thickened and the glomeruli are frequently ischemic In other glomeruli the tufts are hyalinized and the parietal epithelium becomes markedly thickened by fibrous tissue The *tubules* degenerate and in time tubular elements may become cystic or entirely disappear The *interstitium* shows marked fibrosis From this brief description of the histologic changes in the so-called benign form of arteriolar nephrosclerosis it may be seen that the picture closely resembles that present in advanced glomerulonephritis As a matter of fact it is frequently impossible to state on the basis of gross or microscopic study whether the glomerular changes are secondary to arteriolar lesions or whether the reverse is true

In cases of arteriolar nephrosclerosis which have run a rapid course (the so called malignant type) the changes described above are present in varying degrees and superimposed are those thought to be characteristic of the malignant form The kidneys in these cases may be contracted or they may be normal in size or even slightly enlarged The surface is more or less granular and hemorrhages are common The cortex is usually narrowed to varying degrees Microscopic examination reveals the changes already mentioned in the arterioles but in addition necrosis and endarteritis are present Rupture of degenerated arterioles is not uncommon The glomeruli show cellular proliferation as well as swelling and droplet formation The tubules show varying degrees of degeneration and the lumina may be filled with cellular detritus and blood These changes in the tubules and glomeruli are also seen in chronic glomerulonephritis although in the latter disease they are usually more diffuse

Clinical Picture.—The clinical picture of arteriolar nephrosclerosis is dominated by the various manifestations of hypertension For months or years depending upon the rate of evolution of the disease the urine shows no abnormalities Then if cardiac or cerebral complications do not first terminate the disease albuminuria and cylindruria of varying degrees appear In this stage hypertension alone with the symptoms and signs attending it serves to distinguish the disease from glomerulonephritis in the latent phase If the progress of arteriolar nephrosclerosis is rapid the picture of rapidly advancing nephritis appears within a few months If the disease is of the 'benign type renal function may not be compromised for many years despite the persistence of albuminuria Sooner or later however the clinical picture seen in advanced glomerulonephritis makes its appearance Observations made early in the course of the disease may give the only clue as to whether a patient with advanced nephritis is suffering from arteriolar nephrosclerosis or from chronic glomerulonephritis For example if hypertension is known to have been present before the appearance of albuminuria the diagnosis of nephrosclerosis is obvious whereas in chronic glomerulonephritis albuminuria precedes the development of hyper tension The nephrotic syndrome with marked depression of serum proteins and inversion of the albumin globulin ratio also serves as a distinguishing feature since it does not occur in arteriolar nephrosclerosis *e g* the serum protein concentration was found to be greater than 5 per cent in sixteen of seventeen patients dying of the disease at the Presbyterian Hospital *Edema* occurs in about 70 per cent of patients with nephrosclerosis and is due either to associated cardiac insufficiency or to the fact that the remaining glomeruli are incapable of function adequate to maintain water balance

It is often stated that the presence of *hematuria* either gross of microscopic is much more characteristic of glomerulonephritis than of nephrosclerosis but of forty six patients dying of the latter condition three had gross hematuria and red cells were found microscopically in the urine of thirty two It can be shown statistically that the *degree of hypertension* tends to be greater in nephrosclerosis than in chronic glomerulonephritis In the Presbyterian Hospital series of patients with nephrosclerosis examined postmortem twenty six of thirty seven patients had a systolic pressure above 230 mm mercury Thus the incidence of hypertension of this order of magnitude is greater in this group than in the corresponding group with chronic glomerulonephritis However in an individual patient the blood pressure level can have no differential diag

nostic significance The blood pressure shows wide fluctuations depending upon the mental state and the amount of physical activity, but, as the disease progresses, the favorable effect of rest becomes less apparent *Cardiac hypertrophy* occurs with great regularity in arteriolar nephrosclerosis and tends to be slightly greater in degree than in chronic glomerulonephritis *Dyspnea* and *congestive heart failure* with or without pulmonary edema are equally common in both diseases *Headache* as might be anticipated is one of the commonest complaints and was present in 80 per cent of the series studied postmortem at the Presbyterian Hospital It varies in intensity as is true in glomerulonephritis The *eyegrounds* showed definite arterial changes in over 90 per cent of the Presbyterian Hospital series Exudate hemorrhages and papilledema were each present at some time in about 70 per cent of the patients dying of arteriolar nephrosclerosis Many statements in the literature suggest that the retinopathy of arteriolar nephrosclerosis may be differentiated with great regularity from the changes present in chronic glomerulonephritis with hypertension but in the experience of the writer this is not the case The *anemia* associated with advanced nephrosclerosis may be of the same severity and type as that present in glomerulonephritis although it appears to occur a little less frequently Disturbances in *renal function* are naturally dependent upon the extent of the arteriolar nephrosclerotic process, but when the disease progresses to an advanced stage the loss of the ability to concentrate the depression of urea clearance and excretion of phenolsulfonphthalein and the retention of the end products of nitrogen metabolism occur just as in late glomerulonephritis

Diagnosis—The diagnosis of arteriolar nephrosclerosis is suggested by the development of hypertension with the subsequent appearance of albuminuria and cylindruria terminating in uremia The difficulties both clinical and pathologic encountered in differentiating this disease from chronic glomerulonephritis have been discussed They are of only academic importance as the prognosis and therapy of both disorders are essentially the same when that stage is reached in which identical physiologic disturbances are present

It should be kept in mind that arteriolar nephrosclerosis may be associated with lead poisoning Theoretically one might expect improvement in the vascular disease with the treatment of saturnism, but practically no alleviation has been noted Arteriolar nephrosclerosis may result from pyelonephritis and when this is suspected urologic studies may clarify the diagnosis Unfortunately when the stage of arteriolar nephrosclerosis has been reached the mechanism of its production alters neither therapy nor prognosis The variation in the velocity of its course has already been discussed in connection with the terms benign and "malignant' forms

Prognosis—Patients suffering from arteriolar nephrosclerosis die eventually of uremia unless cardiac insufficiency or cerebral hemorrhage terminates the disease It has been pointed out that the disease may be rapidly progressive, running its course in a few months or it may progress gradually over a period of many years In a number of cases the disease may change its nature abruptly the slow progress of the so called benign form becoming accelerated and the rapid downhill course of the so called malignant type then leading to uremia in the course of some weeks

As is also true of glomerulonephritis no prognosis can be given on the basis of a single series of observations unless the picture of advanced nephritis is present In the absence of demonstrable renal insufficiency, it is frequently impossible to prognosticate the course of arteriolar nephrosclerosis even with observations extending over some years The height of the blood pressure is occasionally ascribed to have prognostic significance but the rate of progression of renal insufficiency can in no way be correlated with the degree of hypertension For example the writer had a patient whose blood pressure at thirty three years was 268/160 Her eyegrounds at this time showed arteriolar changes and her urine contained a little albumin This patient was seen regularly over a period of twelve years after which time her blood pressure was still above 250 mm mercury Her urine continued to show only a very faint trace of albumin her blood

urea was normal and at autopsy (death resulting from cerebral hemorrhage) only moderate nephrosclerosis was present

Treatment —In the absence of any specific therapy the medical treatment of nephrosclerosis resolves itself into the management of hypertension and of chronic nephritis both of which are discussed elsewhere in this volume

In recent years a variety of surgical measures has been introduced in the treatment of hypertensive vascular disease The most promising of these consists in the resection of the splanchnic nerves How much permanent relief may be afforded by this method of treatment and how much it may influence the progression of arteriolar nephrosclerosis cannot be stated at this time Nevertheless in selected cases this approach to therapy appears to offer the patient more than does the alternative laissez faire attitude

ROBERT F LOEB

MISCELLANEOUS NEPHRITIDES

Acute Interstitial Nephritis —This constitutes an anatomic rather than a clinical entity and is characterized by a diffuse infiltration of the renal interstitium with red blood cells polymorphonuclear cells and lymphocytes Edema of the tissues may be present also There are no characteristic glomerular or tubular lesions This disorder of the kidneys is usually associated with severe sepsis or with diphtheria and constitutes a postmortem finding without known clinical significance

Transfusion Nephritis —This type of nephropathy (not nephritis) usually follows transfusion from a donor whose blood is incompatible with that of the recipient although occasionally no incompatibility can be demonstrated by the usual methods of blood grouping There is usually a chill after transfusion The patient then may have hemoglobinemia or hematuria and jaundice may appear In the next twenty four to forty eight hours oliguria complete anuria and edema make their appearance The classic picture of uremia develops and may end fatally in ten to twenty days A number of patients recover spontaneously even though almost complete anuria persists for ten to twelve days Anatomic examination reveals that the kidneys are swollen Histologically the capsular spaces and more particularly the tubules are found to be filled with precipitated hemoglobin The glomerular tufts are often ischemic and the interstitium is edematous Large amounts of alkali given by mouth before anuria develops may inhibit the precipitation of hematin in the tubules Other therapeutic measures are palliative

Focal Nephritis —Probably most cases of so called focal nephritis (characterized by albuminuria cylindruria and microscopic hematuria without extrarenal signs and symptoms) are either true glomerulonephritis as has been intimated elsewhere or they are embolic in nature appearing in the course of infection In other cases probably nephritis is not present at all and the albuminuria cylindruria and microscopic hematuria merely represent the result of increased capillary porosity occurring in febrile disease

Syphilitic Nephritis —Recently Rich has described a characteristic histopathologic picture in the kidneys of a number of patients with tertiary syphilis These changes consist in a diffuse infiltration of the interstitium with lymphocytes macrophages and plasma cells The process characteristically shows encroachment of these cell accumulations upon the tubules in which there may be deposits of cholesterol crystals In later stages scarring of the interstitium atrophy of tubules and hyalinization of glomeruli take place The clinical picture in these cases is indistinguishable from certain cases of chronic glomerulonephritis or from cases of arteriolar nephrosclerosis If the etiology of an existing nephritis could be established as syphilitic active specific therapy might alter the course of the disease In patients presenting the clinical picture of arteriolar nephrosclerosis combined with syphilis iodide therapy and small doses of arsphenamine may be administered cautiously with the patient under constant observation If microscopic hematuria or albuminuria increases or if edema or nitrogen retention appears treatment should be discontinued

Arteriosclerotic Nephritis —Arteriosclerosis of the larger branches of the renal

artery at times gives rise to areas of fibrosis in the renal parenchyma characterized on gross examination by large depressed scars It is extremely rare to find the functioning renal tissue reduced by this degenerative process *per se* to the point of serious renal insufficiency even though the kidney reserve may be definitely compromised

THE NEPHROSES

The term 'nephrosis' was suggested in 1905 by Friedrich Mueller to designate such degenerative lesions in the kidney as could not properly be called nephritic *i e* inflammatory Since he did not include the degenerative vascular lesions, the word nephrosis came to imply disease of the renal tubules With this purely histologic connotation numerous clinical conditions known to cause such tubular damage have been classified as types of nephrosis In clinical circles however the purely morphologic approach has fallen into disuse and a more physiologic concept has taken its place The nephrotic syndrome rather than tubular degeneration of the kidneys is now the common denominator in classifying the nephroses This would seem to be an appropriate development, for the life history of mercurial poisoning for example bears no resemblance to that of true nephrosis and whereas the etiology of the former is clear that of the latter is wholly unknown There is little to be gained, therefore by grouping them together in a textbook of medicine under a single diagnostic term

If the presence of the nephrotic syndrome be accepted as the essential criterion, the nephroses include (1) *true or lipoid nephrosis* (2) *the nephrotic stage of chronic glomerulonephritis* (3) *amyloidosis of the kidney* (4) *syphilitic nephrosis* The nephrotic stage of glomerulonephritis has been discussed in relation to that disease Syphilitic nephrosis occurs during the secondary and tertiary stages of the infection and in recent years has been extremely rare at the Presbyterian Hospital in New York City This may be due to the widespread recognition of early syphilis and its adequate therapy Further mention of this entity will be found in the section on syphilis Amyloid disease also is discussed elsewhere

The Nephrotic Syndrome—The nephrotic syndrome may be defined as a clinical state characterized by the presence of edema albuminuria and decreased serum albumin There is usually in addition, an elevation in the blood cholesterol concentration and not infrequently a lowered basal metabolic rate This picture as outlined above is seen chiefly in amyloidosis of the kidneys during a stage of chronic glomerulonephritis and in true or lipoid nephrosis These conditions are grouped together because of their correlation to a common physiologic mechanism *viz* the Starling hypothesis rather than on the basis of a similarity in the histopathology of the renal tubules The first clinical application of the Starling hypothesis as an explanation of the formation of edema in nephrosis was made by Epstein in 1917 He pointed out that a low serum protein implied a lowered plasma osmotic pressure and that thereby the equilibrium between capillary blood pressure and plasma osmotic pressure at the capillary wall was altered in a direction that would further the collection of fluid in the tissue spaces It was subsequently proved by many workers that this decrease in serum protein is relatively greater in the albumin than in the globulin fraction Since the albumin molecule is much smaller than the globulin molecule it exerts a proportionally higher osmotic pressure consequently its loss from the blood stream will cause an even more serious diminution in plasma

osmotic pressure than was originally suspected There can be no doubt that this lowered osmotic pressure plays an important role in the production of edema in the nephrotic syndrome Although the validity of this mechanism in the nephrotic syndrome is unquestioned there are other factors that play a role factors less clearly appraised chief of which is the state of the capillary wall While the evidences of widespread capillary change seen in acute glomerulonephritis are not usually observed in the nephrotic group there are changes in the fluid equilibria in nephrosis which are unaccompanied by parallel changes in the osmotic pressure (protein per cent) of the plasma and for which alteration of the capillary wall would by exclusion seem to be the probable determinant

It has become increasingly apparent that the serum proteins are qualitatively altered in the nephrotic state Several analytic approaches have contributed evidence in support of this thesis Among the methods applied are electrophoretic studies precipitin reactions to specific immune sera and quantification of amino acid content particularly cystine It has not yet been demonstrated that the intrinsic composition of their serum proteins can serve to differentiate the various nephroses

Long before the importance of changes in plasma osmotic pressure was emphasized the influence of sodium chloride ingestion upon fluid exchange had been noted For years the chloride ion was assigned the chief role in the production of edema Blum showed later that whereas sodium chloride led to an increase in edema potassium ammonium or calcium chloride exerted the opposite effect sodium bicarbonate acted similarly to sodium chloride These observations pointed to sodium as the more significant electrolyte and modern work has amply confirmed Blum s investigations The present concept of the relationship of sodium to the accumulation of edema is based on the assumption that no extracellular fluid can exist in the tissues without a skeletal framework of sodium Edema fluid cannot be pure water Hence if a tendency to edema is present (due for example to a decreased serum *albumin*) restriction of sodium will tend to inhibit the production of edema On the other hand easy availability of sodium will accelerate the process other things remaining equal Thus it is obvious that the well known palliative effect of salt restriction on individuals suffering from the nephrotic type of edema has no peculiar specificity but is a benefit indigenous to salt restriction in any form of edema that is not dependent upon seepage through an altered capillary wall

The nephrotic syndrome regardless of its fundamental clinical cause has two important therapeutic approaches sodium restriction and dietary protection of the plasma protein concentration The latter may be accomplished by appropriate investigation of the food habits of the patient and the addition of adequate amounts of protein containing foods when necessary There is little evidence however to indicate that protein ingestion when forced to abnormal levels produces a significant increase in the protein content of the plasma Indeed, it is possible to induce a positive nitrogen equilibrium over long periods of time without any change in the serum protein Furthermore in spite of the consistently low concentration of amino acids in the blood of these patients parenteral administration of amino acids in adequate amounts does not influence the level of serum albumin In striking contrast to the futility of high protein diets in the nephrotic syndrome is the quick response to a normal diet when the low serum protein level is due to malnutrition

Physicians have for some years limited the intake of sodium chloride in edema The value of such therapy is no longer debatable but it is well to remind the reader that thorough sodium restriction includes not only the omission of salt in cooking but also the avoidance of sodium bicarbonate in all forms, both dietary and medicinal

DANA W ATCHLEY

TRUE OR LIPOID NEPHROSIS

Definition and Incidence—True nephrosis is a chronic disease of variable duration in which the nephrotic syndrome exists without evidence of glomerulonephritis or amyloid disease Although some writers have

denied that there is such a separate entity asserting that careful histologic search will demonstrate glomerular damage, an increasing volume of opinion is sustaining the opposite point of view The good prognosis the peculiar susceptibility to pneumococcus infections the higher incidence in children and the entire lack of renal histopathology early in the course are characteristics not to be found in other examples of the nephrotic syndrome It is only fair to add however that satisfactory differential diagnosis may require many months of observation

Nephrosis is a rare disease in adults During thirteen years of an active special clinic for the study of renal disease only three or four cases were discovered On the other hand the pediatrician finds that while it is not a common disease in children it is in no sense a rare one There is no known sex predominance nor have any facts as to racial or geographic distribution entered the literature

Etiology and Pathogenesis—The relationship to infection seen in glomerulonephritis and amyloidosis does not appear to exist in true nephrosis and indeed no convincing etiologic hypothesis has ever been propounded Moreover, no unifying mechanism capable of explaining all the characteristic features is apparent in these cases As has been stated the decrease in plasma osmotic pressure is one of the forces tending to produce edema and the hypothesis that this depletion of plasma albumin is dependent upon its loss as albumin in the urine has been widely accepted The numerous suggestions in explanation of the albuminuria need not be detailed but it should be pointed out that the urine can contain albumin in nephrosis with no determinable histologic abnormality in the kidney While there is a gross statistical correlation between serum protein levels and daily output of urinary albumin closer analysis of individual cases leads to real doubt as to the probability that this is the only factor tending to decrease serum albumin in nephrosis The failure noted above of individuals suffering from nephrosis to rebuild serum albumin in the presence of a positive nitrogen balance is further proof that the albuminuria alone cannot explain the blood changes

The high blood cholesterol and the presence of lipoid deposits in the kidney have caused some writers to suggest that true nephrosis is the result of an obscure disturbance in lipoid metabolism This has led them to designate it as "lipoid nephrosis" An hypothesis that would satisfactorily elucidate the mechanism of such pathogenesis has not been advanced

Pathologic Anatomy—It has been conclusively proved that early in the course of true nephrosis there is no histologic change in the kidney This is true even when the full blown clinical picture is present Later in the disease the convoluted tubules of the kidneys are often dilated their cells show more or less advanced degenerative changes and large quantities of lipoid substances may be deposited in them These lipoids are often doubly refractive There is so much disagreement as to the "typical" histopathology of the glomerulus in true nephrosis that it hardly need be mentioned in a brief textbook discussion The changes in the tubules are definite in the glomeruli variable and slight There are no consistent changes outside the renal area and the cardiovascular system remains quite normal except for scattered atheromatous plaques

Clinical Picture—The average case of true nephrosis (and there is little deviation from this average) is characterized chiefly by the insidious development of generalized edema first gravitational and later an anasarca with fluid in the serous cavities There are no typical symptoms other than the mental and physical discomfort dependent on the monotonous and interminable existence of distended water logged tissues The duration of the disease varies from a few weeks to a few years but the patient eventually recovers and in most instances remains permanently well There may be several remissions during the course of the disease but the albuminuria rarely disappears until the cure is complete Fatal outcome when it occurs is usually due to secondary infection particularly invasion by the pneumococcus peritonitis being the common complication There is little doubt that the sufferer from true nephrosis has some specific lack of resistance to this organism

Physical examination in cases of true nephrosis is negative except for massive edema

Arterial blood pressure is rarely elevated but occasional readings above 150 mm (systolic) do not necessarily imply the presence of glomerulonephritis

The *urine* always contains large quantities of albumin There may be few or many white blood cells but rarely red blood cells Casts may or may not be found Doubly refractile lipoid bodies are seen in the urinary sediment in many of these cases They are not of special diagnostic significance for they appear in the nephrotic stage of glomerulonephritis also

Chemical examination of the *blood* uniformly reveals a low total serum protein content (usually below 4 per cent) and partition of these proteins shows that the serum albumin is greatly reduced with little accompanying change in the globulin fraction Lipemia in individuals with albuminuria has long been observed Bright in describing a typical patient said The serum is milky There is an increase in both fats and lipoids but for practical purposes an estimation of blood cholesterol is the most satisfactory clinical test Most cases have more than 200 mg per cent of cholesterol in the blood while some may have above 1000 mg Blood urea and total nonprotein nitrogen concentrations are normal in most cases but a transient elevation of blood urea is not evidence against the diagnosis of true nephrosis Serum chlorides are above normal if altered at all whereas sodium and bicarbonate concentrations are little changed The erythrocyte sedimentation rate is greatly increased This is probably dependent on the changes in the protein and lipoid contents of the plasma and cannot be interpreted as evidence of infection

The lowered *basal metabolic rate* so commonly a part of the clinical picture of nephrosis occurs also in the nephrotic stage of glomerulonephritis and its significance is not well understood in either relation Patients with this finding can take large quantities of thyroid extract with very little effect on their disease or in some cases on the basal metabolic rate itself

Diuresis may occur spontaneously or a remission may follow an unrelated intercurrent infection such as tonsillitis It should be noted that these remissions may occur with little or no change in the serum protein levels a fact which indicates that other forces than those dependent upon a lowered osmotic pressure must play a role After the edema has gone it is usually apparent that great loss of weight has taken place At times the convalescent patient is genuinely emaciated Part of this weight loss may be due to loss of appetite a complication not infrequently seen in prolonged cases where the patients become greatly discouraged with the apparently endless edema

Differential Diagnosis —True nephrosis may be confused with amyloidosis of the kidney the nephrotic stage of glomerulonephritis syphilitic nephrosis and nutritional edema The nutritional group is easily distinguished by the history and the quick response to adequate diet The Wassermann test and other clinical manifestations of syphilis help in the diagnosis of syphilitic nephrosis as does the fact that the beneficial response to antiluetic therapy may be striking In amyloidosis of the kidney there is usually some other manifestation of amyloid disease or the focus of infection causing amyloid changes is so apparent that classification is relatively easy If further diagnostic aid is required an estimation of the rate of disappearance of congo red from the blood stream is helpful This substance when injected intravenously in appropriate amounts disappears very rapidly in cases of amyloidosis The rate is accelerated in true nephrosis also but when 60 per cent or more has vanished in one hour it is valuable evidence in favor of extensive amyloid infiltration

The most difficult differential diagnosis and one that at times is impossible is that between true nephrosis and the nephrotic stage of glomerulonephritis A satisfactory past history of acute glomerulonephritis contemporary evidence of acute glomerulonephritis (hematuria or red blood cell casts) or signs of advanced chronic glomerulonephritis (hypertension anemia decreased renal function) would eliminate any indecision But many of the individuals with glomerulonephritis display every part of the pattern observed in true nephrosis with no evidence whatsoever of renal damage other than albuminuria Then the final outcome of the disease gives the sole answer Sooner or later the patient who has uncomplicated neph

rosis is likely to recover but if he develops terminal uremia, the underlying process is glomerulonephritis

Prognosis —As has been stated the prognosis *of true nephrosis is relatively* good The writer has seen the duration of the disease vary from several weeks to several years In spite of their susceptibility to secondary infection over half of the patients recover and remain well Although other infections do occur, a large majority is due to the pneumococcus and peritonitis due to this organism is a common complication The use of chemotherapy in the treatment of pneumococcal infections will probably alter most favorably the mortality statistics in this disease

Treatment —The general treatment suggested above for the nephrotic syndrome is advisable in true nephrosis viz adequate protein intake and rigid sodium restriction Sodium chloride and sodium bicarbonate are in common use both in food and as home remedies in either instance they should be carefully excluded The so called salt substitutes are usually sodium salts of organic acids and are therefore likewise to be avoided Moderate restriction of water intake is probably helpful As was pointed out when discussing the nephrotic syndrome excessive protein feeding has not altered the serum protein levels in our experience Protein restriction however is obviously contraindicated for the protein needs of the *nephrotic patient are somewhat increased* by the excessive loss of protein in the urine

The value of bed rest is a practical judgment to be made in the individual case according to the amount of edema and general well being of the patient Thyroid administration is a common custom when the basal metabolism is low It is difficult to see any benefit from it in the average case The apparent hypothyroidism seems to follow the course of the disease rather than to participate in its initiation

When an *extreme degree of edema in itself* produces symptoms *diuretics* may be used The most effective type of such therapy is found in the combination of a saline diuretic (ammonium chloride 3 to 6 Gm a day) with a mercurial diuretic (salyrgan or mercupurin at weekly intervals) If these drugs fail to induce a diuresis their use should be promptly discontinued in order to avoid mercurial poisoning Typhoid vaccine intravenously may cause a marked loss of edema in analogy to the diuresis occurring after acute infection Sweats and purges are useless and, indeed may be harmful An attempt to restore blood protein by transfusions is of little help and the beneficial effect of increasing plasma osmotic pressure by means of infusions of gum acacia is only transient

The crucial therapeutic problem in true nephrosis has been the prevention and treatment of the various pneumococcal infections to which these individuals are so peculiarly susceptible Most of the deaths in this disease have been caused by pneumococcal pneumonia peritonitis or sepsis The introduction of chemotherapy is undoubtedly the most hopeful recent contribution to the treatment of true nephrosis

The use of concentrated human serum (lyophil serum) is in an experimental stage and opinions as to its safety and value differ so greatly that its application to the treatment of nephrosis cannot be recommended at this time

UREMIA

Definition —Uremia may be defined as a clinical pattern associated with renal insufficiency and nitrogen retention Although the uremic syndrome rarely occurs without evidence of maximal impairment of renal function it *has nevertheless* been long recognized that extreme degrees of nitrogen retention may not be accompanied by uremic symptoms and that there is no

constant correlation between the degree of nitrogen retention and the severity of the symptoms The renal insufficiency can be derived from any of the various ources of kidney damage such as nephritis bilateral renal infection mechanical obstruction of the ureters polycystic kidneys poison etc

The uremic state manifests itself in many ways but, for purposes of exposition one may indicate two major types of effect on the organism In one group are found the relatively well understood physiologic com plications of advanced renal insufficiency acidosis dehydration and disordered calcium metabolism On the other hand there are a large number of symptoms and signs that are apparently toxic in origin although the nature of these poisons has defied analysis In this latter group are found such phenomena as headache vomiting itching of the skin pericarditis and anemia

Manifestations Due to Renal Insufficiency.—The *acidosis* which occurs when the kidneys are damaged is dependent upon the important role that the kidney plays in relation to the acid base regulatory mechanism of the body The normal kidney has the faculty of manufacturing ammonia to serve as base for the acids that must be eliminated via the renal route In this way inorganic base is saved and the excretion of excess acid is furthered Phosphate excretion also aids in this process by virtue of the kidney s ability to form urine in which the ratio of the acid sodium phosphate to the alkaline phosphate is higher than that which occurs in the blood When the kidney fails to synthesize adequate amounts of ammonia and phosphate excretion is pathologically diminished two of the important stabilizing forces of the acid base equilibrium are impaired and acidosis occurs The blood CO_2 is then diminished and hyperpnea may result Severe acidosis augments certain of the toxic symptoms such as anorexia and nausea The electrolyte balance is altered in the same direction by loss of sodium Such base loss is not uncommon and is due in part at least to the polyuria caused by loss of the power of urinary concentration

Sodium depletion and the loss of water which occurs with it as part of hyposthenuric polyuria lead to *dehydration* one of the commonest and most distressing symptoms in uremia Anorexia and vomiting markedly augment this tendency Replacement of salt and water in such an event offers an unusually fruitful type of therapy in this distressing syndrome

The serum calcium levels in uremia are often significantly below normal This change is ascribed to the increased phosphate content of the blood and may also be due to a lessening of the percentage of plasma protein if such decrease be present Obvious clinical *tetany* is an occasional complication to be found in the uremic state and certain workers feel that much of the muscular irritability and convulsive tendency is due to a disturbed calcium metabolism It should be noted that the concentration of ionized calcium can be diminished when the total amount appears normal by ordinary clinical determination Tetany may be precipitated very easily in severe uremia by relatively small doses of sodium bicarbonate given to combat acidosis

Urea retention is the most classic physiologic result of renal insufficiency It is by definition always present in uremia and may play a minor role in the causation of such symptoms as headache and nausea Ingestion experiments on human subjects do produce such effects but the blood urea concentrations in uremia evince no consistently parallel relationship to these symptoms Creatinine uric acid amino acids and other end products of protein metabolism are retained in the blood in uremia Their individual or collective relationship to the development of the syndrome is still in doubt

"Toxic" Manifestations.—It would be impossible to report the varied investigations devised to discover the poison that seems to play such an important role in uremia Urea was the first chemical entity proposed but it has long since been discarded as of no etiologic significance Various extracts derived from the blood of patients suffering from this syndrome have been injected into animals and certain toxic effects have been ascribed to them however no convincing solution has yet been presented The consensus of opinion mainly on inferential grounds is that the etiologic agent includes probably many end products of protein

metabolism such as the phenols and guanidine and is the summation of several components

The earliest and most *characteristic symptoms* of the uremic state are weakness and anorexia The patient tires easily and finds active life an increasing effort Anorexia is an important influence favoring weight loss *in fact it may be the only cause of the emaciation* seen terminally Nausea and vomiting are constantly lurking in the background and when vomiting finally appears it is difficult to control

Headaches may appear early, but while they are not infrequent their severity has been somewhat overemphasized Most uremic individuals however complain of dull sensations scarcely painful in the cerebral area

Disturbances in the mental state are varied and when present they offer evidence of an advanced disease Restlessness and insomnia may be practically uncontrollable in one individual whereas another will remain in deep coma Muscular twitching or convulsions are further evidence of central nervous system involvement although tetany may be responsible for a certain amount of muscular hyperirritability It is possible that the itching of the skin should be classified with the symptoms related to the nervous system

Stomatitis diarrhea with ulcerative colitis and membranous lesions of the larynx and trachea are occasional examples of the widespread damage that can appear in the uremic state

Severe *anemia* appears at some time in most cases of uremia It is not benefited by the liver extract which is specific for pernicious anemia Iron administration is equally futile Hemorrhagic tendencies are occasionally seen in severe cases *Pericarditis* is a common late complication No evidence of bacterial infection is available to explain the mechanism of the inflammatory changes It would seem to be another example of toxic damage

The clinical picture of uremia is hardly a characteristic one There may be only one symptom or sign or many Indeed nearly all of the various manifestations that have been enumerated may exist together In addition cardiac insufficiency coronary disease cerebral accidents and visual damage may appear due to underlying glomerulonephritis or hypertensive vascular disease

Extrarenal Uremia —This term has in recent years been applied to those conditions in which renal function is inhibited by a decrease in blood flow through the kidney dependent in most cases upon a contraction of circulating blood volume Dehydration and shock are the commonest clinical conditions producing this entity

Pseudo uremia —It is necessary to interrupt discussion of the uremic state in order to mention a syndrome of headache hypertension convulsions and other cerebral manifestations that occur in two diseases more or less unrelated This syndrome may be confused with true uremia but careful differentiation is necessary for proper prognosis and therapy In acute glomerulonephritis there may develop a rapid elevation of blood pressure accompanied by severe headache papilledema nitrogen retention coma or convulsions This condition is believed by some to be dependent upon edema of the brain It usually yields promptly to such measures as intravenous hypertonic glucose solutions phlebotomy or even lumbar puncture The oral and parenteral administration of magnesium sulfate represent another effective therapeutic approach Pseudo uremia is not a bad prognostic sign if the patient survives the immediate attack in fact such cases seem to evolve less often into chronic glomerulonephritis

The other example of false uremia is seen in hypertensive vascular disease It is less explosive in form here than when it is found in acute glomerulonephritis Headaches retinal pathology and convulsions may occur but nitrogen retention is not a necessary or very frequent accompanying sign There may be other cerebral manifestations such as personality and memory changes or transient paralyses and the suggestion that there are alterations in the cerebral circulation due to vascular spasm or actual damage seems reasonably supported by the evidence at hand Fishberg uses the term hypertensive encephalopathy to cover both the pseudo uremia of acute glomerulonephritis and of hypertensive vascular disease on the assumption that they have a common pathogenesis

Prognosis —The prognosis of true uremia is dependent upon the underlying cause of renal insufficiency When this cause is amenable to treatment as in the case with prostatic obstruction the outcome is favorable When however the basic problem is insoluble as in the case of chronic glomerulonephritis or nephrosclerosis the onset of uremia is an indication that a fatal termination is not far distant An increase in blood urea levels may precede such an outcome by many years and during the course of the disease *correlate quantitatively in a most* unsatisfactory manner with the seriousness of the condition Retention of creatinine on the other hand is found more frequently in the terminal stages of uremia and hence is a bad prognostic sign Other unfavorable manifestations are severe anemia pericardial friction rub or convulsions Prognosis as to duration of life should be very guarded for an occasional patient who apparently is in the terminal stage will have a long remission

Treatment —Therapy in uremia is wholly palliative An understanding of the disturbed physiologic mechanisms suggests certain rational therapeutic approaches If a patient is depleted of salt and water replacement should be effected by intravenous or subcutaneous saline solutions A saline infusion of 1500 cc will often prove of extraordinary benefit but cardiac damage is so common a complication of the uremias that it is necessary to exercise great care not to overload the heart The infusion should be given slowly and be constantly supervised for signs of heart failure When possible the function of the right heart should be measured by frequent venous pressure observations during the course of the injection A rapid rise in venous pressure indicates the necessity for changing from the intravenous to the subcutaneous route In the presence of manifest cardiac insufficiency clysis is the preferable technic The parenteral administration of salt solution should continue until urine volume is definitely increased or the appearance of edema proves that the fluid intake has exceeded the kidney s remaining functional capacity to excrete water The chief indication for active treatment of acidosis is the presence of distressing hyperpnea It may occasionally be combated by the ingestion of bicarbonate of soda by mouth although great caution should be employed to avoid the production of vomiting or alkalosis In the presence of nausea the parenteral route of administration is preferable Tetany is an indication for intravenous calcium therapy (calcium chloride 10–20 cc of a 5 per cent solution), and some clinicians recommend the use of this therapy for twitching and convulsions even when tetany cannot be proved Loss of concentrating ability by the kidney necessitates a *constantly high fluid intake in order to* maintain an adequate urine volume Fluid intake therefore should be carefully regulated

The dietary problem in uremia consists chiefly in overcoming a more or less severe anorexia Any food that will interest the patient without upsetting his gastric equilibrium is valid material for his menu One should strive for a normal well balanced intake Effective protein restriction requires such an increase in total calories that it is rarely feasible and indeed is of little therapeutic value at best No degree of salt restriction is indicated in the absence of edema

The only effective treatment for the anemia is transfusion The use of this expensive procedure in a purely palliative role is a matter for practical decision in relation to individual problems Usually liver extract and iron do not help the uremic patient suffering from anemia

One of the most perplexing situations that can arise in the treatment of uremia is found in the incorrigibly restless patient Fortunately this is an infrequent complication Large doses of chloral hydrate bromides barbiturates morphine and hyoscine may be of little or no avail Even intravenous paraldehyde may be of only temporary aid

When cardiac insufficiency complicates the uremic state all other therapy must be considered secondary to the treatment of this defect It is unwise however to bleed a uremic patient with anemia unless a grave emergency exists Digitalis morphine and oxygen are used here in a fashion identical with that recommended in the absence of renal insufficiency

Purgation colon irrigation and sweating are not only incorrect in theory but *in many*

instances are actually harmful to the very sick patients subjected to these drastic measures

ANOMALIES AND MALFORMATIONS OF THE KIDNEYS

Definition —Anomalies of the kidney include deviation from the normal in number structure, and position the result of arrested or faulty embryonic development

Etiology —The metanephros, or permanent kidney develops from a bud on the posterior wall of the wolffian duct and the metanephrogenic cap of mesoblast The former grows cephalad and forms the ureter kidney pelvis and by dichotomous branching the collecting ducts From the latter develop the convoluted tubules Failure of union of these with the collecting ducts has been postulated as a cause for congenital cystic kidney, but this is probably erroneous The kidney pelvis is opposite the second lumbar vertebra in a 9 to 10 mm embryo and very nearly maintains this position in the adult With the straightening of the back and development of the pelvic curvature there is a tremendous lengthening of the ureter often spoken of as the ascent of the kidney The various anomalies of the kidney can be traced to interruption or aberration of development they are more common in males and tend to run in families

Morbid Anatomy —For purposes of description anomalies may be divided into those of number structure and position *Bilateral absence* (agenesis) of the kidneys is rare and of course incompatible with extra uterine life *Congenital absence of one kidney* is found about once in 1000 autopsies is more common in males and on the left side The ureter is usually absent The solitary kidney is hypertrophied and often diseased The presence of both kidneys should always be established before nephrectomy as more than one patient has died from the removal of a solitary kidney *Hypoplasia* of one kidney is not uncommon Only about forty two cases of *supernumerary* kidneys have been reported

The important abnormalities of form are due to fusion of the kidneys which may be at the upper or, more commonly, the lower poles (*horseshoe kidney*) throughout (*cake kidney*), or the upper pole of one kidney may be fused with the lower pole of the other Persistence of *fetal lobulations* is common and of no significance *Polycystic kidney* (*q v*) should also be included among congenital malformations

One (usually the left) or both kidneys may lie in the true pelvis or in the iliac fossa (*ectopic kidney*) When such an ectopic position is congenital the ureter is short and is distinguished from movable kidney by this fact and the fact that it cannot be replaced in the normal position Occasionally both kidneys lie on the same side of the spine *Aberrant blood vessels* are extremely common but only of surgical interest except when they cause hydronephrosis by pressure on the ureter

Anomalies of the ureter are not infrequent and include bifurcation at times with two pelves complete double ureter implantation in an abnormal position in the bladder or other part of the lower genito urinary tract

Symptoms —The frequency of renal anomalies (8 per cent of routine autopsies) and the increased susceptibility to disease of anomalous kidneys indicate its clinical importance Symptoms are usually due to infection stone or obstruction and are apt to become manifest in early adult life rather than in childhood A horseshoe kidney may occasionally give rise to abdominal symptoms due to pressure of the isthmus on vessels and viscera A pelvic kidney may interfere with parturition

Diagnosis —A presumptive diagnosis of an ectopic or fused kidney can sometimes be made by palpation of a mass Intravenous or retrograde pyelography however is essential for accurate identification

Treatment —In horseshoe kidneys division of the renal isthmus and nephropexy may give relief from abdominal pain Plastic operations or removal of diseased anomalous kidneys in isolated instances have been beneficial The advent of the modern urinary antiseptics has given better control of in

fections but complete cure of the infection is difficult where drainage is poor

CIRCULATORY DISTURBANCES OF THE KIDNEY

Chronic passive congestion occurs most frequently in association with chronic myocardial disease occasionally from obstruction of the inferior cava or from pressure upon the renal veins themselves *Infarcts* may arise from thrombosis in the course of senile atherosclerosis but are usually due to embolism They appear as wedge shaped lesions with the apex toward the medulla either uniformly red or with a gray necrotic center and hemorrhagic border Healed infarcts are represented by deep scars Symptoms of small infarcts are often lacking or are overshadowed by those of acute infection or endocarditis Larger ones give rise to sudden pain in the flank and hematuria There is no special treatment and the prognosis is good as far as the kidney is concerned except when one of the main renal arteries is blocked Multiple large bilateral infarcts occasionally result in sufficient destruction of renal tissue to lead to uremia *Bilateral cortical necrosis* of the kidney is a rare condition occurring usually in the toxemias of pregnancy but occasionally during infectious diseases or after trauma The cortex of both kidneys is yellowish greasy and necrotic sprinkled with hemorrhages and accompanied by thrombosis of the intralobular arteries The symptoms are anuria or marked oliguria albuminuria hematuria and nitrogen retention The etiology is unknown but has been ascribed to vasomotor disturbances with vasoparalysis and secondary thrombosis

NEPHROPTOSIS

(*Movable Kidney*)

Definition —The normal kidney is not fixed but moves slightly with respiration and with change of bodily position These normal movements are slight When the displacement is sufficient to allow the lower pole to be palpated on inspiration the kidney is said to be *movable* With greater degrees of mobility the kidney may descend so that the fingers meet above it or it may fall as low as the iliac fossa *Floating kidney* is one which has become intra abdominal and has acquired a more or less complete peritoneal covering Movable kidney is to be distinguished from ectopic kidney which is congenital and which cannot be replaced in the renal fossa

Etiology —Constitutional factors are important These include a shallow paravertebral fossa often associated with a long flat chest narrow subcostal angle and ptosis of other viscera (Glenard s disease) defects in the perirenal fascia and lack of perirenal fat Faulty posture relaxed abdominal wall following pregnancy and repeated trauma from coughing straining etc are contributory causes Increase in the size of the kidney from polycystic disease or tumor often leads to its displacement Nephroptosis occurs in about 20 per cent of women and 2 per cent of men rarely during childhood most frequently between twenty and forty years of age In women the right kidney is movable about five times as frequently as the left while in men one side is as frequently affected as the other

Morbid Anatomy —A movable kidney may be perfectly normal and symptomless When pathologic changes occur they are the result of interference with the blood supply or kinking of the ureter and are due to congestion or to hydronephrosis

Symptoms —The great majority of movable kidneys give rise to no symptoms Many patients particularly women who present

vague gastro intestinal, dyspeptic or nervous symptoms have a movable kidney But the relation of such complaints to the kidney is highly problematical and frequently calling the patient s attention to the kidney only aggravates the symptoms The degree of mobility has no relation to the type or severity of symptoms These are due to disturbance of the blood supply giving congestion and pain, or to obstruction of the ureter The pain is a dull ache or dragging sensation located posteriorly in the loin or in front over the kidney and is relieved by lying down It may not be present in the morning but comes on during the day and is aggravated by exercise menstruation and constipation Less commonly the pain is acute colicky severe and associated with nausea and vomiting or symptoms of shock retention of urine and increase in the size of the kidney (*Dietl s crisis*) When the occlusion of the ureter is relieved the pain ceases abruptly and is followed by the passage of large quantities of urine Occasionally colicky pain of similar severity may be due to twisting of the kidney pedicle with obstruction of the renal veins Other symptoms accompanying movable kidney as fever pyuria and frequency are due to complicating infection or to stone

Diagnosis —The position and mobility of the kidney are determined bimanually with the patient both recumbent and standing Intravenous pyelography with films taken in two positions is helpful More important than the determination of mobility is the question whether it is the cause of symptoms Urinalysis is of little help for it is usually normal When symptoms are of renal origin they are relieved if the kidney is replaced or can be reproduced by injecting fluid into the ureter Dietl s crises must be differentiated from attacks of renal colic due to stone the rarity of hematuria and frequency of polyuria at the end of an attack in the former and the shadow of the stone on the x ray film in the latter usually suffice

Treatment —In the majority of cases no treatment is necessary When symptoms are definitely related to the kidney an effort should be made to return it to its normal position and keep it there Postural exercises increased diet in an effort to add to the perirenal fat and an abdominal belt with or without a special pad below the kidney are conservative measures which are often successful Pyelitis, if present should be treated Surgical fixation (nephropexy) which fell into disrepute because of many failures to relieve symptoms has a definite place in selected cases Operation for a movable kidney will not relieve psychoneurotic symptoms Surgery should be restricted to patients whose symptoms are known to be of renal origin and in whom medical treatment has failed The chief indication is obstruction to the ureter and abnormality in the outline of the renal pelvis on urography With the improvements in surgical technic the results in properly selected cases are satisfactory in about 75 per cent

HYDRONEPHROSIS

Definition —Hydronephrosis is dilatation of the pelvis and calices of the kidney with pressure atrophy of its substance the result of obstruction

Etiology —Obstruction of the urinary tract causes the greatest degree of hydronephrosis when it is partial gradual or intermittent When obstruction is sudden and complete no urine is secreted increase in intrapelvic pressure is less marked and renal atrophy may be primary or follow a hydronephrosis The obstruction may be anywhere along the urinary tract When below the bladder as in prostatism or urethral stricture the lesion is bilateral infection is predominant and the degree of hydronephrosis less marked The cause of the obstruction may be outside the urinary tract as neoplasms adhesions operative trauma aberrant blood vessels or pressure from a pregnant uterus The common causes of acquired obstruction within the urinary tract

are stone stricture spasm foreign body, and tumor Many cases are due to congenital abnormalities in the ureter or urethra Displacement of a movable kidney may be responsible Occasionally no obstruction can be found

Morbid Anatomy —The degree of dilatation of the pelvis and distortion of the kidney varies enormously At times the sac may contain several liters of fluid As the size of the sac increases the papillae first become flattened then the renal cortex is thinned until finally it is represented only by a thin shell of tissue The outer surface is irregularly lobulated while the larger blood vessels may form definite radial bands on the pelvic wall like the ribs of an umbrella The fluid in the sac is more or less like urine but contains far less urea than normal urine Secondary infection and calculus formation are common occurrences

Symptoms —There may be no symptoms from a slight degree of hydronephrosis In other cases there is vague pain in the loin which is not characteristic When the disease is more advanced the outstanding sign is palpable enlargement of the kidney Other symptoms are pain and tenderness When the obstruction is persistent subjective symptoms are slight and may be limited to dull pain The kidney seldom attains a large size and the urine is normal, for since the ureter is blocked no urine is derived from the affected side If the obstruction is intermittent there may be attacks of pain accompanied by a definite increase in the size of the kidney and oliguria with polyuria when the pain is relieved Accompanying this there may be hematuria When such attacks are severe they are usually due to a movable kidney and are known as *Dietl s crises* When the degree of hydronephrosis is more than minimal the function of the affected kidney is diminished and in advanced cases may even be abolished Hypertrophy of the other kidney may compensate for this defect so that symptoms of renal insufficiency do not develop In bilateral hydronephrosis kidney function is much diminished and uremia may develop When the obstructed kidney becomes infected (pyonephrosis) fever leukocytosis and pyuria are present in addition

Diagnosis —The intermittent type of hydronephrosis is recognized by the association of pain and renal tumor with oliguria and their simultaneous disappearance When the renal mass is large it may be mistaken for a kidney tumor, neoplasm of the retroperitoneal glands encysted ascites or enlarged gallbladder In women ovarian cyst may cause confusion, but is usually more movable Accurate diagnosis depends upon pyelography either intravenous or retrograde Pain of questionable origin may be recognized as renal if it is reproduced by distention of the pelvis at cystoscopy

Prognosis —This depends much upon the cause and degree of the hydronephrosis When unilateral and of moderate degree the condition may never produce serious trouble Spontaneous cure however does not occur When bilateral there is always danger of uremia Finally there is always the specter of infection with the development of pyonephrosis

Treatment.—The cause of the obstruction should be removed if possible This may involve dilatation of a ureteral stricture removal of a calculus or fixation of a movable kidney The sac can frequently be drained by means of a ureteral catheter If useful function of the kidney has been destroyed it is usually better to remove it

J M HAYMAN JR

BACTERIAL INFECTIONS OF THE KIDNEY AND URINARY PASSAGES

(Excluding Tuberculosis)

Definition —The term *bacterial infections* is used to describe diseases due to the actual presence of bacteria in the kidney and urinary passages

Etiology —Bacteria may reach the kidney by way of the blood stream (*hematogenous infection*) by way of the ureter or periureteral lymphatics (*ascending infection*) or possibly directly from the intestines by way of lymphatics especially those which run from the ascending colon and hepatic flexure to the right kidney Hematogenous infections are by far the most frequent While bacilluria may occur as in typhoid fever without detectable evidence

of renal infection the kidney does not filter bacteria and their presence in the urine indicates some degree of renal damage Infection of clinical importance occurs when bacteria come in overwhelming numbers or continuously or are particularly virulent or because of lowered resistance of the urinary passages due especially to obstruction The physiologic hydronephrosis of pregnancy frequently predisposes to pyelonephritis Trauma, either from without or as a result of instrumentation of the urinary tract, is a predisposing factor Infections of the kidney may be caused by almost any organism, but more than half of them are due to *Bacterium coli* Next in frequency are *Staphylococcus* and *Streptococcus* more rarely *Proteus vulgaris* and *Pseudomonas pyocyaneus* In rare instances infection of the kidney may result from invasion by *Actinomyces* and parasites such as *Filaria Bilharzia* or *Strongyloides* Infections of the cortex of the kidney are usually due to pyogenic cocci while those of the portions of the kidney nearer the pelvis and of the pelvis itself are usually due to the colon bacillus

Morbid Anatomy — The pathologic changes in the kidney and pelvis vary with the infecting organisms and the route of invasion Hemolytic streptococcal sepsis usually produces a focal glomerulonephritis or an acute interstitial nephritis In subacute bacterial endocarditis there are the characteristic focal embolic lesions in the glomeruli Staphylococcic infection is usually manifest as small abscesses most abundant in the cortex The rare unilateral *renal carbuncle* is usually associated with furunculosis, whitlow or some suppurative lesion of bone or joint Small abscesses may undergo resolution otherwise they tend to increase in size coalesce and may rupture either into the perirenal tissue leading to the formation of a *perirenal abscess* or into the renal pelvis when pyuria will appear

Other infections involve the renal pelvis (*pyelitis*) and medulla These are usually due to *Bacterium coli* and may be either hematogenous or ascending While it was formerly believed that *pyelitis* and *pyelonephritis* were distinct entities it is probable that infection of the pelvis rarely if ever occurs without some involvement of the collecting portion of the kidney tissue Clinically the term *pyelitis* is used to describe those cases in which the infection is not severe enough to lower the function of the involved kidney

Pyelonephritis may be acute or chronic and unilateral or bilateral In the acute stage, ureter and pelvis show various degrees of inflammation the mucous membrane is red thickened and at times shows small ulcers or a pseudomembrane While the kidney may appear normal grossly, microscopic examination reveals scattered patches of cloudy swelling necrosis or suppuration in the papillae and pyramids of the medulla When the disease is chronic the kidney presents areas of cloudy swelling suppuration, or scar formation the intervening parenchyma remaining comparatively normal in appearance At times there is a complicating diffuse glomerulonephritis or arteriolar sclerosis Under such conditions the kidneys are small with narrowed cortex and show distortion flattening and reduction in size of the thickened pelvis Dilatation of the ureter may or may not be present When destruction of kidney substance is sufficiently extensive death in uremia is inevitable

Symptoms —The symptoms of abscess of the kidney depend on their size and number Small abscesses occurring in the course of septicemia may give no localizing symptoms The sudden onset of chill fever pain in the loin and tenderness on palpation of the kidney or in the costovertebral angle should arouse suspicion of renal suppuration in the presence of known infection elsewhere in the body The urine may present no abnormalities save for the presence of the infecting organism on culture Extension of the infection into the perirenal tissue (*perirenal abscess*) gives pain and later swelling in the costovertebral angle pain on motion of the trunk or spasm of the psoas muscle The more chronic cases of this nature often present considerable *diagnostic difficulty* being confused with biliary disease when the right kidney is involved or with splenic lesions when the left

The symptoms of *acute pyelonephritis* vary greatly There may be no constitutional symptoms and no manifestation other than albuminuria and pyuria with some frequency or burning on urination In the so called typical attack the onset is sudden or may

follow a few days of malaise with chill fever of 39° C or more headache prostration pain in the loin which may radiate along the course of the ureter and leukocytosis as high as 20 000 or higher In some cases leukocytosis is absent Chills and remittent fever may last for several days The urine contains bacteria albumin and varying amounts of pus The largest amounts of pus are found when the renal pelvis and ureter are predominantly involved The reaction of the urine is neutral or acid when *Bacterium coli* is present alkaline with *Proteus vulgaris* Red cells are frequent in the sediment but gross hematuria is rare

Chronic bilateral pyelonephritis is more common in women and often begins as an acute pyelonephritis in childhood or during pregnancy In men it is usually associated with retention of urine secondary to hypertrophy of the prostate gland The clinical picture is variable and frequently the symptoms are so mild that the disease escapes recognition until the terminal stage A history of an acute attack followed by persistent albuminuria with intermittent pyuria should arouse suspicion Recurrent bouts of fever with headache lumbar pain and costovertebral tenderness are increasingly common as the disease progresses The urine is dilute increased in volume and contains a variable amount of pus and albumin As the disease progresses renal function becomes impaired and uremia ultimately terminates a picture which may be identical with that seen in other forms of chronic Bright s disease The progress of the disease is slow and patients may present elevation of blood nitrogen for years while remaining in relatively good health Hypertension occurs in only one-quarter of all cases but in those cases with impairment of renal function it is present in 50 per cent Usually the hypertension is not of the malignant type the majority of cases showing a systolic pressure of less than 180 Edema is rare except that due to heart failure *Chronic unilateral pyelonephritis* can usually be distinguished from bilateral involvement only by urologic study Its recognition however is important since hypertension may occur even with unilateral disease and its cure has followed removal of the diseased kidney

Diagnosis —The diagnosis of renal infection is rarely difficult if its presence is suspected Unexplained fever chills or malaise, bladder symptoms as frequency burning or dysuria should lead to further study Pus and bacteria in the urine obtained by catheter in the female are convincing evidence of renal infection These urinary abnormalities serve in particular to differentiate infections of the kidney from acute disease of other abdominal organs as the gallbladder or appendix In tuberculosis of the kidney the onset is insidious gross hematuria more frequent while dysuria and frequency are more prominent Bacteria are not found by ordinary methods but tubercle bacilli can be demonstrated in a smear of the urinary sediment or by guinea pig inoculation All patients presenting evidence of urinary tract infection of uncertain cause should have the benefit of x ray examination in order to rule out stone as a predisposing factor and if the infection persists urologic study including pyelograms to detect renal anomalies or partial obstruction with hydronephrosis Culture of the urine is essential for an accurate diagnosis of the infecting organism It is often impossible to diagnose a cortical abscess early in the disease until it ruptures either into the pelvis discharging pus in the urine or spreads into the perirenal tissues The diagnosis of perirenal abscess may be extremely difficult In the presence of pain in the costovertebral angle with muscle spasm and scoliosis the demonstration of a high fixed diaphragm obliteration of the psoas shadow or irregularity in the outline of the kidney by x ray examination are helpful Treatment of course is surgical The high incidence of pyelonephritis as the etiologic agent in severe renal disease indicates the necessity for thorough investigation of the urinary tract in all cases of impaired renal function

Prognosis —The prognosis in acute pyelonephritis is excellent the attack usually lasting one or two weeks The severity of constitutional symptoms however bears no relation to the time necessary for the disappearance of bacilluria and pyuria In pyelonephritis secondary to obstruction of the urinary tract or stone the chronic form of the disease develops with great regularity unless the underlying cause is removed

Treatment —Acute pyelonephritis with

fever should be treated by bed rest, a soft diet and liberal amounts of fluid 3000 to 4000 cc daily If the urine is highly acid the intense urgency and dysuria can often be relieved by making the urine alkaline The administration of the older urinary antiseptics such as methenamine (0.5–3 0 Gm three times a day), pyridium (0 2 Gm, three times a day) or acriflavine (0 3 Gm three times a day) did not strikingly hasten the sterilization of the urine Methenamine is effective only in an acid urine, so that the addition of sodium acid phosphate or ammonium chloride is often necessary The introduction of the newer urinary antiseptics, mandelic acid and the sulfonamide derivatives has proved to be a tremendous advance in the treatment of urinary infections, and they have superseded the older drugs almost entirely

Mandelic acid was introduced by Rosenheim as a substitute for beta hydroxybutyric acid which had been shown to be the bacteriostatic agent in the urine of patients on a ketogenic diet In order for mandelic acid to be effective it must be present in a concentration of 0.5 to 1 0 per cent and the urine must be strongly acid pH 5.5 to 5 0 It is usually given in doses of 3 Gm four times a day after meals for adults as calcium or ammonium mandelate the latter in the form of syrup or elixir The daily urine volume should be maintained at about 1000 cc to insure adequate concentration The pH of the urine should be tested with chlorphenol red or nitrozene test papers and ammonium chloride or nitrate 3 to 6 Gm daily may be given if necessary The drug is particularly effective for *Bacterium coli* and *Streptococcus faecalis B pyocyaneus Aerobacter aerogenes* and staphylococci also respond to treatment but less effectively In cases of infection with *Proteus vulgaris* it is usually impossible to acidify the urine sufficiently for the drug to be effective The drug causes toxic symptoms in a small percentage of patients, these are nausea and vomiting diarrhea and hematuria Treatment should not be continued for more than one or two weeks In the presence of advanced renal insufficiency with loss of concentrating power, it may be impossible to attain the necessary concentration of the drug in the urine as well as to lower the pH to 5.5 in spite of the fact that the patient may develop a severe acidosis The use of the drug is contraindicated in such conditions

The sulfonamide group of compounds in general has proved to be the most satisfactory therapeutic agent The effectiveness is due to the fact that the chief route of excretion is through the kidneys and in its passage a high concentration is attained in the urine With these concentrations which may be ten to thirty times higher than that obtained in blood a bactericidal as well as bacteriostatic effect is produced Consequently it becomes possible to cure infections of the urinary tract caused by organisms which in other tissues are not susceptible to the sulfonamides Of the variety of compounds introduced for clinical trial sulfanilamide sulfathiazole and more recently sulfadiazine have been of most value Sulfanilamide is most effective against *B coli* and less so against staphylococci and *B proteus* It is effective at any pH but more so when the urine is alkaline A concentration of 200 to 300 mg per cent of free sulfanilamide in the urine is required This may be obtained by the administration of from 2 to 5 Gm daily in divided doses at 4 or 6 hour intervals with an equal quantity of sodium bicarbonate A urine volume of 1000 cc is preferable but this may be increased if fever or symptoms of cystitis are present Sulfathiazole because of its efficiency against staphylococci *B proteus Aerobacter aerogenes* as well as *B coli* has definitely relegated all other antiseptics to secondary positions A much lower concentration in the urine is required 25 to 50 mg per cent being often sufficient for cure for many strains In the treatment of staphylococcus infection an alkaline urine is preferable but for *Streptococcus faecalis* the pH of the urine should be not greater than 5 0, regulation of pH is not essential for *B coli* Doses of from 1 to 3 Gm daily in divided doses are adequate in most cases Sulfadiazine has as yet not been used as extensively as the other sulfonamides but the early reports indicate that it may be more effective than sulfathiazole for *B coli B proteus* and *Pseudomonas pyocyaneus* but of less value for staphylococci Two to 4 Gm daily in divided doses may be given Other sulfonamides such as

prontosil sulfapyridine and sulfacetimide have been advocated for the treatment of urinary infection but they have not been shown to be more effective than the three sulfonamides discussed

In using the sulfonamides the drug should be continued until two catheterized specimens of urine taken at four day intervals are found to be sterile to culture Usually a course of from one to two weeks suffices but smaller doses (1 Gm daily) may be given over longer periods of time (Helmholtz) especially where renal function is poor The sulfonamides should be administered with caution because of their toxicity Toxic manifestations include fever skin eruptions hemolytic anemia and neutropenia Sulfanilamide causes no renal complications but sulfathiazole may produce hematuria and nitrogen retention due usually to precipitation of the conjugated form in the tubules Although acetyl sulfadiazine is much more soluble than acetyl sulfathiazole renal damage may also occur even though less frequently Fluids should not be restricted therefore when sulfathiazole or sulfadiazine is used

In cases of *acute pyelonephritis* associated with stone or obstruction to the urinary passages satisfactory *treatment* of the infection may be impossible until these have been corrected by surgical means

The *treatment* of *chronic pyelonephritis* consists primarily in prevention and in the removal of obstruction and stones For the acute exacerbations of infection the sulfonamide derivatives appear to offer the best results and may at least delay the progress of the disease to the stage of serious renal failure If urologic study shows that the pyelonephritis is unilateral function of the other kidney is good and if there is an associated hypertension surgical removal of the infected kidney should be considered

The *treatment* of *perinephric abscess* and *renal carbuncle* like other accumulations of pus is surgical drainage

Infections of the Bladder —The bladder mucosa is strikingly insusceptible to infection so that in almost every instance *cystitis* is secondary to infection higher in the urinary tract to obstruction to the outlet of the bladder with retention of urine to genital infection or to trauma from stone or contaminated instruments When the primary cause is removed the infection clears up spontaneously The bacteria found are those mentioned under pyelonephritis In rare instances, the gonococcus invades the bladder the lesions being almost entirely confined to the trigone The pathologic changes are those of acute and chronic inflammation The symptoms are frequency, pain and pyuria Urination is more frequent during the day than at night The pain is usually described as burning is referred to the meatus and only gradually subsides after micturition has been completed In addition to variable amounts of pus there is not infrequently some blood present, especially in the last urine voided In chronic cystitis all symptoms are as a rule much milder Accurate diagnosis depends upon cystoscopic examination The most effective treatment consists in removal of the underlying cause Palliative measures include abundant fluids alkalinization of the urine hot sitz baths irrigation of the bladder and the instillation of the antiseptics such as colloidal silver preparation or 1 10 000 silver nitrate Oral antiseptics such as methenamine may be tried but are of doubtful value

NEPHROLITHIASIS

(*Renal Calculus*)

Definition —The formation in the calices or pelvis of the kidney of concretions of crystalline urinary constituents which may be held together by a stroma of organic material

Etiology—Nephrolithiasis is about three times as common in males as in females and is most frequent between the ages of thirty and fifty It is said to be infrequent in the Negro Heredity is unimportant except with cystine stones which occur with an hereditary disturbance of metabolism Calculi are commonly composed of *uric acid urates calcium oxalate calcium phosphate* or mixtures of *calcium and ammoniomagnesium phosphate* more rarely of *calcium carbonate cystine* or *xanthine*

Calculi are formed from urinary constituents which remain in solution under normal conditions, why they precipitate in some individuals to form stones is obscure The theory that the constituents of the urine are kept in solution by the protective action of nonprotein colloids and that stone formation results from a disturbance of this equilibrium has not been supported by experimental work A number of contributory factors are recognized These include climate diet hyperparathyroidism disorders of metabolism and local conditions in the urinary tract especially stasis infection and marked changes in the reaction of the urine Stones are more common in hot dry climates where the urine volume is small than in more humid regions Excessive ingestion of nucleoproteins may favor the formation of uric acid stones and the excretion of oxalic acid is increased by a diet rich in rhubarb egg plant and certain other foods A high incidence of stone is reported in districts where the water contains a large amount of calcium carbonate Experimentally stones can be readily produced in rats by diets deficient in vitamin A But it is not clear whether these are due primarily to the vitamin deficiency or to infection changes in the epithelium of the pelvis relative excess of vitamin D or some other factor The relation of vitamin A deficiency to nephrolithiasis in man is undecided Probably inadequate or unbalanced diets are of more importance in the formation of stones in children than in adults The work of Albright has established the high incidence of stone in hyperparathyroidism with its accompanying hypercalcemia These patients may or may not show osteitis fibrosa cystica or osteoporosis This suggests studies of blood calcium and phosphorus in all cases of renal stone The *influence of abnormal* metabolism is also seen in the high incidence of stone in gout and in the rare cystine stones Feeding cystine to cystinuric patients however does not increase the excretion of cystine but the administration of the sulfur containing amino acids methionine and cysteine causes a marked increase in cystinuria Brand and Cahill believe that the error in metabolism consists *in failure of the proper handling of cysteine* derived from food and that cysteine is converted into cystine by the kidneys of the cystinuric patient Urinary stasis whether the result of obstruction in the lower urinary tract or of prolonged confinement to bed favors the formation of stones Infection not only provides a nidus of bacteria but because of the frequent association of alkaline urine favors the precipitation of phosphates *If urea splitting organisms are present* recurrence of stone is likely to occur in 75 per cent of cases Randall believes that calculus formation is dependent upon a preexisting renal lesion and has demonstrated areas of calcification without evidence of inflammation or infection in the renal papilla He believes that it is upon a nidus of this type that calculi of various composition develop

Morbid Anatomy—The size of the concretions varies from small particles like sand (*urinary gravel*) to large oval or branching (*stag horn*) calculi which fill the whole renal pelvis and branch into the calices Stones may continue to be formed and passed for years without serious kidney damage and with no more inconvenience than the attacks of renal colic Much more frequently, however movements of the stone lead to trauma to the pelvis or ureter with severe colic hemorrhage and secondary infection Persistent obstruction of the ureter leads to hydronephrosis or pyonephrosis with destruction of the kidney Stones are *bilateral* in about 10 per cent of cases and then almost always associated with infection A stone rarely persists in a normal bladder If the nucleus comes from above the potential vesical calculus is usually passed retention and growth in the bladder result from obstruction giving urinary stasis and residual urine Trauma inflammation of the bladder and infection follow

Symptoms —These vary with the size shape and position of the stone Minute smooth stones or gravel may be passed without symptoms A smooth stone fixed in one of the calices and unaccompanied by infection may remain for years without giving rise to either signs or symptoms Even a large calculus filling the entire pelvis may be symptomless The most common symptom is intermittent dull pain in the flank or back intensified by motion or a sudden jolt Abnormalities of the urine occur at one time or another in 80 per cent of cases of these albuminuria which may be minimal is the most constant while hematuria and pyuria each occur in about half the cases The classic attack of *renal colic* occurs when a stone is small enough to enter the ureter but large enough to obstruct it The pain is of excruciating severity begins in the back or flank and radiates first across the abdomen and then down along the course of the ureter to the genitalia and inner aspect of the thigh The pain is frequently sufficiently severe to induce nausea vomiting profuse sweating faintness and shock If there is infection there will be fever and leukocytosis in addition There is often frequency and urgency but the quantity of urine passed is small An attack may last only a few minutes but usually persists for several hours A patient may have but one attack of colic and pass the stone without further difficulty or with multiple stones there may be repeated attacks over a period of years After the attack is over the patient frequently complains of soreness along the course of the ureter and tenderness on palpation Palpable enlargement of the kidney is uncommon Albuminuria and microscopic hematuria are almost invariably present during the acute attack and may persist for several days Occasionally there may be gross hematuria

Intermittent or partial obstruction of a ureter or pelvis leads to the development of hydronephrosis and usually of secondary pyonephrosis with progressive destruction of the kidney If the condition is bilateral renal insufficiency and uremia may develop When the obstruction is complete it causes anuria from the affected kidney Complete anuria may occur with bilateral calculi, when one ureter is blocked if the function of the other kidney has been destroyed or with reflex inhibition of the unaffected kidney This last condition is rarely demonstrated and in some cases should be attributed to shock and low blood pressure rather than to a reflex

Diagnosis —In patients suffering from typical attacks of renal colic, the diagnosis can be made with comparative ease from the clinical history and is supported by the presence of blood or numerous crystals in the freshly voided urine A catheter specimen should be obtained in women Never-

Fig 108 —Retrograde urogram showing large oval calcium carbonate stone at the left uretero-pelvic junction (Courtesy of Dr Harry Hauser)

theless the diagnosis can only be established by x ray or pyelographic study for the pain is frequently not referred in the usual manner and may simulate that of appendicitis gallbladder disease peptic ulcer coronary thrombosis or even of disease of the vertebrae or spinal cord Similar colicky attacks of pain also occur in Dietl s crisis ureteral spasm and stricture and in pyelonephritis and renal tumor if the ureter is obstructed by pus or clotted blood When anuria is the only symptom it may be due to shock, stone nephritis or bichloride of mercury poisoning

Etiology—Nephrolithiasis is about three times as common in males as in females and is most frequent between the ages of thirty and fifty It is said to be infrequent in the Negro Heredity is unimportant except with cystine stones which occur with an hereditary disturbance of metabolism Calculi are commonly composed of *uric acid urates calcium oxalate calcium phosphate* or mixtures of *calcium and ammoniomagnesium phosphate* more rarely of *calcium carbonate cystine* or *xanthine*

Calculi are formed from urinary constituents which remain in solution under normal conditions, why they precipitate in some individuals to form stones is obscure The theory that the constituents of the urine are kept in solution by the protective action of nonprotein colloids and that stone formation results from a disturbance of this equilibrium has not been supported by experimental work A number of contributory factors are recognized These include climate diet hyperparathyroidism disorders of metabolism and local conditions in the urinary tract especially stasis infection and marked changes in the reaction of the urine Stones are more common in hot dry climates where the urine volume is small than in more humid regions Excessive ingestion of nucleoproteins may favor the formation of uric acid stones and the excretion of oxalic acid is increased by a diet rich in rhubarb egg plant and certain other foods A high incidence of stone is reported in districts where the water contains a large amount of calcium carbonate Experimentally stones can be readily produced in rats by diets deficient in vitamin A But it is not clear whether these are due primarily to the vitamin deficiency or to infection changes in the epithelium of the pelvis relative excess of vitamin D or some other factor The relation of vitamin A deficiency to nephrolithiasis in man is undecided Probably inadequate or unbalanced diets are of more importance in the formation of stones in children than in adults The work of Albright has established the high incidence of stone in hyperparathyroidism with its accompanying hypercalcemia These patients may or may not show osteitis fibrosa cystica or osteoporosis This suggests studies of blood calcium and phosphorus in all cases of renal stone The influence of abnormal metabolism is also seen in the high incidence of stone in gout, and in the rare cystine stones Feeding cystine to cystinuric patients, however, does not increase the excretion of cystine but the administration of the sulfur containing amino acids, methionine and cysteine causes a marked increase in cystinuria Brand and Cahill believe that the error in metabolism consists in failure of the proper handling of cysteine derived from food and that cysteine is converted into cystine by the kidneys of the cystinuric patient Urinary stasis, whether the result of obstruction in the lower urinary tract or of prolonged confinement to bed favors the formation of stones Infection not only provides a nidus of bacteria, but because of the frequent association of alkaline urine favors the precipitation of phosphates If urea splitting organisms are present recurrence of stone is likely to occur in 75 per cent of cases Randall believes that calculus formation is dependent upon a preexisting renal lesion and has demonstrated areas of calcification without evidence of inflammation or infection in the renal papilla He believes that it is upon a nidus of this type that calculi of various composition develop

Morbid Anatomy—The size of the concretions varies from small particles like sand (*urinary gravel*) to large oval or branching (*stag horn*) calculi which fill the whole renal pelvis and branch into the calices Stones may continue to be formed and passed for years without serious kidney damage and with no more inconvenience than the attacks of renal colic Much more frequently, however movements of the stone lead to trauma to the pelvis or ureter with severe colic hemorrhage and secondary infection Persistent obstruction of the ureter leads to hydronephrosis or pyonephrosis with destruction of the kidney Stones are bilateral in about 10 per cent of cases and then almost always associated with infection A stone rarely persists in a normal bladder If the nucleus comes from above the potential vesical calculus is usually passed retention and growth in the bladder result from obstruction giving urinary stasis and residual urine Trauma inflammation of the bladder and infection follow

of the ureter or other manipulation with the ureteral catheter Stones in the pelvis can often be removed by pyelotomy but when there is marked renal destruction and large or multiple stones nephrectomy is advisable In spite of the best surgical technic and careful after treatment recurrence occurs in about 16 per cent of aseptic and 50 per cent of infected cases

AMYLOID DISEASE OF THE KIDNEY

(*Amyloid Nephrosis*)

Definition —A disease of the kidney due to the deposition of amyloid in the media of the arteries and glomerular capillaries and characterized clinically by albuminuria and edema

Etiology —Amyloidosis occurs almost exclusively in chronic cachexia most commonly in tuberculosis and in long standing suppuration as osteomyelitis empyema or lung abscess Rarely it occurs in the absence of suppuration in syphilis multiple myeloma or neoplastic disease The deposit was called amyloid by Virchow because it becomes walnut brown when stained with iodine it is a protein however and not a carbohydrate as suggested by the name Amyloid deposits have been produced experimentally by repeated injections of sodium caseinate bacteria heterologous sera and homologous globulin Considerable evidence has been brought forward to support the theory that amyloidosis is associated with hyperglobulinemia

Morbid Anatomy —Deposits of amyloid are most common in the spleen then in the kidney The amyloid kidney may be normal in size but is usually moderately enlarged The capsule strips readily revealing a smooth glossy or greasy surface On section the cortex is widened and the markings indistinct Microscopically amyloid is deposited in the vessel walls This is seen first along the inner surface of the basement membrane of the glomerular capillaries The final result is the conversion of the glomerular tuft into a bloodless amyloid sphere and consequent degeneration of its tubule The afferent arterioles frequently show deposits of amyloid between the cells of the media or under the endothelium The straight vessels of the cortex and the larger arteries are not involved as regularly or as early Occasionally amyloid is found under the basement membrane of the tubules otherwise the tubular changes resemble those of lipoid nephrosis In some cases there is sufficient destruction of nephrons to produce a small contracted kidney and renal insufficiency

Symptoms —Usually amyloid disease of the kidneys is of little clinical importance the picture being dominated by the under lying disease Albuminuria is usually present and an abnormal number of casts of all types except blood casts are found in the urine When the albuminuria is great enough to lower the plasma proteins the picture resembles that of lipoid nephrosis The urine volume however is usually greater and the specific gravity lower than in that disease Hypercholesterolemia is also less constant Hypertension and eyeground changes are unusual The edema fluid is of the nephrotic type containing 0.5 per cent or less protein A certain number of patients who live long enough develop nitrogen retention and renal insufficiency

Diagnosis —In the presence of tuberculosis or long standing suppuration if there is enlargement of the spleen and liver and

At times the shape and type of the shadows seen on an x ray plate are characteristic Cystine stones often coalesce to form large stones of a homogeneous wax like appearance Calcium oxalate stones may have a snowflake form with spicules radiating from a central focus Lamellar stones are usually phosphate in composition Large stag horn stones are either calcium phosphate calcium carbonate, or cystine Frequently the shadows are inconclusive Suspicious shadows may represent concretions in a vein or in the gut rather than in the urinary tract Uric acid urate, and cystine

Fig 109—A large calcium carbonate stag horn stone in the pelvis of the left kidney (Courtesy of Dr E Freedman)

stones often fail to give a visible shadow while denser calculi may be obscured by bone Intravenous pyelography may outline the stone but frequently ureteral catheterization and retrograde pyelography are necessary

Prognosis—The *prognosis in patients* with nephrolithiasis is extremely variable depending upon the size shape and position of the stone the presence of obstruction and of infection Small stones retained by gravity in the lower calyx may do no harm intermediate sized ones should be watched at intervals by means of the x ray while stones more than 1 cm in length are unlikely to pass spontaneously Irregularly shaped stones are less likely to be passed All stones tend to grow as long as urine is secreted by the kidney It is the general opinion that any stone retained in the upper urinary tract ultimately leads to the destruction of the kidney Renal calculus *is one of the* most common causes of infection and hydronephrosis, which may give rise to renal insufficiency uremia generalized sepsis or less frequently ulceration and perforation of the renal pelvis or ureter When anuria persists for more than a few hours the outlook is grave in the absence of surgical intervention When the conditions responsible for the formation of a stone persist after its removal recurrences are prone to occur

Treatment—While therapy depends upon the size and location of the stone and the presence of such complications as hydronephrosis infection and renal insufficiency general measures are of importance Fluid ingestion should preferably exceed 3000 cc daily in order to reduce the concentration of the urine The diet of patients with oxalate or uric acid stones should contain minimum quantities of these substances Such measures would be of more avail if stone formation were simply a matter of urinary concentration In the presence of infection (and provided renal function is good) mandelic acid or the sulfonamides may be of value in controlling this complication Cystine stones may frequently be dissolved by making the urine alkaline For this *purpose sodium* or potassium citrate, 1 to 2 Gm in solution three times daily may be used Treatment by vitamin supplement and acidification of the urine is still in the experimental stage, reported results still being inconclusive

For the pain of renal colic morphine in large doses is usually required A hot tub bath or local application of heat may help Atropine or nitroglycerin may be tried The *intravenous injection of* 15 cc of 10 per cent calcium chloride has been recommended but is not without danger

While expectant treatment may be adopted when there is a small stone and no infection in the *hope that it* will pass spontaneously the vast majority of cases require special surgical and urologic procedures At times a stone can be removed by dilatation

confined to the subcapsular zone The contents of the cysts are watery urinous hemorrhagic or viscid The pelvis and ureter are not obstructed but may be transformed to a mere slit The interlobular arterial branches show marked compression The disease is often associated with other malformations in the genito urinary tract or with cysts in the liver, and more rarely in the spleen and pancreas

Symptoms —If the degree of involvement is slight there may be no symptoms the condition only being recognized at autopsy When the reduction in renal substance is more extensive the symptoms are those of arteriolar nephrosclerosis diminished kidney function albuminuria polyuria low fixed specific gravity of the urine nitrogen retention anemia weakness and gastro intestinal symptoms Death is usually in uremia Cardiac failure is rare Hypertension and cardiac hypertrophy are present in the majority of advanced cases but less marked than in arteriolar nephrosclerosis The genesis of the elevated blood pressure may be similar to that which Goldblatt produced in dogs by constricting the renal arteries and be due to compression of the interlobular arteries by the enlarging cysts In other cases the presenting symptoms may be spontaneous painless hematuria which with a mass in the flank may lead to the erroneous diagnosis of tumor At times the passage of blood clots may cause renal colic Gross hematuria occurs in one third of cases At times the greatly enlarged kidney may give a dragging pain in the kidney region often increased by exertion and relieved by lying down The large polycystic kidney tends to slip down and in doing so may cause hydronephrosis by angulation of the ureter Sometimes it becomes infected

Diagnosis —Bilateral tumor of the kidney associated with hematuria or the symptoms of arteriolar nephrosclerosis offers little difficulty Only one kidney can be felt in about 20 per cent of cases and occasionally neither is palpable In all instances however the pyelogram is characteristic showing an elongation of the pelvis and calices with curved indentations caused by the individual cysts

Prognosis —In the newborn the disease is rapidly fatal In adults it may be latent for years and then progress rapidly to uremia or cerebral hemorrhage and death Occasionally intermittent hematuria or progressive renal failure may last for several years

Treatment —The treatment is chiefly medical identical with that for arteriolar nephrosclerosis Hematuria will usually respond to rest Puncture of the cysts to relieve pressure on the remaining parenchyma has not proved successful Nephrectomy should not be performed except for the most grave reasons such as infection or alarming hemorrhage and then only after

Fig 110 —Retrograde pyelograms in bilateral polycystic kidneys showing elongation of the pelvis flattening of minor calices and circular indentations due to the cysts (Courtesy of Dr E Freedman)

the other kidney has been shown to have fair function and to be only moderately involved in the cystic process

Other Forms of Cysts —*Multiple retention cysts* are common in the contracted kidney of arteriolar nephrosclerosis and chronic nephritis They are due to the occlusion of tubules by fibrosis Large *solitary cysts* are rare occur usually at the lower pole project from the surface of the kidney and may produce a dull dragging sensation accompanied by a palpable mass The fluid is usually yellow resembling blood serum or lymph It is not urine These cysts may be

albuminuria amyloid disease of the kidney should be suspected Glomerulonephritis in a cachectic patient may give the same clinical picture but red cells are present in the urine On the other hand the nephrotic syndrome without amyloid may of course exist in chronic disease The congo red test of Bennhold is of value in supporting a diagnosis of amyloidosis if it is positive This test depends upon the fact that the amyloid in the tissues takes up the dye and holds it for long periods Dye is injected intravenously and samples of blood are collected in four and sixty minutes From this the percentage of the dye disappearing in one hour can be calculated, in normal persons this is less than 60 per cent The test is useful as confirmatory evidence of amyloidosis if 90 per cent or more disappears in one hour A negative test does not exclude amyloid In chronic nephrosis the dye also leaves the blood stream with abnormal rapidity a large amount of it being found in the urine

Prognosis—The prognosis is that of the basic disease which usually leads to death within a year after the diagnosis of amyloidosis has been made But in some cases of tuberculosis of the bone or of syphilis, amyloidosis may last for years If the underlying cause can be removed as by amputation of a septic limb or treatment of syphilis the disease may become stationary or even regress Treatment is that of the primary disease An ample diet high in proteins is usually indicated for the primary condition and may combat the protein lost in the urine

CYSTS OF THE KIDNEY

By far the most common type of cyst of the kidney of clinical importance is *congenital polycystic disease* In this condition the normal renal tissue is in large measure encroached on and replaced by multitudes of cysts of widely varying size While always congenital symptoms usually appear either in infancy or between the fortieth and sixtieth years of life recognition of the condition is rare in childhood It is nearly always bilateral although one kidney may be more affected than the other The disease shows a decided familial and hereditary tendency

Etiology—The idea that cystic disease was due to failure of the embryonic convoluted tubules to unite with the collecting tubules *i e* that the cysts were retention cysts even without communication with the duct system seems to have been disproved by the studies of Kampmeier and of Norris and Herman The latter believe that for a long period in fetal life development of the kidneys is not abnormal Focal cystic dilatation of uriniferous tubules and collecting ducts occurring after differentiation of the metanephrogenic anlage and after the union of its elements with collecting tubules is followed by isolation of segments of these nephrons as cysts Increase in size of the cystic dilatations may result from the continued proliferation of epithelium and from rupture of septa and walls of tubules giving rise to anastomoses The increase in size of the cysts after birth usually brings about destruction by pressure and by vascular changes of whatever normally formed renal tissue exists These changes are thought to be degenerative since they resemble the stages in the normal degeneration of the mesonephros and of normally vestigial elements of the metanephros

Morbid Anatomy—The kidney retains its normal shape the degree of enlargement depending on the number and size of the cysts scattered throughout it Usually it is two or three times the normal size occasionally much larger The external surface is rough and knobby due to many closely set projecting cysts On section nearly all the renal tissue seems to have been replaced by cysts giving a honeycomb appearance The small amount of remaining parenchyma may be scattered irregularly between the cysts or

palpable mass is present in less than 20 per cent of early cases but as the tumor grows progressively can often be felt before death The growth generally preserves the usual shape of the kidney and may be uniformly smooth Very often it is irregular lobulated or nodular When the tumor is large the flank is deformed and the shape of the mass may be apparent on inspection Small tumors are frequently movable but the larger ones are generally fixed Varicocele may result from direct pressure of the growth on the left spermatic vein or from complete blocking by infiltration In rare instances marked circulatory disturbances with edema and ascites may occur from obstruction of the vena cava Fever is said to be present in 20 per cent of cases in those where no signs of *infection* can be detected Hypertension is found in 50 per cent of cases but is presumably coincidental since removal of the affected kidney produces no consistent alteration *in blood* pressure

Prognosis and Treatment.—The sole treatment of malignant renal tumor is nephrectomy which to be curative depends on early and accurate diagnosis Radiation in the opinion of most observers plays only an auxiliary role The presence of metastases or marked functional impairment of the opposite kidney contraindicates surgery X ray of the lungs and long bones for metastases should be performed in every case before surgery is attempted The *prognosis* of renal tumors is poor Less than 20 per cent of cases recover from malignant renal disease The immediate operative mortality is about 15 per cent 20 per cent are found to be inoperable and about 45 per cent die of metastases within a year or two

either congenital or acquired Tubular obstruction and ischemia are two of the known factors responsible either for their production or the rapid increase in growth Treatment consists in complete removal of the cyst, or drainage with destruction of the secreting membrane *Echinococcus cysts* occur in the kidney in 2 per cent of infestations They are unilateral and give only the symptoms of a slow growing tumor unless rupture occurs If rupture is into the renal pelvis the passage of the cyst contents down the ureter often provokes the symptoms of colic, or hematuria and for a time hooklets may be found in the urine Much more rarely the cyst ruptures into the intestine or peritoneum leading to pyonephrosis or peritonitis Such cysts are usually discovered by accident and require no treatment Ruptured cysts are prone to infection and therefore require nephrectomy

TUMORS OF THE KIDNEY

Neoplasms of the kidney may be primary or metastatic the former either benign or malignant They may be classified also according to their origin from renal parenchyma or from the urinary passages

Morbid Anatomy—Benign tumors rarely reach a size of clinical importance and include fibroma lipoma, angioma and adenoma Some adenomas are believed to be of embryonal derivation while others apparently arise as the result of regeneration following chronic fibrotic disease in the organ Malignant tumors of the kidney occur at two widely separate periods of life from birth to five years and after forty The common malignant tumor of childhood is the *embryonal nephroma* (*Wilms' tumor*) This tumor grows rapidly so that when first seen *it may fill the whole side of the* abdomen The commonest malignant tumor of adults is the *nephroma* (hypernephroma) which arises in the cortex forming a rounded or lobulated mass which at first encroaches on the normal renal tissue by compression only Grawitz believed the tumor was derived from misplaced rests of adrenal cortex This theory has been challenged by Gasparian and many others who believe that the great majority of these tumors are derived from adenomata or arise more directly from renal epithelium and that they are really adenocarcinomas Other malignant tumors of the adult are *carcinoma simplex or adenocarcinoma* sarcoma and embryoma Tumors of the pelvis and ureter are much rarer and include *papilloma* of the renal pelvis which is benign in its earlier stages but possesses *malignant potentialities papillary carcinoma* and the *squamous cell carcinoma* usually found as an accompaniment of the irritation caused by stone or chronic infection

Symptoms—The three cardinal symptoms of renal neoplasms are hematuria pain and the presence of a tumor mass in the loin Unfortunately these are rarely present early, or they are so trivial that they are neglected by the patient and overlooked by the physician Hematuria is the most constant and outstanding symptom of tumor of the kidney In the renal cancers of adults it is usually the earliest symptom but, in Wilms tumor in children it is a relatively late manifestation The bleeding generally comes on insidiously and is characteristically intermittent lasting only a few hours or days Pain occurring in 50 per cent of cases is frequently inconstant and vague but may be colicky due to passage of blood clots or dull and aching as a result of distention of the pelvis or capsule Neuralgic pains which may be severe usually mean local spread of the tumor to adjacent nerve trunks Pressure on neighboring viscera may also produce pain gastro intestinal symptoms being not uncommon Metastases to bones especially the vertebrae femur humerus and skull may give rise to pain in those regions Metastases to lungs are usually silent A

spleens may be found that are apparently normal Its average normal adult weight is about 150 Gm

Movable Spleen —A movable spleen (*floating spleen lien mobile*) may be found in any part of the abdomen Osler cites one that was found in an inguinal hernia and I have found it in the pleural cavity Such a spleen may become fixed in the abnormal position by adhesions and present great difficulty in diagnosis Movable spleen is either part of a general enteroptosis (Glénard s disease) or follows the enlargement of chronic splenic disease the derangements caused by an abdominal malformation *Symptoms* may be absent or general (especially digestive or circulatory), and may be referred chiefly to some other organ that has been disturbed If the shape and notches of the spleen can be palpated *diagnosis* is easy The absence of the normal splenic dulness and the fact that the mass can be returned to the normal position of the spleen (in the absence of adhesions) are also of diagnostic aid *Treatment* is usually desirable to forestall com

DISEASES OF THE SPLEEN AND RETICULO-ENDOTHELIAL SYSTEM

DISEASES OF THE SPLEEN

It has long been known that the spleen is not an organ necessary for life in fact the ancients, on the erroneous supposition that the speedy giraffe did not possess a spleen are said to have excised the spleens of runners in order to increase their efficiency Although since the time of Malpighi clinical and experimental investigations of splenic functions in health and disease have been numerous and ingenious it is only in the present generation that more concise concepts of its function have been obtained The author attempted in 1926 to assemble these in an article in Physiological Reviews since which time additions to knowledge of its functions have been neither negligible nor important

As the chief member of the hemolytopoietic system the spleen is unquestionably concerned intimately with blood cell formation and destruction Like the liver it may easily revert to its embryonic function of forming leukocytes and erythrocytes as occasion demands and it continuously forms *lymphocytes and* monocytes in common with other tissues Blood cell formation is also controlled indirectly by the spleen through its influence on the bone marrow Whether or not blood cell destruction begins within the circulation by fragmentation or by hemolysis the spleen is in either case directly concerned The fact that phagocytosis of cell debris or if necessary of whole cells takes place not only in the spleen but also in the other parts of the reticulo-endothelial system, may be taken as an explanation of the return to normal function after several months that occurs after splenectomy The spleen is probably also indirectly concerned with destruction of blood in other ways The clinical importance of this function especially when it is increased by disease is shown by the great diminution in the destruction of blood that follows splenectomy in hemolytic jaundice and pernicious anemia The unique vascular arrangements of the spleen (see Fig 111) produce potentialities for storage of erythrocytes (the red pulp) and action upon them (those in the splenic vein are less resistant to hemolysis than those entering by the splenic artery) and for rapid shunts that have significance in certain clinical conditions The reservoir function involving both elasticity and contractility which has been shown to *be practically important* under carefully controlled experimental conditions is probably of less importance in man than in the more muscular spleens of the animals studied

The majority of the accumulated evidence indicates that the spleen plays a role of some clinical importance *in relation to immunity* It has a selective affinity for bacteria fixes toxins and produces antibodies but here *also the spleen* cooperates with other tissues which can quickly assume these functions after its removal Its frequent involvement in infections is a clinical demonstration *of this* important relationship and the serious *lesions* that may result as for instance in tuberculosis syphilis or malaria are examples of the not uncommon phenomenon that on sufficient provocation an organ may become the chief victim of the very process which it is designed to combat A relation of the spleen to immunity is also indicated in *rats* infected with *Bartonella muris* where the *infection dormant* in intact animals is stimulated to a fatal course by splenectomy *Its* relation to tumor growth is also of interest Grafts in the spleen are said to take less frequently and to be smaller than elsewhere and intrasplenic inoculation apparently aids in raising resistance to tumor grafts elsewhere in the body Removal of the spleen also is said to stimulate the growth of tumors and to diminish resistance though the best recent evidence is against any special antineoplastic power in the spleen Positive experimental evidence of the spleen's protective power against bacteria has been difficult to obtain in recent years and still more so in the case of neoplasms where skepticism appears to be well justified

Secondary involvement of the spleen is important in many diseases whereas its primary diseases are few It will therefore be necessary here to mention briefly the splenic features of various diseases that are treated more fully elsewhere as well as the *primary diseases of the organ*

Anomalies of the Spleen —*In a few cases* the spleen has been found to be completely absent usually when there are other anomalies It may be subdivided into numerous splenunculi (as is normally the case in certain fish) or a spleen of normal size and shape may be accompanied by one or more accessory spleens These usually share in its pathologic changes and should *therefore be removed with* the spleen in such conditions as hemolytic jaundice Accessory splenic tissue may be found in such unexpected places as the stomach gall bladder testis groin and retroperitoneum Congenital abnormalities of position are usually due to or associated with other congenital defects deviations from the normal shape or size are seldom of clinical importance As the spleen is the most variable in size of the abdominal viscera large or small

infarct is found at autopsy An infected embolus causes a *septic infarct* rich in microorganisms with a characteristic serpiginous border and frequently terminating with the formation of an abscess It is much rarer than the simple infarct indeed this type was noted only four times in our series Infarction may be due to a thrombosis that is autochthonous in the splenic artery or retrograde in the vein A correct *diagnosis* is often difficult The commonest *symptom* is local pain especially if perisplenitis develops with tenderness over the somewhat swollen organ but, as has already been mentioned some acute splenic tumors partially twisted pedicles or abscesses also cause these symptoms *Surgical intervention* is not required unless continued chills and septic fever indicate the formation of abscesses The treatment otherwise is that of the underlying condition

CHRONIC SPLENOMEGALY

(Amyloid Spleen Splenomegaly in Cirrhosis Tuberculosis Syphilis Malaria)

The various forms of chronic splenomegaly have certain pathologic features in common There is generally an early congestion and hyperplasia with obscuration of the malpighian follicles followed later by atrophy and fibrosis Splenomegaly also plays an important part in such conditions as the leukemias pernicious anemia Hodgkin s disease rickets to which sections the reader is referred

Amyloid Splenomegaly—Amyloid disease of the spleen is of clinical interest on account of its possible confusion with other types of chronic splenomegaly Caused by some chronic condition such as tuberculosis osteomyelitis and so on elsewhere in the body amyloid disease occurs more frequently in the spleen than in any other organ (156 times in the 5000 autopsies mentioned as compared with eighty three times in the liver and seventy eight times in the kidney) When the enlargement is *diffuse*—the sago spleen involvement of malpighian follicles being of pathologic interest only—the spleen may attain an extreme size and cause considerable disturbance by dragging or by pressing on surrounding organs *Diagnosis* is aided by the manifestations of a chronic disease elsewhere and by the signs of amyloid change in other organs (digestive disturbances enlargement of the liver urinary changes etc) The congo red test may be of diagnostic value in obscure cases especially if positive The *treatment* consists in general hygienic measures with the main effort directed against the primary disease Regression of the amyloid infiltration has

plications If a belt and pad or bandages prove unavailing operation is necessary In the presence of positive symptoms or the likelihood of recurrence, splenectomy is indicated

Torsion of the pedicle is a complication of *lien mobile* which usually causes acute violent symptoms demanding immediate surgical relief Sudden *pain and enlargement of* the spleen with signs of shock and often fever and vomiting are the characteristic signs A partial or more gradually produced twist causes less severe symptoms

Rupture—Traumatic rupture of a normal spleen is possible although this accident is usually found to occur in an organ that is diseased Rupture occurs more commonly in malarial splenomegaly, and may take place spontaneously during acute typhoid fever *especially if malaria has caused* enlargement, or after torsion of the pedicle Rupture has not infrequently occurred in therapeutically induced malaria Rarely one finds "spontaneous rupture of a normal spleen" in the sense that following some entirely inadequate cause (such as leaning over) the spleen ruptures and no recognizable lesion is found In one of our cases thrombosis of an intrasplenic branch of a sclerotic splenic artery was followed by a subcapsular hematoma with rupture and death from the extensive hemorrhage Agonizing abdominal pain was marked The *symptoms* resemble those of torsion with signs of internal hemorrhage Pain in the left scapular region and nonshifting paravertebral dulness are of diagnostic importance Rapidly increasing anemia and a marked leukocytosis may ensue *Surgical treatment* is of course imperative If the rupture is secondary to an infarct or abscess the symptoms of the primary cause are added and signs of general peritonitis soon develop

Referring to the infrequency of the three conditions above mentioned in our series of more than 10 000 autopsies the spleen in one instance was replaced by several splenunculi varying in diameter between 1 and 3 cm No cases of movable spleen or torsion and only three of rupture were encountered but such figures of course would vary greatly with varying material

Congestion and Acute Splenic Tumor—Because of the peculiar anatomy of the spleen as well as its functional relation to infections and toxemias active congestion occurs frequently The passive congestion of chronic heart failure or cirrhosis produces the familiar cyanotic induration The acute splenic tumor of infectious diseases is the commonest pathologic change found in this organ The spleen is probably enlarged *in all* acute infections of sufficient severity frequently to the extent of being palpable This is especially true of subacute bacterial endocarditis, when the pain and extent of sudden enlargement may be sufficient to cause diagnostic confusion with acute surgical conditions No special treatment for these secondary conditions is indicated

Abscesses of the spleen are usually multiple, are relatively rare, and usually result from the breaking down of a septic infarct More rarely abscesses may follow trauma or such infectious diseases as typhoid malaria phlebitis, and erysipelas In rare instances the whole organ may be converted into a sac of pus (Osler) Of fifty-one cases in more than 10 000 autopsies the infection was transmitted by blood or lymph channels in the majority by extension in some The *symptoms* are often subordinated to those of the primary source of the trouble until rupture and general peritonitis ensue or the condition may not be discovered until autopsy Sudden local pain and tenderness sometimes associated with the characteristic friction rub of perisplenitis and the usual signs and symptoms of severe suppuration may permit *diagnosis* *Laparotomy* is then indicated The prognosis is grave the operative mortality reaching 20 per cent Splenotomy may be preferable to splenectomy if many old adhesions are present

Infarction of the spleen occurs much more often than is recognized clinically It was found 202 times in a series of 5000 autopsies (140 anemic 62 hemorrhagic) but had undoubtedly occurred in many of these cases without causing symptoms or requiring special treatment In the *Fleckmilz* (spotted spleen) of *Feitis* multiple infarcts are produced by acute and chronic arterial disease (see Fig 112)

If caused by a sterile embolus the infarct is simple and usually anemic and is followed eventually by fibrosis and shrinkage Not infrequently however a fresh hemorrhagic

no means uncommon in the spleen the originally suggested mycotic etiology of this condition is denied by most

Kala azar —This tropical disease caused by *Leishmania donovani* is one of the commonest causes of splenomegaly in the Orient, the spleen may reach extreme size The enlargement is chiefly due to hyperplasia of reticulo-endothelial cells invaded by the parasite Identification of the parasite perhaps obtained by splenic puncture furnishes a sure *diagnosis* *Treatment* is naturally that of the underlying condition though in some cases splenectomy has also been found useful

E B Krumbhaar

TUMORS AND CYSTS

Tumors of the spleen although rarer than in most abdominal viscera are probably more common than is generally recognized The benign types—fibroma lymphangioma and hemangioma—are of little or no clinical importance I have seen however, a case of the last named where bleeding through the thin capsule required splenectomy and another where hemorrhage into the organ had produced a large cyst with pressure atrophy of most of the spleen Of the malignant tumors lymphosarcoma reticulum cell sarcoma and endothelioma may be primary whereas carcinoma is always secondary Some 200 primary tumors of the spleen have been reported in the literature Of the forty secondary malignant tumors in our series the primary site was in the breast in seven cases the stomach in five pancreas in three prostate in two and esophagus appendix lip and penis in one each There were twelve secondary sarcomata and one myeloma

Lymphosarcoma (which according to Custer is the commonest cancer of children) is also the commonest primary cancer of the spleen at any age It is composed of lymphocytes of uniform appearance and maturity the more immature the cell the more malignant the tumor and the more rapid the growth The inconstant signs (pain tenderness fever pressure phenomena blood count changes sensitivity to radiation and so on) may permit sufficiently early diagnosis for splenectomy to be curative Custer points out that splenic puncture should be avoided because of the likelihood of fungating growth from the wound

Diagnosis is usually made too late to permit effective treatment although a certain number of primary malignant tumors have apparently not recurred after removal by splenectomy Pain and a steadily growing mass in the left abdomen, with rather quickly developing anemia and emaciation are the traditional signs but these are by no means always present

Cysts of the spleen may be simple (congenital or acquired), parasitic or neoplastic and single or multilocular *Simple cysts* whether the result of trauma infolding of the peritoneum dilatation of lymph spaces breaking down of hematomata necrosis or infarction are comparatively rare Fowler has seen ninety eight nonparasitic cysts and Lombard and Duboucher have recorded 158 encysted hematomata Splenic cysts are most commonly found in women of child bearing age and the acquired types are thought to be usually associated with trauma When sufficiently large to attract notice the cysts usually appear as a slowly growing mass in the left hypochondrium and cause soreness and a dragging sensation If extensive calcification of the wall exists the diagnosis may be made by x ray Fluctuation is of course an important sign when present and a diagnosis can be made in some cases by tapping In general however exploratory laparotomy is preferable on account of the danger of spreading parasitic cysts over the peritoneum *Parasitic cysts* (echinococcus) are discussed elsewhere *Neoplastic cysts* are rare angiomata may assume cystic proportions while dermoid cysts are much more common than the two reported in the literature would suggest Dr Custer found five in 5000 autopsies Splenectomy is accomplished easily has never been reported to be fatal and should be performed if the symptoms warrant it

E B Krumbhaar

THROMBOSIS

Thrombosis of the splenic vein may be either partial or complete and produces symptoms that may be acutely fatal or may

lately been reported after cure of the primary disease

Cirrhotic splenomegaly is not infrequently such a prominent and early manifestation of hepatic cirrhosis that it produces special symptoms and is even thought by some to contribute to the cirrhotic process in the liver or at least to be due to the same toxic cause This is probable not only on account of the "upstream relation of the spleen to the liver in the portal circulation but also because successful removal of the spleen in such cases improves existing anemia and lessens the amount of ascites and collateral circulation Whether or not the obstruction to the portal circulation is the sole underlying cause enlargement of the spleen quickly becomes hyperplastic as well as congestive and according to Eppinger's theory of hypersplenism may well bring about an excessive destruction of erythrocytes and a consequent moderate or even severe anemia Disturbance by the cirrhosis of the liver's function as a storehouse of the antianemic substance will also be a contributory factor Some authorities regard this type of congestive splenomegaly as the chief variety of the Banti syndrome

Syphilis of the spleen, aside from the transient acute enlargement of the secondary stage may be either a diffuse fibrosis or, much more rarely gummatous and may occur either congenitally or as an acquired disease Syphilis is especially to be suspected in the splenic enlargements of early childhood *Diagnosis* depends on the combination of an otherwise unexplained splenomegaly with the signs or history of syphilis a positive Wassermann reaction and a marked anemia and tendency to jaundice and ascites *Treponema pallidum* has occasionally been found Although ordinarily part of the general luetic process and to be treated accordingly, syphilis of the spleen sometimes demands independent recognition *Treatment* in certain cases when the spleen continues to be enlarged and causes discomfort and when the positive signs of general syphilis remain after adequate treatment, the question of splenectomy arises As in syphilis of the central nervous system the exciting agent sometimes seems to be so protected (in a by path so to speak) that it withstands specific treatment and maintains an active focus of infection Successful splenectomy in such cases has sometimes permitted further treatment to become efficacious

Tuberculosis of the spleen, although a common secondary infection (606 instances out of 5000 autopsies) occasionally, like syphilis forms a resistant focus from which further infection continues to be disseminated In addition to the terminal miliary forms the spleen may be greatly enlarged by extensive infiltration with caseated or fibrotic tubercles or may rarely be the site of a single, palpable, nodular tuberculoma—often when no tuberculous lesions are demonstrable in other organs According to Winternitz this 'primary type attacks both sexes equally and at any age but is most often seen in patients from twenty to forty years of age In 70 per cent of fifty one cases reviewed pain and swelling of the organ were found usually with chronic digestive or respiratory disturbances fever weakness and emaciation An unexplained moderate polycythemia is sometimes found If tuberculosis is present or develops elsewhere correct diagnosis should often be possible On the other hand, the acute type with collapse fever chills and backache and the atypical forms present great diagnostic difficulty Except for the rather high postoperative mortality, splenectomy is said to be a satisfactory form of treatment

Malaria of the Spleen—In chronic malaria the spleen may reach great size As in syphilis and tuberculosis it may become a reservoir which resists specific treatment and permits the continuance of the disease In malaria as in kala azar the spleen because of its very function of destroying red blood cells is exposed to infection by the organisms which it liberates The large hard pigment laden spleen of chronic malaria need not be described here Attention should however be called to the numerous and complex adhesions which greatly increase the difficulties of removal Nevertheless splenectomy in selected cases has been followed by a consistently decreasing mortality and the patients who survive are greatly improved

A siderotic splenomegaly has been described (Gandy Gamna nodules) Marked fibrosis with iron and calcium deposits is by

Banti s concept than with the view that all congestive plenomegalies must be due to hypertension in the portal system

Morbid Anatomy —The morbid anatomic changes of the Banti syndrome are not especially distinctive The greatly enlarged hard spleen in early cases may show increase in the reticulum with a cellular hyperplastic pulp and degenerative changes in the follicular arterioles as well as congestion Later the follicles become small and scarce as fibrosis of the reticulum trabeculae and capsule increases Hemorrhages and infarcts are not uncommon The lymph nodes are normal the bone marrow hyperplastic and the liver (in the third stage) shows an ordinary peri portal cirrhosis

Symptoms —The disease according to Banti s concept usually begins in young otherwise healthy adults of either sex and if untreated proves fatal after several years The onset is insidious with a gradually increasing weakness and pallor Digestive disturbances and abdominal discomfort may first call attention to the enlarged smooth hard spleen The anemia is moderate and may be either microcytic or macrocytic in type the resistance of the red blood cells is slightly increased and the signs of active formation of blood cells are but slight Neutrophilic leukopenia is characteristic although leukocytosis may occur after hemorrhage or intercurrent infection Hemorrhage of obscure origin usually from the gastric veins or esophageal varices is not uncommon It may be fatal moderate and chronically recurrent or so slight as to be detected only by the presence of occult blood in the stools

Disregarding Banti s unrecognizable second stage his third stage is ushered in by the symptoms of cirrhosis of the liver with recurrent painless ascites occasional jaundice and increased anemia and emaciation The urinary changes are more marked and urobilin is present in increasing amounts in the urine and feces With marked terminal exhaustion fever and cardiorenal troubles are not uncommon After several months or a few years an intercurrent infection or hemorrhage causes death

Diagnosis —The diagnosis of Banti s disease is necessarily made chiefly by exclusion The various chronic splenomegalies mentioned, like *hemolytic jaundice* and *Gaucher s disease* have more or less distinctive signs and when the liver is cirrhotic a careful history of the order of appearance of symptoms must be chiefly relied upon to demonstrate the primary trouble The patient s age at time of onset anemia leukopenia and chronicity are guiding features of the disease *Portal* or *splenic vein sclerosis* or *thrombosis* or in fact anything causing increased portal pressure, may present an indistinguishable picture antemortem *Laënnec s cirrhosis* with an unusually enlarged spleen may cause diagnostic difficulties if first seen when the disease is well established *Hanot s cirrhosis* if there is any such condition is said to develop in even younger individuals and is differentiated by the large liver the greater tendency to jaundice and hepatic symptoms the abdominal crises and leukocytosis *Pernicious anemia* in the stage of remission *aleukemic stages of leukemia* and *atypical Hodgkin s disease* may present difficulties which usually disappear on prolonged study Under such circumstances it is obvious that the diagnosis will not infrequently be wrongly made antemortem or even sometimes postmortem The more careful and intelligent the study the less frequently will the error be made

Prognosis —Spontaneous recovery is unknown Exacerbations may alternate with minor impairment of health for a number of years sometimes more than ten until in the last stage definite invalidism supervenes Death often comes from ruptured varices

Treatment —If the operative risk is not too great and adhesions not too extensive *splenectomy* even in the third stage is by all odds the preferable treatment In preparation for this or if operation is inadvisable the usual hygienic and medicinal measures should be utilized Though most authorities have found that marked or even complete relief usually follows splenectomy cases have been reported that have been thought to show not only that the cause of the disease is not removed by splenectomy but that the patient may be no better off than before the operation Hemorrhages from cirrhotic varices may be helped by the operation though the patient otherwise improved by the operation is still liable to

persist for many years It may be due to trauma endophlebitis extension of near by infection pressure from tumors or adhesions and many other causes

Symptoms—As a result of the blockage the spleen becomes greatly congested and enlarged (600–1000 Gm) and the current in the gastric veins (*vasa brevia*) may be reversed (*i e* toward the stomach) This is apt to cause the copious and recurrent gastric hemorrhages which are such prominent symptoms In acute thrombosis sudden abdominal pain pallor weakness and signs of collapse may precede a fatal gastric hemorrhage In the chronic form there is frequently a recurrence of abdominal symptoms for several years, there are obvious gastric hemorrhages or occult blood is present in the stools and there is a tendency toward jaundice (complicating portal thrombosis) The spleen becomes palpable in spite of the accompanying ascites and the anemia and leukopenia are often disproportionately severe It is this combination which makes the differentiation from *Banti s disease* so difficult Gradually increasing phlebosclerosis may produce a similar picture If the thrombosis involves the mesenteric veins, hemorrhoids will be added to the picture and if the portal vein is involved *caput medusae* and other signs of collateral circulation appear The symptoms may on the other hand be obscure and confined to gradual abdominal enlargement so that preoperative diagnosis is nearly impossible *Diagnosis* is always difficult and is seldom made before death Recurrent splenic episodes are apt to be significant If a correct diagnosis can be made *splenectomy* should be performed

E B KRUMBHAAR

BANTI S SYNDROME

(*Splenic Anemia*)

Definition—By those who accept Banti s disease as a separate entity, it is regarded as a chronic disease of unknown origin primary in the spleen and characterized by splenomegaly anemia and leukopenia a tendency to gastric hemorrhage increased formation and destruction of blood cells and later by cirrhotic changes in the liver with ascites and jaundice To others it is a syndrome of varied etiology to some it is merely the result of increased pressure on the splenic veins

History—The term splenic anemia" was first used in 1866 by Gretsel in the case of a child with splenomegaly and anemia but no leukocytosis Through the articles of H C Wood Osler and others this group term gradually became familiar In 1883 Banti first observed that cirrhosis of the liver and primary splenic enlargement occurred together and later described different phases in a detail which is accepted by no one today

Etiology—Banti thought that the noxious agent was brought to the spleen by the splenic artery and a splenotoxin" In his original paper he emphasized the absence of detectable causes Of the various microorganisms that have been thought from time to time to play an etiologic role none is accepted today Except for the better ability to distinguish similar conditions therefore there has been no advance in the study of this problem for many years Most writers regard the Banti picture not as a specific disease entity but a syndrome that may be produced by a variety of causes some even wish to abolish the term entirely using some general term such as 'congestive splenomegaly" It should at least be accepted that conditions such as cirrhosis of the liver venous thrombosis etc which produce a long standing increase in pressure in the splenic or portal vein can produce a practically indistinguishable picture In favor of the separate entity view, however are differences in the general picture such as the early age of onset the considerable improvement that may follow splenectomy the occasional existence of splenomegaly before cirrhosis and disappearance of an observed cirrhosis after splenectomy Congestive splenomegaly has been occasionally reported without venous obstruction (Ravenna Arch Int Med *66* 879 1940)—regarded as an active congestion for which disturbances in the splenic arterial system have been suggested as a cause There is a type of congestive splenomegaly in children (see Arch Path *27* 935 1939) not as ociated with *disease or* obstruction of the splenic vein in which splenectomy usually leads to *recovery* In the absence of evidence of obstruction it seems no more difficult to reconcile this with

NaCl and is complete at about 0 34 In hemolytic jaundice the figures are from 0 04 to 0 16 per cent higher The number of reticulocytes is greatly increased (from a normal of less than 1 per cent up to 15 or 30 per cent even more than 00 per cent have occasionally been reported)

In the exacerbations especially marked and characteristic in the acquired form Widal s crises of deglobulization the patient may suddenly become seriously ill with fever abdominal pain increased anemia jaundice (nonobstructive), and leukocytosis Unexplained obdurate ulcers of the foot have been frequently observed and also osseous changes such as thickened enlarged frontal and parietal bones (Turmschädel) and mottling of the marrow spaces

Diagnosis —The decreased resistance of the erythrocytes to hypotonic salt solution is practically pathognomonic The blood findings (especially reticulocytosis and microcytosis) and acholuric jaundice should also aid in the differentiation of other forms of splenomegaly although the hemolytic type of pernicious anemia may present difficulties The presence of gallstones should not be allowed to mask the condition

Prognosis.—The danger to life is slight except in the exacerbations of severe cases In most instances however the damage to health is considerable

Treatment —Splenectomy has proved with but few exceptions to be a practical cure bringing quick and permanent relief of symptoms Accessory spleens should also be removed With the improvement in the recognition of the disease and its operative treatment the mortality has now fallen below 3 per cent Even this low death rate should suffice however to prevent surgical intervention if the patient suffers little or no inconvenience After splenectomy the blood count rises to or toward normal the jaundice disappears and the excretion of urobilin diminishes the resistance of the red cells usually increases but fails to become normal

Before splenectomy for the acquired form where the results are less satisfactory careful search must be made for the underlying cause If this can be removed the symptoms of hemolytic jaundice may also disappear If splenectomy is performed it is advisable to remove any removable intra abdominal chronic foci of infection at the same time Splenectomy should not be performed during an exacerbation if the individual can be tided over with drugs and transfusions Successful splenectomies however have been reported even during acute hemoclastic crises In Whipple s combined spleen clinic 13 of 17 splenectomies gave excellent results whereas 14 nonsplenectomized cases showed no improvement In his atypical group' i.e icteric splenomegaly secondary to other conditions splenectomy was a failure

E B KRUMBHAAR

MISCELLANEOUS CONDITIONS

Myeloid Metaplasia —In accord with its embryonic function the spleen easily reverts to blood cell formation on demand (myeloid metaplasia) This is most strikingly seen in osteosclerosis of the bone marrow and in erythroblastosis fetalis and Cooley s anemia It chiefly involves erythropoiesis It has been found after hemorrhage hemolysis and infection and has been produced experimentally by Custer

Under the name *Agnogenic Myeloid Metaplasia* Jackson et al have described a splenomegaly of unknown origin differentiated with difficulty from various other splenomegalies and important because in this type both splenectomy and irradiation are contraindicated

In *Hodgkin s disease* the spleen is rarely the primary site though it is not infrequently the chief site of involvement

Thrombocytopenic Purpura —In this condition discussed elsewhere the spleen plays an important if not altogether clear role Whether by destroying platelets or inhibiting their formation in the bone marrow —there is evidence for both these modes of action—the spleen appears to be the major offender and when it is removed the platelet count rises and signs and symptoms subside

Giant lymph follicle hyperplasia, a condition described by Brill et al is a precancerous condition of the spleen and or lymph nodes an item of special nosologic interest as it can apparently develop into either lymphosarcoma or lymphatic leu

fatal hemorrhage Ligation of the gastric coronary veins at time of operation lessens this chance Occasional emergency laparotomies for hemorrhage from varices have led to splenectomy, with consequent permanent improvement in the patient s general condition In A O Whipple s interesting spleen clinic splenectomy tried in thirty one cases of Banti s syndrome was followed by improvement in two thirds of the cases of Laennec s cirrhosis and with even better results in other cirrhoses splenic vein thrombosis and so on *Transfusions* are valuable if the anemia is severe or after dangerous hemorrhage If ascites is troublesome and diuretics prove useless *paracentesis* may be necessary *Talma s operation* (omentopexy) may be combined with splenectomy if cirrhosis and ascites are already present Ligation of the splenic artery is indicated where extensive adhesions or other complications do not permit splenectomy

E B KRUMBHAAR

HEMOLYTIC JAUNDICE

(*Spherocytic Anemia Hemolytic Splenomegaly Acholuric Hemolytic Icterus with Splenomegaly Cholemie Familiale Anemia Icterohaemolytica*)

Definition —Hemolytic jaundice is an inherited chronic disease primarily due to increased fragility of spheroidal erythrocytes and characterized by anemia increased destruction of blood cells acholuric icterus and splenomegaly

History —First observed by Murchison in 1885 hemolytic jaundice was established as a clinical entity by Hayem in 1898 Widal s empha is on the exacerbations or crises of deglobulization led to the differentiation of an acquired form known as the *Hayem Widal type* Two years later Minkowski recorded its familial occurrence and after Chauffard called attention to the fragility of the erythrocytes which is its essential feature the familial form became known as the *Chauffard Minkowski type* This name also included the isolated congenital cases The acquired type is now generally though not universally regarded as a dormant variety eventually recognized during an exacerbation

Etiology —The disease is due to an inherited weakness of the erythrocytes a trait dominant in the mendelian sense The small spheroidal erythrocytes have been shown by Haden to rupture more easily in hypotonic solutions and presumably also in the blood stream, because of their loss of biconcavity The *acquired form* the activation of a *latent congenital case* may be secondary to some acute infection (malaria tuberculosis syphilis dysentery cholangitis), but in many cases the exciting cause cannot be determined

Morbid Anatomy —The excessive blood destruction causes deposition of blood pigment throughout the hemolytopoietic system The spleen is greatly enlarged (500-1500 Gm), and the pulp and to a lesser degree the sinuses are much congested The bone marrow is hyperplastic if the anemia is sufficiently severe Gallstones probably due to inspissation of the increased bile secretion are common

Symptoms —Splenomegaly is often the first sign of the disease The size of the spleen and the abdominal discomfort increase during exacerbations The *jaundice* is distinct but not intense and is not associated with clay colored stools or with the presence of bile pigments in the urine *i e* it is nonobstructive Urobilin is present in urine stools or duodenal contents in greatly increased amounts constituting an important diagnostic sign The van den Bergh test and icterus index give high values the former being usually of the indirect type

The *anemia* varies greatly in different cases tending to be more marked in the so called acquired form of the disease The patient may be more icteric than sick (Chauffard) or may be incapacitated by an anemia that verges on the pernicious type In a series of the congenital type of hemolytic jaundice studied by me some years ago the red blood cell count averaged over 3 000 000 whereas in the acquired form it averaged about 2 000 000 in ten recorded cases it was below 1 000 000 The *quantity* of hemoglobin is proportionately low anisocytosis is marked and microcytes are especially common The cell volume is less diminished than the diameter the cells assuming a more spherical form (*spherocytosis*) The resistance of the red cells to hypotonic salt solution is greatly lowered Although this test varies somewhat with the individual and the method used normally hemolysis begins at about 0 44 per cent

conjunctivae commonly seen on both sides of the cornea' Skeletal changes—due to the presence of the characteristic cells in the long bones—have been detected roentgenographically during life and at autopsy A connection with amaurotic family idiocy has been observed

Diagnosis—While diagnosis is usually made on pathologic material the family history early onset great chronicity, size of the spleen and pigmentation of the skin may afford the clue Several times the correct diagnosis has been discovered by splenic puncture a procedure that is not without danger

Prognosis and Treatment—Splenectomy is the only treatment that has proved of value As the operative mortality is still rather high and the disease a very chronic one the operation should not be attempted without considerable thought If it is successful the chances for improvement are great although as the disease coincidentally involves other parts of the reticulo endothelial system complete cure is hardly to be hoped for If its progress outside of the spleen is sufficiently slow however the improvement may be lasting

E B KRUMBHAAR

NIEMANN PICK S DISEASE

(*Lipoid Histiocytosis*)

A disturbance of the reticulo endothelial system not unlike Gaucher s disease except that it occurs in young children is more severe and more quickly fatal and the characteristic large cells react to lipoid stains

This frequently familial condition is limited almost entirely to the Jewish race and occurs about six times as frequently in females as in males It usually begins in the early months of life and is accompanied by marked feeding disturbances with resultant undernourishment and mental retardation Spleen liver and lymph nodes will be found enlarged with some brownish pigmentation of the skin a slight but progressive anemia and moderate leukocytosis No treatment of lasting value has been discovered Death regularly occurs in the first few years of life from manition or intercurrent infection At autopsy the large foamy cells are found widespread through the reticulo endothelial system They give positive lipoid and negative iron stains Lecithin appears to be the most important abnormal constituent of the diseased tissues

E B KRUMBHAAR

HAND CHRISTIAN S DISEASE

The combination of exophthalmos diabetes insipidus and softened areas in the flat bones was first observed by A Hand in 1893 but escaped general notice until Christian s description in 1919 In some respects intermediate between the other two diseases its lipoid cell accumulations are chiefly in the flat bones those in the orbit causing the exophthalmos (which may be unilateral) and those at the base of the skull the diabetes insipidus Fibrosis may become a prominent feature The spleen and liver are often enlarged Anemia and hypercholesterolemia are characteristic The onset is in early childhood and without racial or familial predisposition Dwarfism is common and hemorrhages or fractures may lead to osteitis fibrosa The bony lesions are easily seen in the x ray (For details of diagnosis see table in Nelson s Loose Leaf Medicine) While no specific treatment is available good hygiene and low fat diet are indicated

GROUPS TWO THREE AND FOUR

Group 2 mentioned above (with hyperplastic changes in blood and tissues) includes at least one primary condition—*monocytic leukemia* (leukemic reticulosis) —and one secondary—*infectious mononucleosis* Both are noted elsewhere in this volume

In **Group 3** (hyperplastic changes in tissues only) are (1) the rather ill defined group of the aleukemic reticuloses (cp *non-lipoid histiocytosis* and *aleukemic monocytic leukemia*) and (2) the neoplasm *reticulum cell sarcoma* (retothelial sarcoma) Non lipoid histiocytosis is either to be associated with the leukemias or regarded as an obscure acute hyperplasia of cells of the reticulo endothelial system characterized by enlargement of lymph nodes or spleen a febrile course anemia leukopenia and thrombocytopenia and fatal termination First to be noticed in this condition may be the enlargement of cervical or other lymph nodes

kemia The huge follicles are distended with lymphoblasts

Splenectomy appears to be contraindicated in the leukemias the polycythemias, almost all cancers cirrhosis and most primary anemias (erythroblastosis fetalis etc) It is especially valuable in familial hemolytic jaundice and in thrombocytopenic purpura *though it can* be said that successful removal of the other chronically enlarged *spleens that have become obviously detri*mental is followed by improvement The decision to operate on the individual case must depend both on the state of the disease and the available surgical skill

E B KRUMBHAAR

DISEASES OF THE RETICULO ENDOTHELIAL SYSTEM

As a working classification of diseases of this system we may consider those with (1) *predominant lipoid metabolic changes* (2) *hyperplastic changes in blood and tissues* (3) *hyperplastic changes in tissues only* (4) *changes of unknown nature*

GROUP ONE

Gauchers Niemann Picks Hand Christians diseases and xanthomatoses can be best considered together as more or less independent lipoid diseases of the reticulo endothelial system (Aschoff 1913) those groups of cells of the spleen liver lymph nodes bone marrow lung and elsewhere that are especially concerned with phagocytosis various phases of immunity metabolism and so on Derived from cells in the reticulum and from specialized endothelium reticulo endothelial cells are here regarded as identical with the large mononuclear and transitional cells of the blood the monocyte macrophage histiocyte endothelial leukocyte and cells with various other names They aid in the disposal of effete erythrocytes bacteria and other particulate matter are increased in monocytic leukemia typhoid infectious mononucleosis and other infections and become stuffed with complex lipoids in lipoid nephrosis diabetic lipemia high cholesterol diet xanthelasma generalized xanthomatosis and the three diseases about to be mentioned

GAUCHERS DISEASE

(Large Cell Splenomegaly)

Definition —Gauchers disease is a rare condition characterized by chronic anemia and a marked splenomegaly due to peculiar large lipoid containing cells which are also found in other parts of the hemolytopoietic system

Etiology —First described by Gaucher in 1882 as a *primary epithelioma the changes* were later shown to be a specific form of endothelial or reticular cell hyperplasia the cause of which is now regarded as an inherited disturbance of lipoid metabolism

Morbid Anatomy —Although the cells typical of the enlargement can be found histologically in bone marrow lymph nodes and liver they are most abundant in the spleen This organ is greatly enlarged (average 3600 Gm) smooth a brownish red color perhaps interspersed with small yellow dots on section the normal landmarks are found to be obscured or invisible There are occasional minute hemorrhages or infarcts Histologically the characteristic cells are round and large (20–40 microns or more in diameter) with one or more small eccentric nuclei and much pale faintly acidophilic fibrilloid cytoplasm which does not react to ordinary lipoid stains but does *contain iron* compounds The lipoid has been identified as kerasin *although apparently* other lipoids may also be present

Symptoms —Gauchers disease begins insidiously in infancy or childhood usually before the thirteenth year with a predilection for females and Jews and pursues a very chronic course (average of twenty years) The enlargement of the *spleen* which may reach enormous proportions is sometimes *discovered accidentally* or as the result of local symptoms or else the anemia with its train of symptoms may be the first to become apparent The tendency to hemorrhages submucous or subcuticular the anemia and leukopenia are *all less marked* than in Bantis disease The liver may be considerably *enlarged in* advanced cases (Kupffer cells) though jaundice and ascites *are* rare The superficial lymph *nodes* are not enlarged A brownish discoloration *of* the skin has been noticed also a peculiar yellowish wedge shaped thickening *of* the

DISEASES OF THE BLOOD

INTRODUCTION

The blood normally consists of a circulating liquid plasma in which by virtue of its motion is maintained in suspension slightly less than an equal volume of corpuscles red cells white cells and platelets The function of the red blood cells is to hold in non diffusible form the hemoglobin essential for the transport of oxygen by the blood stream An important function of the white blood cells is to act as phagocytes to assist in the defense against infection The platelets are allied with the vascular endothelium in subtle ways necessary for the maintenance of its integrity Enzyme systems in the plasma provide a second line of defense for the blood vessels converting soluble fibrinogen to fibrin at the site of an injury Disorders of the blood and blood forming organs result in abnormalities of the corpuscular composition (anemias leukemias agranulocytosis and erythrocytosis) or of the coagulating ability (prothrombin deficiency and hemophilia) of the blood and in "spontaneous lesions of the small blood vessels (purpuras) permitting hemorrhage In addition are included conditions developing when the precursors of the adult leukocytes exhibit neoplastic growth usually (leukemias) but not necessarily (Hodgkin s disease) affecting significantly the morphologic composition of the blood stream In disease histologic changes occur especially in the bone marrow lymph nodes or spleen as well as in the circulating blood Conditioned by the fundamental features of the underlying blood dyscrasias may develop the secondary manifestations of deficient oxygen transport infection hemorrhage or invasion of vital organs by neoplastic processes

The fact that certain blood dyscrasias may to superficial examination successfully imitate cardiac renal nervous or even orthopedic conditions indicates that at least an initial determination of the hemoglobin level and an inspection of a blood film should be a routine diagnostic performance in every patient It is to be emphasized that as in any branch of medicine correlation of histologic findings with the results of history and physical examination is often essential for accurate diagnosis The microscopic examination of the blood and recently of biopsy specimens of the blood forming tissues has rightly occupied the attention of those interested in the study of blood dyscrasias Quantitative methods for describing the average volume diameter and hemoglobin concentration of the erythrocyte have replaced earlier qualitative estimates Supravital staining has increased the delicacy of microscopic methods for the identification of leukocytes To these descriptive aspects of hematology a physiologic orientation has been added by the demonstrated effectiveness of liver or iron therapy in appropriate types of nutritional anemia and the recognition that exposure in occupation or through chemotherapy to certain compounds containing the benzene ring may result in hemolytic or aplastic anemias agranulocytosis thrombocytopenic purpura or even leukemia

Anemia exists when the concentration of hemoglobin in the blood stream irrespective of the number of red blood cells falls below normal Consequently there are two great classes of anemia (1) those in which blood production though increased is less than the rate of increased blood loss or destruction (2) those in which for one of several causes the rate of blood production falls below the normal rate of blood destruction In certain anemias both classes of disturbance are involved and there is not general agreement as to the one predominating

In the first class of anemias physiologic hyperactivity of the bone marrow is usually reflected in the peripheral blood stream by increases in reticulocytes granulocytes and platelets An acute hemorrhage or hemolytic process causes an almost immediate increase in granulocytes and platelets but the reticulocyte response as in the restoration of nor

(less often of the spleen) or fever of septic type followed by weakness, prostration emaciation and occasionally jaundice of low grade The anemia shows a progressive decrease in *all* of the formed elements of the blood, there is usually a relative lymphocytosis but absolute lymphopenia Differential diagnosis from aleukemic lymphadenosis aleukemic myelosis, lymphosarcoma agranulocytosis tuberculosis and Hodgkin s disease depends finally on lymph node or bone marrow biopsy There is replacement of lymphoid tissue of the node with complete destruction of architecture through proliferation of both reticular and endothelial elements these are large pleomorphic (round to stellate) cells with basophilic polychromatic vacuolated cytoplasm often exhibiting phagocytic properties or with long delicate cytoplasmic processes' (Custer) nuclei are vesicular with from one to three nucleoli Giant cells are characteristic (Sternberg Reed or Langhans varieties), with cell infiltration of other viscera notably liver and kidney The treatment is still symptomatic with attempt to remove foci of infection Irradiation does not seem to be of any value

Reticulum cell sarcoma is a malignant neoplasm primary in the lymph nodes spleen bone marrow etc It is easily confused with other tumors or enlargements of these organs and undoubtedly many such cases were formerly called large round cell ' ' mixed cell or spindle cell sarcoma Its pleomorphic cells are in close contact with the delicate argyrophilic reticulum and its cytoplasm may even be seen joining the reticulum fibers Phagocytosis and Reed Sternberg types of giant cells are common It most commonly appears in a single chain of lymph nodes which rapidly become matted together with eventual metastases far or near

In Group 4 should be placed *Hodgkin s disease* (discussed elsewhere in this book) an important disease of obscure etiology

blood fails to clot sufficiently rapidly to prevent bleeding from injuries to blood vessels too gross for platelet plugging

Erythremia characterized by a chronic and often marked increase in the concentration of circulating red blood cells and hemoglobin resembles the effect of chronic arterial anoxemia in experimental animals and in man In the idiopathic disease there is, however no degree of arterial oxygen unsaturation comparable to that in the so called "secondary polycythemias Reznikoff has presented histologic evidence for fibrosis of the capillaries of the bone marrow in polycythemia vera It is possible that this lesion may result in anoxemia of the bone marrow because of local stagnation of blood flow or interference with oxygen diffusion from the capillaries Others believe that polycythemia vera is a low grade neoplastic condition of the erythrocyte forming cells

The treatment of blood dyscrasias presents as striking contrasts in effectiveness as exist in any field of medicine Replacement of specific nutritional deficiencies by therapy with liver and stomach preparations or with iron is highly efficacious in nutritional macrocytic and hypochromic anemias respectively but is quite useless in other types of anemia Splenectomy removes the chief hemolytic organ in congenital hemolytic jaundice and so is regularly effective It may be useful in certain acquired types of hemolytic anemia especially when the spleen is large and the fragility of the red blood cells is increased Splenectomy is the only measure effective with some regularity in the treatment of thrombocytopenic purpura It fails in certain acute types and in any case the beneficial results may be only temporary Chemotherapy with quinine or sulfonamides in hemolytic anemias due to malaria or streptococcal septicemia respectively may be dramatically effective The sulfonamides deserve further trial in the control of infections especially of the oral cavity secondary to leukemia agranulocytosis and aplastic anemia Irradiation is a purely palliative though often valuable procedure For reducing the local lesions of lymphosarcoma or of Hodgkin s disease x ray therapy must be intensive By contrast is the increasing recognition that in the chronic leukemias the use of small amounts of more general irradiation given at regular intervals of a week or two is a suitable and safe method Radioactive phosphorus another form of irradiation has not yet been shown to have significant advantages over properly applied x ray therapy in leukemia Transfusion is a useful but purely passive form of therapy It neither stimulates nor depresses the hematopoietic organs By its use the blood volume may be augmented in severe hemorrhage and the hemoglobin may be increased in anemias with critically low values In thrombocytopenic purpuras platelets can be temporarily added to the blood stream and in hemophilia the clotting time of the blood may be temporarily reduced Transfusion does not raise the leukocyte count for more than an hour or two In addition specific or general therapeutic measures of value in other types of disease have their indications and their propriety in the treatment of patients with blood dyscrasias

ANEMIA

Definition —The term anemia is applied to any deficiency in the quantity or quality of the blood as manifested by a reduction in the number of red corpuscles or in the amount of hemoglobin usually in both

Etiology —In the past anemia has been

mal bone marrow function by liver extract or iron in appropriate anemias, begins only after three or four days and is maximal usually before the tenth day Increased blood destruction is usually evidenced by increased amounts of the pigment derivatives of hemoglobin bilirubin in the plasma and urobilinogen in the feces

In the second class of anemias, the bone marrow is assumed to be hypofunctional because of nutritional or endocrine deficiency toxic inhibition invasion by foreign cells or fibrous tissue or for unknown causes In general as exemplified by the blood picture in aplasia of the bone marrow, the reticulocytes granulocytes and platelets in the peripheral blood tend to be reduced in numbers Exceptions to this rule exist and the highly cellular bone marrow of pernicious or certain 'aplastic anemias may belie its apparent physiologic hypofunction Indeed certain authorities believe on the basis of bile pigment outputs that such anemias are in reality predominantly hemolytic in nature With certain exceptions, especially in the differential diagnosis of myelophthisic anemias including aleukemic leukemia and agnogenic myeloid metaplasia bone marrow biopsy despite its descriptive interest affords little information of diagnostic value which cannot be obtained by other means Critical observations on the percentage of reticulocytes during an initial ten day period should always be made following a suspected hemorrhage or acute hemolytic episode or when liver extract or iron is administered

Little difficulty in the diagnosis of the typical case of leukemia is encountered provided the blood is examined Clinically however especially in its acute forms and in children leukemia may assume the features of an infection and indeed may imitate other clinical conditions as diverse as pyorrhea arthritis or neuritis It is easily possible to fail to recognize the aleukemic forms and to confuse with leukemia such conditions as infectious mononucleosis marked leukocyte responses to infection or agnogenic myeloid metaplasia Some of the difficulty will be avoided if the fact is kept in mind that in the peripheral blood of leukemias should appear in addition to abnormal leukocytes evidences of disturbed erythrocyte production leading to significant anemia and abnormalities in the number of platelets In order to effect the differential diagnosis referred to above or to determine the nature of a process causing lymph node enlargement without diagnostic changes in the blood stream (e g Hodgkin s disease), lymph node or bone marrow biopsy or splenic puncture may be required

Certain cyclic compounds such as arsphenamine aminopyrine and the sulfonamides possess the property of producing in relatively rare instances serious toxic effects on the blood forming organs These are manifest as agranulocytic angina, thrombocytopenic purpura or aplastic anemia representing predominant injury to leukocyte thrombocyte or erythrocyte production individually or in combination It is clear that an unknown factor of individual susceptibility exists In other instances of these conditions but with a frequency which diminishes somewhat with the care employed in seeking a pertinent history no evidence of exposure to toxic compounds is found With the possible exception of the use of nucleic acid derivatives in agranulocytic angina the therapy of these conditions is unsatisfactory unless following removal of the offending agent or for unknown reasons there is spontaneous recovery

The pathologic physiology underlying the hemorrhagic conditions represents disturbances of individual components of a complex of physical and chemical factors In the normal individual if a small blood vessel is punctured it first contracts then blood platelets become adherent to the edges of the wound and finally the blood clots probably as the result of one or more enzymatic reactions which are set in progress by thromboplastic substances present at the site of injury The platelets then cause a firm clot by shrinking the strands of fibrin In the purpuras the clotting mechanism at least in the test tube is entirely or almost normal The defect is a congenital or acquired weakness of the vascular wall or a lack of platelets or a combination of both If prothrombin is deficient as in hemorrhagic conditions of the newborn or in certain instances of liver disease or if an unidentified enzyme associated with a globulin fraction of the plasma is deficient as in hemophilia the

are chiefly reticulocytes and often reach a peak of from 10 to 15 per cent on the fourth to seventh day Occasionally normoblasts and very immature leukocytes are seen The red cells are replaced more rapidly than the hemoglobin so that hypochromia results

Diagnosis—The history and often the continuation of hemorrhage the appearance of prostration and air hunger the weak rapid pulse and falling blood pressure and the characteristic blood picture of a leukocytosis and appearance of young red cells are all evidences of the loss of blood

Prognosis—The outcome of the condition depends entirely upon the amount and rapidity of blood loss the promptness with which treatment is started and the ease with which the hemorrhage may be stopped Thus if one third of all the blood is lost suddenly death may follow unless the fall in blood volume is immediately corrected although an individual may be deprived of almost two thirds of his blood within twenty four hours and still recover Ruptured gastric varices or an exsanguinating hemoptysis is stopped with difficulty while bleeding from an external wound is in most cases readily controlled

Treatment—The entire treatment of acute loss of blood consists in measures for stopping the hemorrhage and for immediately increasing the blood volume Unless contraindicated because the hemorrhage is from the upper portion of the gastro intestinal tract fluids should be given by mouth at once Blood pressure readings should be taken every half hour, and if the critical level (75 to 90 mm of mercury at systole) is approached emergency treatment should be instituted at once Transfusion of 500 to 1000 cc of blood from a compatible donor is the most efficacious form of treatment although bank blood and plasma or serum can be used with excellent results to ensure maintenance of a safe blood volume and in most cases much time can be saved by using these substances Temporarily saline may be injected intravenously or better still 300 to 500 cc of 10 per cent glucose solution followed by a hypodermoclysis of 1000 cc of saline The patient should be kept quiet If necessary morphine may be given Warmth is essential but care must be taken to avoid still further loss of fluid by perspiration If the blood volume can be maintained above critical limits and the hemorrhage stopped the majority of patients recover While iron may be given as a rule in a previously normal individual the substances which produce hemoglobin are ample in the body stores A high protein and adequate mineral and vitamin diet is desirable

Defective Blood Formation—*Classification*—Defective formation of blood may be due to one of the following

(*A*) Nutritional deficiency which may be subdivided still further into lack of
- 1 blood building substances such as iron and protein,
- 2 the materials effective in the treatment of pernicious anemia owing to a deficiency of either the intrinsic or extrinsic factor of Castle or of both,
- 3 thyroid secretion and, perhaps vitamin C,
- 4 possibly copper and other heavy metals

(*B*) Depression of the bone marrow by
- 1 chemicals such as benzol arsphenamine gold salts and the sulfonamides,
- 2 toxins elaborated in nephritis or in chronic infections,
- 3 physical agents such as x ray and radium and
- 4 mechanical interference as in leukemia Hodgkin s disease neoplasms and osteosclerosis

(*C*) Unknown causes, as in 'aplastic' or refractory anemia

Iron Deficiency Anemia—Iron deficiency occurs in (1) chronic blood loss (2) chlorosis (3) defective iron ingestion or difficulty of absorption (4) the removal of iron from the pregnant mother by the fetus (5) nutritional deficiencies in childhood (6) idiopathic hypochromic anemia and (7) gastro intestinal conditions for example following gastric operations idiopathic steatorrhea and hookworm infestation

The problem of adequate supply of iron and other substances necessary to produce hemoglobin and red blood cells has been demonstrated by Whipple and his co workers to be essentially one of balance During growth pregnancy and menstruation in

divided in two groups—primary and secondary—a classification based on the fact that the etiology of certain blood deficiency diseases was unknown Although this classification of anemia is still used, it is evident that any given case of anemia is secondary to one of the following three causes (1) loss of blood, (2) defective formation of blood (3) increased destruction of blood By the ordinary methods of examination, hydremia such as occurs in pregnancy would be included as a type of anemia The morphologic classification of anemias is of great value and depends upon the size of the red blood cell To determine this direct measurements of the diameter of the erythrocytes may be made or hematocrit values may be obtained and these compared to normal standards for given red blood cell counts Thus anemias may also be grouped as (1) macrocytic hyperchromic (pernicious anemia), (2) microcytic hypochromic (iron deficiency anemia), and (3) normocytic normochromic anemia (sudden loss of blood hemolysis) Many exceptions and varying combinations of these morphologic changes may occur but in most anemic patients the above classification is of great service in diagnosis Excellent classifications are available in the publications of Castle and Minot Vaughan and Wintrobe

Blood Loss —*Etiology* —Acute blood loss presents primarily a problem of reduced blood volume Although this results in anemia, the hemoglobin and red blood cell count in the absence of complications usually return to a normal figure within two months Acute blood loss takes place in traumatic severance of blood vessels rupture of viscera lesions of the gastro intestinal tract particularly gastric or duodenal ulcers typhoid fever and erosions of gastric and esophageal arterioles or varicosities hemorrhagic pancreatitis ectopic gestation placenta praevia pulmonary tuberculosis and after operations

Recurrent chronic blood loss is most frequently seen from hemorrhoids gastric and duodenal ulcers uterine lesions and gastric and esophageal varicosities occurring in cirrhosis of the liver Since anemia resulting from recurrent hemorrhage is to a great extent dependent upon the loss from the body of iron and other substances necessary for normal hematopoiesis a better concept of the mechanism underlying this condition is obtained if chronic blood loss is considered under the heading of "Defective Blood Formation' Therefore this description will deal with acute blood loss

Symptoms and Signs —The symptoms and signs of acute blood loss are very striking The patient feels weak and faint, becomes dizzy and quite thirsty and may vomit The *pulse* is rapid and weak the *skin* dusky, pale and cold the *temperature* subnormal at first and later may be slightly elevated and the *respiration* at first deep and rapid becomes weak and shallow The individual is *restless* and if hemorrhage continues delirium frequently ensues Finally a cold perspiration breaks out and the patient rapidly passes into a state of *shock* and coma During this condition the change in *blood pressure* is characteristic At first the diminution of the blood volume causes a reflex constriction of the arterioles which prevents any marked change in blood pressure and may even cause a slight rise With continued loss of blood the pressure declines gradually until at systole it is between 75 and 90 mm of mercury This is called the *critical pressure* If bleeding continues the pressure drops suddenly and markedly and shock supervenes All the symptoms and signs of acute loss of blood are due to anoxemia and depend upon a diminution of blood volume

Blood Picture —The immediate result of an acute hemorrhage is a decrease in blood volume The earliest change in the blood picture is a *polymorphonuclear leukocytosis* with an increase of immature polymorphonuclears (shift to the left) and of platelets which usually begins within fifteen minutes of an acute hemorrhage and reaches its peak within a few hours At first the concentration of red cells and hemoglobin remains about normal because the plasma volume is decreased Soon, with dilution of the blood by fluid drawn from the tissues the diminished quantity of erythrocytes and hemoglobin becomes manifest Following severe hemorrhage the greatest dilution occurs after two or three days or more if the intake of fluids is restricted the blood may not return to normal for two months Within the first forty eight hours after a brisk hemorrhage young cells appear in the circulation These

evidenced by a rise in the quantity of pigment in the serum bile stools and urine and an increase in the activity of the bone marrow which is made apparent by the presence of many young cells in the blood especially reticulocytes

While the immediate cause of hemolytic anemia is the destruction of erythrocytes in many cases the basic deficiency may be an abnormality of red blood cells so that they are easily hemolyzed

Classification—Hemolytic anemia may be due to (1) extrinsic and (2) intrinsic causes

1 Extrinsic (*a*) Chemicals—The use of coal tar derivatives and lead compounds are frequently associated with anemia The anemia of lead poisoning probably is due to the action of lead on the surface of the erythrocytes The cells become more fragile and are less able to withstand the trauma of circulation In Italy the raw fava bean or its blossom causes a severe hemolytic anemia in sensitized persons The sulfonamide drugs may cause a hemolytic anemia

(*b*) Infections—Hemolytic anemia is associated with hemolytic streptococcus infections and malaria Anemia occurring with most other infections is usually due to a depression of the bone marrow

2 Intrinsic Hemolytic spherocytic jaundice sickle cell anemia paroxysmal hemoglobinuria and acute hemolytic anemia of Lederer form an important group of hemolytic anemias

Hemolytic spherocytic jaundice is associated with splenomegaly and will therefore be discussed with the diseases of the spleen It is of interest however to point out here that the patient often suffers from a chronic anemia characterized by marked destruction of blood The spleen liver and kidneys become tinged with blood pigment there is a marked hyperplasia of the bone marrow and the number of microcytes and of reticulated cells in the blood is increased Although the diameter of the cells is small the volume of each cell is normal or greater than normal The young erythrocytes may come to constitute 25 to 30 per cent and even 90 per cent of the total number of red cells Bile is usually absent in the urine except during exacerbations but urobilin is present One of the characteristic features of this condition is the marked decrease in the resistance of the red blood cells to hypotonic saline solution Normal erythrocytes begin to hemolyze in a saline solution of about 0 45 per cent and are completely laked by concentration of 0.35 to 0.3 per cent In hemolytic jaundice hemolysis may begin at 0 7 per cent and be complete in solutions of 0.5 to 0 45 per cent The red blood cells are globular or spherocytic in shape instead of biconcave It is for this reason that they are less able to exist in hypotonic saline and are so easily broken up in the circulating blood

Sickle cell anemia occurs in Negroes rarely in white people is probably familial and is characterized by a reduction in the number of erythrocytes in the blood the appearance of sickle-shaped red cells rheumatoid manifestations leg ulcers bone changes and attacks of acute abdominal pain Patients suffering from this disease have a red cell count of approximately 2 500 000 a color index slightly below 1 a moderate leukocytosis and a distinct eosinophilia Nucleated red cells and some diffuse and punctate basophilia are commonly present Often the characteristic sickle shaped cells do not appear until after the blood has been allowed to stand for several hours or has been subjected to decreased oxygen tension and examined in moist preparations A specific lesion in this condition is described which consists of a malformation of the sinuses around the malpighian bodies of the spleen

Recently Dameshek has reviewed the hemolytic anemias and discussed such conditions as target cell anemia abnormal hemolysins the role of stasis especially in the paroxysmal nocturnal hemoglobinuria as described by Ham march hemoglobinuria and the very interesting condition of erythroblastosis fetalis studied by Levine and his co workers and shown to be due to immunization of an Rh negative mother by an Rh positive fetus with the production of agglutinins which cause hemolysis of the fetal blood cells

General Symptoms and Signs—These depend upon the condition from which the anemia results In general the patient feels weak tires easily becomes dyspneic on exertion and may complain of faintness vertigo and palpitation Pallor a rapid pulse

creased intake is necessary If any condition interferes with absorption there will be a deficiency of iron for the manufacture of hemoglobin It has also been shown that deficiency of protein will limit hemoglobin production even *if iron intake is adequate*

Although the classic type of chlorosis so commonly described in the latter half of the nineteenth century found in the Irish immigrant servant girl and associated with improper nutrition poor hygiene, hard work constipation and menstrual disturbances has practically disappeared, hypochromic microcytic anemia is a fairly frequent occurrence now in women between the ages of thirty and fifty This condition is usually associated with an achlorhydria or hypochlorhydria excessive menstrual flow harshness of skin or hair brittle convex or ridged fingernails and frequently with a glossitis When the sore, red tongue and dysphagia have dominated the picture this anemia has been called the Plummer Vinson syndrome Hematologically the striking features of iron deficiency from any cause whether it be from chronic hemorrhage or faulty intake are the relatively marked decrease of hemoglobin compared to the red blood cell reduction and the small size of the cells giving a low volume index usually less than 0 8

Pernicious and Other Macrocytic Anemias —Pernicious anemia and certain other macrocytic anemias are excellent examples of deficiencies of a red cell maturative factor which is contained in certain liver extracts These conditions caused by the lack of some nutritive material necessary for blood building will be discussed in the chapter dealing with pernicious anemia

Anemias Due to Lack of Thyroid Secretion and Vitamin C—Thyroid lack may cause a normocytic a macrocytic hyperchromic or an hypochromic anemia Bomford believes that the thyroid affects erythropoiesis only indirectly through its effects on the consumption of oxygen by the tissues and on gastric secretion Iron therapy for the hypochromic or liver extract for the hyperchromic anemia as well as thyroid substance are indicated

Recently vitamin C deficiency as a cause of anemia has been questioned It has been pointed out that hemorrhage and iron deficiency are frequently found in cases of scurvy and probably play the major role in the production of the anemia

Miscellaneous Anemias Due to Decreased Blood Production—The other causes of depression of bone marrow function such as the chemicals listed above nephritis chronic infections tertiary lues rheumatic fever subacute bacterial endocarditis and long continued sepsis as illustrated by empyema and osteomyelitis and the depression due to x ray and radium produce a variable picture When tumors crowd out the hematopoietic tissue as in multiple myeloma, metastatic carcinoma Hodgkin s disease and leukemia at first an initial irritation of the marrow may cause an increase of polymorphonuclear leukocytes platelets and young red cells but this may be followed by a blood picture suggesting hypoplasia

Aplastic anemia may be caused by certain intoxicating agents, chief among which are benzol radium x ray trinitrotoluol arsphenamine and the sulfonamides Occasionally it is associated with severe or chronic sepsis tertiary lues and arteriosclerosis, and recently nephritis has been shown to play an etiologic role The bone marrow may show aplasia or red marrow with fatty and fibrous replacement The fact that the peripheral blood suggests an aplastic bone marrow is no indication that this lesion will be found Careful study of bone marrow in so called aplastic anemia has shown great variability and frequently hyperplasia Of course even if the bone marrow presents a hyperplastic anatomic appearance it may be hypoplastic functionally The blood is deficient in red cells and hemoglobin but no hypochromia is present Lymphocytes predominate although leukopenia is invariable and thrombocytopenia marked A prolonged bleeding time and poor clot retraction are characteristic

The etiology of idiopathic aplastic or refractory anemia is unknown Rhoads and his co workers suggest abnormalities of the liver may occur which result in failure of detoxication of a possible endogenous toxic aromatic hydrocarbon This substance may cause hemolysis and bone marrow hypoplasia

Increased Destruction of Blood—Abnormal destruction of blood may vary from slight to severe Increased destruction is

evidenced by a rise in the quantity of pigment in the serum bile stools and urine and an increase in the activity of the bone marrow which is made apparent by the presence of many young cells in the blood especially reticulocytes

While the immediate cause of hemolytic anemia is the destruction of erythrocytes in many cases the basic deficiency may be an abnormality of red blood cells so that they are easily hemolyzed

Classification—Hemolytic anemia may be due to (1) extrinsic and (2) intrinsic causes

1 EXTRINSIC (*a*) CHEMICALS—The use of coal tar derivatives and lead compounds are frequently associated with anemia The anemia of lead poisoning probably is due to the action of lead on the surface of the erythrocytes The cells become more fragile and are less able to withstand the trauma of circulation In Italy the raw fava bean or its blossom causes a severe hemolytic anemia in sensitized persons The sulfonamide drugs may cause a hemolytic anemia

(*b*) INFECTIONS—Hemolytic anemia is associated with hemolytic streptococcus infections and malaria Anemia occurring with most other infections is usually due to a depression of the bone marrow

2 INTRINSIC Hemolytic spherocytic jaundice sickle cell anemia paroxysmal hemoglobinuria and acute hemolytic anemia of Lederer form an important group of hemolytic anemias

Hemolytic spherocytic jaundice is associated with splenomegaly and will therefore be discussed with the diseases of the spleen It is of interest however to point out here that the patient often suffers from a chronic anemia characterized by marked destruction of blood The spleen liver and kidneys become tinged with blood pigment there is a marked hyperplasia of the bone marrow and the number of microcytes and of reticulated cells in the blood is increased Although the diameter of the cells is small the volume of each cell is normal or greater than normal The young erythrocytes may come to constitute 25 to 30 per cent and even 90 per cent of the total number of red cells Bile is usually absent in the urine except during exacerbations but urobilin is present One of the characteristic features of this condition is the marked decrease in the resistance of the red blood cells to hypotonic saline solution Normal erythrocytes begin to hemolyze in a saline solution of about 0 45 per cent and are completely laked by concentration of 0 35 to 0 3 per cent In hemolytic jaundice hemolysis may begin at 0 7 per cent and be complete in solutions of 0.5 to 0 45 per cent The red blood cells are globular or spherocytic in shape instead of biconcave It is for this reason that they are less able to exist in hypotonic saline and are so easily broken up in the circulating blood

Sickle cell anemia occurs in Negroes rarely in white people is probably familial and is characterized by a reduction in the number of erythrocytes in the blood the appearance of sickle-shaped red cells rheumatoid manifestations leg ulcers bone changes and attacks of acute abdominal pain Patients suffering from this disease have a red cell count of approximately 2 500 000 a color index slightly below 1 a moderate leukocytosis and a distinct eosinophilia Nucleated red cells and some diffuse and punctate basophilia are commonly present Often the characteristic sickle shaped cells do not appear until after the blood has been allowed to stand for several hours or has been subjected to decreased oxygen tension and examined in moist preparations A specific lesion in this condition is described which consists of a malformation of the sinuses around the malpighian bodies of the spleen

Recently Dameshek has reviewed the hemolytic anemias and discussed such conditions as target cell anemia abnormal hemolysins the role of stasis especially in the paroxysmal nocturnal hemoglobinuria as described by Ham march hemoglobinuria and the very interesting condition of erythroblastosis fetalis studied by Levine and his co workers and shown to be due to immunization of an Rh negative mother by an Rh positive fetus with the production of agglutinins which cause hemolysis of the fetal blood cells

General Symptoms and Signs—These depend upon the condition from which the anemia results In general the patient feels weak tires easily becomes dyspneic on exertion and may complain of faintness vertigo and palpitation Pallor a rapid pulse

slight fever some dependent edema and systolic murmurs are often present As the changes in the blood depend upon the etiology and severity of the anemia no single description can fit the great number of variations which occur If the anemia has developed gradually patients may show very *few symptoms in bed with red blood cell* counts of 1 000 000 and hemoglobin values of 2 9 gm or 20 per cent

Blood Picture —Some of the most striking features of the blood picture in anemia have been mentioned in the description of each type The volume index may be a guide to the type of anemia present A low index implies lack of hemoglobin as seen in iron deficiency and chronic hemorrhage An index more than 1 suggests a defect in cell production and is characteristic of pernicious anemia It occurs however in sprue cirrhosis of the liver carcinoma of the pylorus pregnancy and other conditions

In most anemias due to defective formation of blood the hemoglobin reduction is greater *than that* of the red blood cells This is not true however, in the macrocytic anemias such as pernicious anemia unless iron deficiency complicates the condition Abnormalities of the white blood cells changes in size shape and staining properties of the red blood cells variations in platelets and in such properties as bleeding time and clotting time are variable and are taken up in the more comprehensive works to which the reader is referred In the hemolytic anemias the icteric index is increased but it is important to realize that in many anemias increase of serum pigment or pigment excretion may be due to hemolysis of *intrinsically abnormal red blood cells*

Treatment —The success of the treatment of anemia depends entirely upon whether or not the cause may be removed Anemia due to hemorrhage can be cured by stopping the loss of blood If necessary surgical intervention should be undertaken Frequently a supportive transfusion may be necessary before the patient can undergo an operation *Once the cause* of the hemorrhage is removed recovery is usually assured The patient should have the benefit of abundant fresh air sunlight and a nourishing diet which should contain spinach meat liver eggs apricots peaches *foods* containing vitamin C and sufficient proteins Administration of iron as well as of other

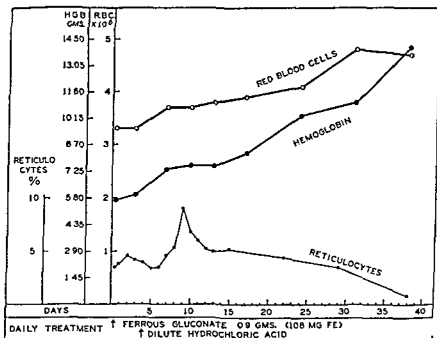

Fig 118 —The blood changes following treatment in a case of hypochromic microcytic anemia with achlorhydria and profuse menstruation (iron deficiency) Although the dosage of iron given was only about one-third that usually advised in such cases there was a satisfactory reticulocyte hemoglobin and red *blood* cell response

factors necessary for the production of hemoglobin and red blood cells may accelerate bone marrow function

The defective formation of blood due to leukemia or tumor invasion can only be treated symptomatically Usually as the leukemia yields to radiation or potassium arsenite the red blood cell and hemoglobin values rise When the condition is due to toxins such as benzol or when it is caused by sepsis these factors must be eliminated and supportive transfusions of blood employed

Iron therapy is indicated in all cases of hypochromic anemia and to be effective must be given in adequate doses While as much as 1 gm (15 grains) of iron daily has been advocated large amounts of iron may be retained even when relatively small doses are administered and Hahn and his co-workers found that in their experiments with radioactive iron absorption depends upon the body s need for iron Ferrous salts are usually more easily tolerated than ferric salts or reduced iron Ferrous sulfate 1.5 gm (22½ grains) iron and ammonium citrate 6 gm (1½ drachms) or reduced iron 1 gm (15 grains) daily are adequate doses A reticulocyte response within ten days presages a return of hemoglobin to normal within three or four weeks with proper therapy There is no justification for parenteral administration of iron Some patients tolerate large quantities of iron if the maximum dose is approached gradually Individuals frequently tolerate certain iron compounds and not others In general iron therapy tends to cause fewer gastro intestinal disturbances if given after meals There is some evidence that iron absorption is enhanced by the hydrochloric acid contained in the gastric juice Therefore in the presence of achlorhydria the administration of dilute hydrochloric acid with meals 2 to 4 cc (½ to 1 drachm) may be tried Liver therapy most effective when given parenterally should be undertaken in cases of macrocytic anemia due to nutritional defect such as addisonian pernicious anemia and in pernicious anemia of pregnancy This liver fraction is soluble in water and in 70 per cent alcohol A fraction which is insoluble in 70 per cent alcohol has been used by Whipple in the treatment of anemia in dogs subjected to blood loss The anemia complicating hypothyroidism must be treated with thyroid extract as well as the specific substance necessary for regeneration of hemoglobin or erythrocytes

The causes of blood destruction must be removed if possible This is relatively easy when the diminution of blood is due to some exogenous poison In infections the treatment depends entirely upon the eradication of the infecting organism Splenectomy is specific therapy for spherocytic hemolytic jaundice

In adults the administration of copper *salts and other heavy metals or large doses* of vitamins have as yet little evidence to support their use

In general the treatment of anemia consists first in removing the cause and then assisting the hemogenic function of the body which under normal circumstances is capable of maintaining an adequate supply of blood When such a procedure is impossible therapeutic measures including transfusions must be considered only palliative

PERNICIOUS ANEMIA

(*Addisonian Pernicious Anemia Addison's Anemia Biermer's Anemia Primary Anemia*)

Definition —Pernicious anemia is a disease due to *deficiency in the body of material derived from food and manifest as a macrocytic anemia associated with disturbances of the gastro intestinal tract and frequently of the neural system If untreated* the disease progresses by relapses and remissions to a fatal issue Under adequate treatment with a suitable preparation of liver or *stomach the blood remains normal* symptoms but not all signs of disorder of the digestive system vanish and no progress or development of neural system lesions occurs

History —James S Combe of Edinburgh described a case of pernicious anemia in 1822 Thomas Addison of Guy's Hospital London recognized idiopathic anemia as a clinical entity in 1849 and published his best known description in 1855 in a monograph On the Constitutional and Local Effects of Disease of the Suprarenal Capsules" Anton Biermer of Zurich drew attention to the disease on the continent in 1872 under the name progressive pernicious anemia Treatment was universally unsuccessful until in 1926 Minot and Murphy discovered that the daily ingestion of large amounts (200 ± Gm) of mammalian liver was an effective remedy In 1928 Castle demonstrated the part the stomach plays in the causation of the disease

Incidence —*Pernicious anemia rarely* occurs before the age of thirty The majority of cases develop in the fourth and fifth decades of life and are about equally divided between the two sexes The disease occurs especially in the northern parts of the north temperate zone of America and Europe where there are probably not less than 35 cases per 100 000 population It is prone to develop in blue eyed individuals of the Nordic race whose hair has turned prematurely gray and who have broad facies and a large body frame On the other hand some patients show none of these features When complete family histories are available about 18 per cent of the patients will be found to have one or more close relatives who have or have had the disease

Etiology —There is an almost constant absence of hydrochloric acid in the gastric juice which may appear years before the anemia and almost always remains in spite of liver therapy The atrophy of the stomach responsible for this condition suggested to C Handfield Jones in 1855 and to Fenwick in 1870 that failure of digestion was responsible for the condition This idea became over shadowed by the conception of infective causes and mechanisms not involving the gastro intestinal tract The importance of gastritis, however was emphasized by Faber and Hurst and the idea that the condition represented a dietary deficiency arose about the time liver therapy was first studied Castle has shown that the disease is due to a nutritional deficiency conditioned by a defect in the gastric secretions and that this disease and certain other macrocytic anemias are related to a common etiologic mechanism The normal individual secretes a gastric (intrinsic) factor which reacts with a food (extrinsic) factor for the production of the supply of liver extract to maintain normal blood formation The material is absorbed and stored in the liver and certain other tissues In pernicious anemia during a relapse "liver extract" is essentially absent in the patient's liver The thermolabile gastric factor is secreted in man particularly from the fundic and cardiac portions of the stomach and in pigs especially from the pyloric portion and probably from the duodenum Its nature is unknown, it has not been identified with any recognized constituent of the gastric secretion *The thermostabile* food factor is present in a number of natural sources (meat eggs cereals etc) of the vitamin B complex Castle has represented the factors *involved in the* production of the substance that is deficient in pernicious anemia and related macrocytic anemias by the schematic formula

$$\frac{F \times G}{I} = LE$$

F stands for food factor G for gastric factor and I for intestinal impermeability or any defect causing malabsorption or alteration of those substances or a product of their effective interaction L E stands for "liver extract the independently effective thermo stabile factor found in mammalian liver Probably in none of the anemias produced by alteration in this mechanism is any *factor* on the left of the equation completely normal and there is a variable participation of defects of one or both of the factors in the numerator or some increase of the denominator value Any or all of such changes from the normal if sufficiently great will

create a decrease of "liver extract" and so produce macrocytic anemia which will respond to the parenteral administration of liver extract

If the dominant defect is in the food the anemia will vanish when either extrinsic factor or liver extract is fed Extrinsic factor deficiency occurs in some cases of pernicious anemia of pregnancy in certain cases of sprue and idiopathic steatorrhea and in unusual cases in the temperate zone which are often clinically indistinguishable from addisonian pernicious anemia The mechanism for the production of many cases of macrocytic anemia of the tropics is not clear These cases can be cured by crude liver extract but not with the purer liver extracts effective in pernicious anemia Autolyzed yeast is also effective in these cases but does not benefit patients with addisonian pernicious anemia If the dominant defect is in the gastric factor the anemia will not respond to the extrinsic factor but to liver extract This is typical of addisonian pernicious anemia The macrocytic anemia of fish tapeworm infestation presumably arises from alteration in factor E G or both If factor I is sufficiently increased the patient may respond to no type of material given by mouth but will respond to parenterally administered liver extract Thus defective absorption of necessary material may occur for example in sprue and prolonged diarrhea as from dysentery Intestinal stenosis and short circuits may lead to the picture of pernicious anemia perhaps by enhancing the absorption of products that impair the internal metabolism of liver extract Infections intoxications and severe damage to vital organs inhibit the effect of liver extract In different patients the action or optimal dose of parenterally administered liver extract may vary considerably

Increases of extrinsic factor and in residual amounts of intrinsic factor probably explain the spontaneous remissions of pernicious anemia formerly observed Complete recrudescence of the intrinsic factor is rare Lack of the intrinsic factor may occur when there is free gastric hydrochloric acid In typical addisonian pernicious anemia achlorhydria accompanies the essential defect but the intrinsic factor may be present with achlorhydria in other conditions or types of anemia It has been suggested that lack of intrinsic factor may be dependent upon gastritis arising from infections or toxic causes and that hereditary influences play a role Apparently the defect may rarely arise because of extrinsic destruction of the stomach mucosa by polyps or cancer or from gastrectomy Miller and Rhoads have produced a lack of gastric factor achlorhydria and macrocytic anemia in swine by a diet defective in vitamin B_2 (G) or a closely related substance The applicability of these observations to the etiology of macrocytic anemia arising from defective diet can scarcely be doubted but to ascertain how far dietary deficiency is operative originally in pernicious anemia requires further study

The thermostabile material in normal human and animal liver effective in pernicious anemia is soluble in 70 per cent alcohol in contrast to the material precipitated by 70 per cent alcohol which Whipple has shown is effective in hypochromic anemia due to blood loss The exact nature of the active principle which is nonprotein is unknown In addition to liver kidney brain and other tissues contain potent material which perhaps is different in character from that of liver In 1929 Sturgis and Isaacs showed that desiccated hog s stomach was as effective in pernicious anemia as liver Its effectiveness is dependent on the interaction of the intrinsic and extrinsic factors in gastric tissue The intrinsic factor in hog s stomach in contrast to the active principle of liver is readily destroyed by heat Because of the presence of extrinsic factor in liver extract and liver their potency may be enhanced some ten to twenty times by incubation with intrinsic factor

Pathology —The body usually shows no important loss of weight The skin and sclerae often possess a yellow tint The heart presents one of the finest examples of fatty tigering The tongue usually appears smooth and often red with absence in large part of the papillae There is atrophy both of the mucous membrane and underlying muscle With denudation of the epithelium vesicles may be present and sometimes shallow whitish ulcers Atrophy of the gastric mucosa with signs of inflammation is common The slightly enlarged liver has an

abundance of iron in the periphery of the lobules and in the Kupffer cells the pale centers of the lobules show fatty degeneration Free iron is found in other organs especially the lungs and spleen, and in the kidneys within the epithelium of the first convoluted tubules The spleen is usually enlarged but seldom double normal in size it may show myeloid formation which resembles in character the marrow of the bones Pigment metabolism is obviously abnormal and the blood plasma often contains increased amounts of pigment The van den Bergh reaction is an indirect positive Increased excretion of urobilin is a feature The accumulations of pigment and iron are rapidly utilized when specific treatment is begun

The red bone marrow is increased, soft and of deep red color There is a very great proliferation of primitive red cells often in sheets obliterating other structural details Only very few normoblasts can be found The white cell forming centers and megakaryocytes are fewer than normal Successive biopsies as Peabody has shown indicate that the marrow returns to normal in remissions Rhoads and his associates have suggested that in the presence of liver extract deficiency, aromatic compounds may increase the destruction of red cells which leads to anemia and that liver extract acts to detoxify injurious substances rather than to supply a building stone for the formation of blood However this may be within a few days following the administration of liver extract many primitive cells in the bone marrow have vanished and in their place normoblasts have appeared Their subsequent development into reticulocytes can account for the temporarily large increase of these cells in the peripheral blood

The characteristic lesion in the spinal cord is subacute combined degeneration a diffuse symmetric, marginal degeneration affecting the dorsal and lateral columns and usually first found in the upper thoracic and cervical portions There is early demyelinization often preceded by visible swelling of the myelin Later the axons degenerate The foci of degeneration (Lichtheim foci) usually appear first in the posterior columns later in the lateral columns and on each side of the anterior median fissure Glial proliferation is a relatively late phenomenon always incomplete and leaving a honeycombed appearance The dorsal roots may be affected early, and later the ventral roots Rarely similar degeneration occurs in the brain Peripheral nerve lesions are also found

Symptoms and Signs—Pernicious anemia as Addison wrote "makes its approach in so slow and insidious a manner, that the patient can hardly fix a date to his earliest feeling of that languor which is shortly to become so extreme This languor or weakness is often the first symptom of which the patient complains Other symptoms of anemia *per se* are of course common Digestive symptoms are the initial ones in about 30 per cent of cases and often may precede the anemia by years Burning and soreness of the tongue particularly of the anterior half is more apt to occur early than late in the course of the disease usually it is severe but for a few days at a time The red inflamed surface with vesicle formation leads to the smooth shiny atrophic tongue characteristic of the disease This condition may arise without any painful glossitis Sepsis commonly seen about the teeth may aggravate it The process may extend down the esophagus to the stomach All types of digestive symptoms may occur though indigestion does not necessarily coincide with a falling red cell count Distress from gas and mild intermittent diarrhea as well as constipation are common Gallbladder disease is frequent

Neural and rarely mental symptoms may be present long before there is clear cut evidence of macrocytic anemia Such symptoms appear first in at least one fourth of all cases This is particularly true of the older individuals In the natural course of the untreated disease symptoms referable to the neural system sooner or later develop in about 80 per cent of all cases and are not related to the degree of anemia Usually symptoms of neural involvement are confined to slight disorders of sensation persistent and usually symmetrical numbness and tingling of the hands and feet Among the earliest and commonest signs is diminution of vibration sense usually first detected in the lower legs Loss of the sense of position is apt to be manifest later All degrees of flaccid and spastic paralyses especially of the legs less often of the hands may be

seen Marked spastic ataxia indicates degeneration of the posterior and lateral columns of the spinal cord and occurs in about 10 per cent of all patients with nervous symptoms however the incidence of ataxia should decrease with early diagnosis and adequate therapy since proper therapy can prevent the development or progress of neural lesions When the posterior columns are involved ataxia absent reflexes and hypotonicity are prominent signs When the lateral columns are affected spasticity especially of the legs exaggerated reflexes hypertonicity and extensor reflexes occur In the advanced picture of combined sclerosis involvement of the sphincters of the bladder and rectum and contractions of the legs are prominent Stocking hyperesthesia or anesthesia may occur due to peripheral nerve involvement

Defects of the special senses can often be attributed to anemia *per se* Retinal hemorrhages are common but give little disturbance of vision The symptoms and signs referable to the circulation such as dyspnea are those common to anemia and may lead to a faulty diagnosis of cardiac disease Angina pectoris resulting from anemia may disappear as the blood becomes normal The blood pressure is usually low Impairment of renal function as measured by fixation of specific gravity is common when anemia is pronounced The disturbance subsides as anemia lessens The nonprotein nitrogen of the blood is seldom elevated above 50 mg Small amounts of albumin and casts are frequent in the urine and slight edema is common so that cases may be wrongly diagnosed as nephritis Encroachment on the myocardial reserve from anemia may lead to edema but it probably often results from low plasma proteins and changes in capillary permeability Pyelitis and cystitis are frequent complications especially in women

Fever usually irregular and of low grade is common in relapse The frequently described lemon yellow color of the skin and conjunctivae due particularly to bilirubinemia is by no means invariable Indeed the jaundice and pallor are usually not marked unless the red cells are below 2 000 000 per cubic millimeter Pigmentation on the exposed parts of the body and mucosae may be found Vitiligo often combined with brownish pigmentation, is not rare Although petechiae may appear anywhere especially beneath the tongue they are rarely numerous The spleen though slightly enlarged and palpable in about 40 per cent of patients who before the days of liver therapy had suffered relapses is now rarely palpable Likewise the liver was often moderately enlarged Such enlargements when due to the disease usually disappear with liver therapy *Relapses* and *remissions* of symptoms and anemia formerly such common and important features of the disease are now rarely observed except when therapy is omitted or the diagnosis unestablished for a long time

The Blood —The red cells are reduced to a greater extent than is the hemoglobin the difference giving rise to a high color index The total red count may be below 1 000 000 per cubic millimeter and is frequently below 2,500 000 when the patient is first seen and is feeling comparatively well The blood picture is typically that of a macrocytic anemia the mean corpuscular volume varies from about 110 to 160 cu microns Some increase in size of the cells is often observed before outspoken reduction in the total number of cells The mean corpuscular hemoglobin concentration is 32 per cent or more Many large oval deeply stained red cells usually macrocytes are a particular feature Microcytes also occur A graphic picture of the size of cells obtained from a Price-Jones curve shows typically a very abnormally wide distribution in diameter with a peak in the vicinity of 8.5 cu microns instead of as normally about 7 3 cu microns The common macrocytic picture may be modified by the presence of a complicating iron deficiency to a normocytic or mildly hypochromic type Poikilocytosis may be extreme Diffuse and punctate polychromatophilia is common but reticulocytes above 5 per cent are unusual in the untreated patient A variety of nucleated red cells may be seen normoblasts being the commonest Megaloblasts of Ehrlich are more commonly observed in pernicious anemia than in any other disease Primitive erythroblasts are rare

The white cells and particularly the platelets are usually diminished in number The

lymphocytes are apt to be relatively increased and the Arneth count of the polymorphonuclears shifted to the *right* Occasionally without known cause the eosinophils are moderately increased As *in normal individuals* they may reach over *50 per cent* after raw liver feeding but not after cooked liver or oral liver extract *therapy* As remission is inaugurated by adequate therapy, *particularly from red cell levels below 3 000 000* per cubic *millimeter there* occurs with regularity a temporary pronounced increase of reticulocytes (For details of this reaction see Lancet 2 319 1935) All the abnormalities *in the blood* including the increase of pigments vanish as the red cells and hemoglobin increase Achromia however may appear as the red cell count approaches normal

Diagnosis—The diagnosis of pernicious anemia is not to be based on the blood alone The history tuning fork and stomach tube are as *important instruments* for correct diagnosis as a well stained blood smear A diagnosis of pernicious anemia will rarely be in error if macrocytic anemia with slight icterus sore tongue achlorhydria and persistent paresthesias are present The typical blood picture is easily recognized but when the red count is but little reduced it is much more difficult to judge the significance of the findings A slight increase of mean corpuscular volume and a few large oval cells and microcytes is often suggestive A high color index and increased mean corpuscular volume however do not necessarily indicate pernicious anemia since other types of macrocytic anemia occur which are unrelated to pernicious anemia Furthermore the types of macrocytic *anemia mentioned* under etiology which are related to pernicious anemia may present an identical blood picture and many of the signs and symptoms of addisonian pernicious anemia The distinction from the latter types which cannot be described here is, however more a matter of nosologic than of physiologic moment Confusion must not be made however with the macrocytic anemia of leukemia with low white cell *count* and of the idiopathic aplastic' or refractory anemias A bone marrow biopsy may be helpful but of more value is a therapeutic test with liver extract given intramuscularly making observations on the course taken by the reticulocytes In the *chronic* aplastic anemias achlorhydria is only sometimes present *glossitis is at least* very rare signs of involvement of the neural system are absent, and the distribution curve of cell size is not so wide as in pernicious anemia in marked relapse The anemia of chronic nitrogen retention is sometimes macrocytic in character, the clinical and chemical findings should distinguish this condition Macrocytic anemia may occur *with cirrhosis of the* liver but there is rarely *great variability in the cell size as in* pernicious anemia The signs of hepatic disease are usually apparent Sometimes cirrhosis of the liver and pernicious anemia coexist The anemia of myxedema and the association of myxedema and pernicious anemia in the same patient and less often of diabetes may offer opportunity for diagnostic error The basal metabolism may be somewhat below or above normal in pernicious *anemia it tends to be low in* cases with neural lesions Other types of anemia such as occur in chronic hemolytic jaundice, may superficially resemble pernicious anemia Care must be taken to distinguish neural system symptoms from those due to multiple sclerosis and other disorders of the spinal cord

It is important to establish the diagnosis before the blood picture has been obscured by therapy If this is not done and if both liver and iron have been given it may become impossible to decide without omission of treatment whether or not liver therapy is necessary for the rest of the patient's life

Treatment—The fundamental principle *in the treatment of pernicious* anemia is the *continued* administration of adequate amounts of potent material for the given individual patient The object is not only to eradicate symptoms or place them under control but also to restore the patient's nutritional state to normal for the rest of his life The aim must be not only to return the hemoglobin and red cells to normal levels and keep them there but also to maintain a normal color index cell size *and cell* volume The amount of material necessary to accomplish this may be less than the amount needed to prevent the development or progress *not only* of neural lesions but

also of gastro intestinal disturbances The omission of treatment may not cause relapse for many months rarely for years but usually the individual will soon find that he is sick again and that often neural symptoms have developed or progressed quite unnecessarily Infections the presence of toxic substances increased metabolism arteriosclerosis or severe damage to vital organs may inhibit the action of liver extract and the presence of such complications often calls for a larger amount of material than would be necessary in patients without complications

source of active material for oral administration is provided by the combination of liver and gastric tissue No product should be employed unless objective proof of its effectiveness in known amounts is available Concentration of potency is achieved only with some loss of active material The United States Pharmacopoeia has defined for convenience a unit of liver extract as the amount of material which when given daily to patients with pernicious anemia has produced satisfactory hematopoietic response This amount is not necessarily effective in the control of neural manifestations

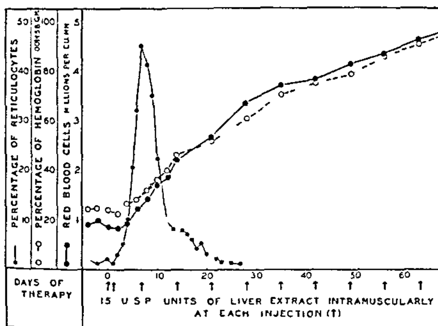

Fig 114—The response of the blood to liver extract in a case of pernicious anemia

Today it is not necessary for patients to eat 200 Gm of liver daily for concentrated preparations of liver and stomach are available and permit large amounts of potent material to be easily given Liver extract is at least sixty times as effective by injection as when given by mouth The parenteral route preferably intramuscular is the one of choice in sick individuals in those requiring large doses and in those with neural lesions The procedure is economical and gives assurance of sufficient material entering the body on selection of an appropriate dose If oral therapy is employed good results will be obtained with either stomach or liver preparations The most concentrated

tions A unit given daily in uncomplicated cases with an initial red blood cell level of about 1 500 000 per cubic millimeter or less will cause an increase of about 2,500 000 per cubic millimeter in a month

In discussing dosage it must be borne in mind that the amounts mentioned may be excessive in some cases and undoubtedly inadequate in others A severely anemic patient should be given intramuscularly 15 units of liver extract in 1 or more doses within six hours This implies a dose of *Liquor hepatis purificatus* (U S P XI) of from 1 to 15 cc derived from about 50 to 100 Gm of liver according to the preparation used This amount will usually suffice

to produce clinical remission If the case requires more than the usual amount of effective agent 5 units a day or 10 every other day for the next five to seven days is usually a wise procedure Thereafter, 10 units a week in single or divided doses is conservative At this stage orally administered material [*Extractum hepatis Liquor hepatis* or *Stomachus* (dried stomach) (U S P XI) or the stomach liver combination (Extralin) (N.N R)] can be substituted in doses of 1 unit a day The amount of liver extract will have been obtained from about 300 to 600 Gm of liver Many patients can be successfully treated by daily oral doses but the need of some patients is such that they cannot obtain enough by mouth

Effective treatment may produce subjective improvement within forty eight hours especially when liver extract is given in large doses by the parenteral route The patient first appears to be more alert to have more color and a better appetite By the end of two weeks he is much better fever if due to the disease, is gone and his blood is well on the way to normal with the plasma pigment normal Usually the lingual symptoms will have vanished the papillae of the tongue will have started to regenerate and the gastro intestinal symptoms will have greatly lessened On the contrary neural symptoms will rarely be altered at this time When the red cells reach 3 000 000 per cubic millimeter the patient can take up light exercise If achromia and other signs of iron deficiency develop which may be minimized by a diet rich in animal protein and iron daily oral doses of iron such as 15 grains (1 Gm) of ferrous sulfate should be given

In the course of two months from the beginning of treatment the patient usually attains a normal blood and the appearance of the tongue and the gastric mucosa is normal In spite of this achlorhydria almost always persists By now milder neurologic symptoms often have disappeared and more pronounced ones lessened The problem now arises as to proper dosage for continued therapy Unfortunately there is no way at present of knowing except by the method of trial and error Adequate treatment for pernicious anemia must never stop If neural symptoms are present the dose should not be decreased A dose of 10 units intramuscularly once in two weeks may be sufficient but, as practically all patients will have to continue to take some active principle, there is slight advantage in reducing the dose below a convenient level which has been found safe Too often one sees serious progress or development of neural lesions arising from too little potent material The failure of treatment implies an incorrect diagnosis inadequate dosage or strength of material or complications severe enough in themselves to be disastrous to the patient

The intramuscular injection of liver extract *may produce local pain and tenderness* rarely slight fever Allergy plays a role in some reactions It is wise therefore to employ at first a small dose which may be repeated in the same or larger amounts a few hours later, or as the circumstances suggest Intravenous injection demands attention to all the details required for this method of administering drugs

The treatment of pernicious anemia means more than the administration of substances to offset the deficiency The patient should be *in bed* while anemia is marked and the *diet* should be one optimal for health and containing a liberal amount of meat green vegetables and fruit The precise diet for each case will vary depending upon the desirability of the patient s gaining or losing weight the state of the digestion etc Rather often these patients do not tolerate fat well Occasionally *diluted hydrochloric acid* (U S P) in 2 to 4-cc doses may aid to minimize digestive symptoms but if these have not largely vanished within a month disease of the gallbladder should be suspected

Transfusion of blood is rarely indicated It should be performed if a very anemic patient at rest in bed shows signs of circulatory failure Sepsis and other complications must be attended to according to indications but if possible such procedures should be postponed until the red cells are near their normal level

It is of the utmost importance to give detailed attention to the results of neural involvement Suitable *physical therapy* meticulously carried out is invaluable Daily massage and passive motions should be given from the beginning and later on pro

cedures for retaining muscles are indicated Paresthesias often diminish as the red count increases above 3,500 000 per cubic millimeter and frequently disappear later Little change in the objective neurologic examination may be apparent then or subsequently but occasionally striking changes are observed Symptomatic improvement may be marked and is prone to occur to some degree in a large percentage of cases Patients originally unable to walk may become sufficiently improved to return to their occupation after several weeks or many months of treatment The sooner treatment is begun the better are the results Swelling of the myelin sheath ceases and further destruction of the axis-cylinders is prevented The treatment induces glial productivity Disorders due to peripheral nerve involvement can be expected to vanish relatively rapidly Every encouragement to practice walking and coordination without unduly fatiguing the patient should be given Indeed in practice every aspect of the patient as a human being and every factor in his case must be carefully attended to

Prevention —Prevention largely consists in the establishment of early diagnosis and adequate treatment A diet nicely adjusted with respect to all its constituents at an optimum will minimize the occurrence of certain cases *of macrocytic anemia Because* pernicious anemia may appear in families it is desirable for near relatives to be examined, scrutinizing particularly the state of their gastric secretion and blood from time to time in an effort to detect a latent case

Prognosis —The prognosis has been indicated above In well treated cases without complications it is excellent The properly treated patient loses all signs and symptoms of pernicious anemia except those caused by neurologic changes (which may retrogress) and those of achlorhydria and deficiency of the gastric intrinsic factor

PURPURA

Definition —Purpura is a condition characterized by extravasations of blood into the skin and mucous membranes The areas of discoloration may vary from the size of a pinpoint (petechiae) to much larger areas known as ecchymoses

Occurrence —Purpura occurs as a symptom of many diseases and may be produced in various ways It is also a prominent feature of two distinct idiopathic conditions in which it is (1) associated with other exudative lesions joint and visceral symptoms and presents no recognized pathology of the blood (*idiopathic purpura*) and (2) characterized by paucity of the blood platelets and spontaneous hemorrhages from mucous membranes (*idiopathic thrombopenic* or *thrombocytopenic purpura* purpura hemorrhagica) A third less clearly defined idiopathic form of purpura is known as *purpura fulminans* There are also other rare idio

pathic and atypical conditions in which purpura may be a prominent symptom

Types.—*Symptomatic purpura* is usually *simple* and not dependent upon demonstrable disturbance of the blood nor associated with bleeding from the mucosae. It may result from mechanical causes, venous stasis, or from emboli as in endocarditis. It may appear in any infectious disease and constitutes the usual exanthem in some, notably epidemic cerebrospinal meningitis. Rashes, like those of scarlet fever and measles which are usually not purpuric, may be modified by the extravasation of blood into the skin when the infection is severe. The hemorrhages may be seen in nutritional disorders, in many toxic states including those resulting from the administration of drugs (as copaiba, iodides, quinine, atropine, etc.), and in cachectic patients, in chronic nephritis, endocrine disorders, disease of the liver and occasionally in diseases entailing degenerative lesions of the spinal cord.

Symptomatic Purpura with Blood Defects.—Purpura may be symptomatic of an abnormality of blood coagulation, as for example in prolonged jaundice, severe liver disease, *erythremia* and *some forms of* sepsis. When associated with a marked reduction of platelets in a recognized disease it is known as *symptomatic thrombopenic* or *thrombocytopenic purpura*.

Symptomatic Thrombopenic or Thrombocytopenic Purpura (Purpura Hemorrhagica).—This is associated with bleeding *from the mucosae as in the idiopathic condi*tion. The decrease in the number of platelets can be brought about by:

(1) Destruction or depression of the activity of their parent cells, the megakaryocytes of the bone marrow, such as occurs in aplastic anemia which may be idiopathic or result from benzol poisoning, arsphenamine, bacterial toxins or excessive irradiation with roentgen rays and the like.

(2) Displacement of megakaryocytes by abnormal cells as in the leukemias, metastatic tumors and other conditions.

(3) Destruction of platelets or their removal *from* the circulation as for example in poisoning from some drugs and in certain allergic and toxic states.

Idiopathic Purpura (*Primary or Anaphylactoid Purpura*).—*Definition*.—A frequently recurrent but rarely fatal morbid state, characterized by purpura and often associated with other exudative lesions, joint manifestations and visceral symptoms but without known abnormality of the blood.

History.—Schönlein described cases with joint manifestations and Henoch those with intestinal crises. Osler clearly showed that the type with purpura, erythema and allied skin conditions especially with visceral disturbances may be considered essentially a clinical entity with protean manifestations.

Etiology.—Children and young adults are usually affected but no age, sex, or race is exempt. The cause of the condition is unknown. Infection probably accounts for some cases, others because of their resemblance to serum sickness and because sensitization to a specific protein or to certain food is *sometimes demonstrable are apparently* manifestations of allergy. Hypersensitivity to cold may be a cause.

Purpura simplex may be hereditary and familial and is more common in women than men, occurring in later generations at progressively earlier ages. Rheumatic fever, arthritis and fibrositis is common in this group.

Morbid Physiology.—The permeability of the small blood vessels is altered and mechanical factors probably influence the distribution of the lesions. The manifold lesions may be explained by the extravasation of varying proportions of plasma and formed elements of the blood and by local vascular changes. Every lesion, internal or external—purpura, erythema or edema according to the blood elements that permeate the vessel walls—is to be *considered focal*.

The *blood* undergoes no constant change. Anemia may be present and the white count is sometimes slightly elevated. The platelet count is not low and the clotting time is essentially normal.

Symptoms and Course.—Idiopathic purpura is divided artificially into various types *according to the anatomic* distribution of the lesions. Patients may exhibit purpura only (purpura simplex) or there may be concomitant articular symptoms (Schonlein's disease, purpura rheumatica). Some develop symptoms attributable to visceral lesions, those of the intestines causing crises of abdominal pain (Henoch's purpura). Various

combinations of skin joint, and visceral lesions are seen The patient may exhibit at one time purpura alone at another, urticaria or erythema while visceral symptoms may develop with or without skin manifestations Those who exhibit purpura alone are usually free from significant constitutional disturbance The eruption may be local or general one group or more of lesions appearing during the course of several days The lesions then usually subside but may recur at intervals of weeks or even years In others an attack of the disease begins with fever malaise and a sore throat which are followed shortly by polyarticular pains Days or even weeks later perhaps after all initial symptoms have subsided an eruption may appear which is often purpuric and commonly associated with urticaria and erythema Edema is variable in degree The arthritic and cutaneous lesions usually subside in a few days but often recur together or independently at intervals of one to six weeks

The extravasation of plasma and cells into some viscus may take place whenever there are exudative skin lesions or arthritis not only in close association with the appearance of such symptoms but often when they are absent They are rarely found elsewhere than in the intestines or kidneys Fever and malaise generally precede the localizing symptoms Foci of hemorrhage and edema in the gastro intestinal tract give rise to crises of pain which is often colicky to diarrhea melena and even to intussusception Similar infiltration in the kidney may result in hematuria escape of albumin and depression of renal function and thus simulate acute nephritis Uremic symptoms are exceedingly rare Severe visceral disturbances seldom last more than a few days although like arthritis they often dominate the picture Their intensity fluctuates Recurrent attacks sometimes ensue for many years

Complications are infrequent Endocarditis has been reported to occur Enlargement of the spleen frequently develops in children who have had repeated attacks of the disease but is uncommon in adults

Diagnosis —In the presence of purpura or exudative skin lesions and when the platelet count is normal the diagnosis is usually simple If purpura is associated with urticaria erythema or edema it is apt to be of this idiopathic variety Diseases of which purpura may be a symptom must be excluded as well as *thrombopenic purpura*

The articular pains may suggest *rheumatic fever* but purpura itself is rare in this condition *Scurvy* is readily differentiated by careful examination of the dietary history and administration of antiscorbutic substances

The cases most difficult to diagnose are those in which visceral symptoms develop without skin lesions The crises of pain so closely resemble those of certain acute abdominal conditions that operation cannot always be forestalled Operation causes no abnormal hemorrhage because the elements associated with the coagulation of the blood are essentially normal Symptoms referable to the genito urinary tract often lead to a diagnosis of *acute nephritis* and in the absence of skin lesions this cannot be, positively ruled out In every child with severe abdominal pain or hematuria the possibility of idiopathic purpura must be considered and the skin examined for exudative lesions

Prognosis —The outlook as to life is nearly always excellent Individual attacks last ordinarily from one to six weeks while recurrence at intervals of months or years is not unusual As the individual grows older the disease tends to become milder or to disappear

Treatment —There is no specific treatment for the disease In an effort to alter favorably the endothelial permeability many substances have been advocated but none produces a cure Symptoms must be treated as they arise and good hygiene instituted If the ingestion of particular food stuffs causes symptoms they should be excluded from the diet and if the patient is unduly sensitive to some protein adequate desensitization may be attempted

Idiopathic Thrombopenic (Thrombocytopenic) Purpura (*Idiopathic Purpura Hemorrhagica Morbus Maculosus of Werlhof Pseudohemophilia*) —*Definition* —Idiopathic thrombopenic purpura is a disease that may be acute or chronic and is characterized by a marked and unaccountable diminution in the number of blood platelets spontaneous hemorrhages from mucous membranes and purpura

History.—Werlhof in 1731 first differentiated the condition from other varieties of hemorrhagic disease In 1887 Denys noted the platelet reduction Hayem and Bensaude and Rivet called attention to the chronic type of the disease and Kaznelson in 1916 showed the striking results that follow splenectomy

Etiology and Morbid Physiology.—The cause is obscure Females are affected more often than males Young individuals are more often afflicted than older ones Acute cases suggest an allergic state The chronic form is sometimes congenital or familial and may be of quite a different nature from the acute Postmortem examination has revealed no characteristic lesions Signs of extensive capillary hemorrhage are the outstanding feature and are associated with a diminution of platelets but there may be other unknown factors causing the increased capillary permeability Probably two conditions exist that may be called idiopathic thrombopenic purpura one where the megakaryocytes are decreased and which represents an aregenerative type of bone marrow disease and second a condition where there is no abnormality of these cells The latter may be considered more truly idiopathic or essential thrombopenic purpura Cases are also recorded with morphologic variation in the megakaryocytes

Experiments have shown that injection of the serum of rabbits immunized against the platelets of the guinea pig causes destruction of normal guinea pig platelets Moreover guinea pigs which have received inoculations of antiplatelet serum, rapidly develop all the features of clinical thrombopenic purpura These animals megakaryocytes are normal An allergic state as a cause of thrombopenic purpura is supported by its provocation by 'sedormid' nirvanol arsphenamine gold quinine and other drugs by food sensitization and by its occurrence one to three weeks after subsidence of an acute infection Some cases are associated with focal infection and rarely, with tuberculosis—conditions which aggravate chronic cases Endocrine disorders are suspected in some cases and rarely dietary deficiency may play a role Causative agents should be sought but in many cases the etiology of thrombopenic purpura remains unknown

Clinical experience indicates the importance of a capillary defect in the etiology of purpura hemorrhagica Bedson and Roskam s experimental studies show that both thrombopenia and altered vascular reactivity play a role Macfarlane has seen normal capillaries contract after injury, but when the bleeding time is prolonged, contraction is greatly decreased

Hemorrhage in purpura hemorrhagica is not always closely related to the degree of thrombopenia The circulating blood platelets are often large and abnormally granular They may be absent or as is usual present in numbers below 100 000 per cubic millimeter Bleeding usually ceases when they are above this number The bleeding time is prolonged sometimes for hours The coagulation time is rarely more than slightly prolonged but because of the paucity of platelets the loosely woven clot does not retract The degree of anemia is particularly dependent on loss of blood but defective blood formation also may be influential The red and white blood cell picture is usually similar to that seen after mechanical chronic loss of blood but if cases with signs of an aregenerative marrow are considered idiopathic purpura hemorrhagica then leukopenia and all signs of marrow depression may supervene In acute cases immature bone marrow cells that cannot be accounted for by blood loss may appear in the circulation Lymphocytosis without leukopenia may be pronounced

Symptoms.—*Spontaneous capillary bleeding* from and into mucous membranes is the clinical feature that distinguishes thrombopenic purpura from most other forms The bleeding may occur into any tissue It varies from slight oozing from a single source to profuse bleeding from many sources Hemorrhage from the mucosae of the nose and mouth is particularly common and that from the uterus and into the retina frequent The cutaneous hemorrhages may be extensive but more often consist of but a few petechiae and are rarely associated with other exudative lesions The vulnerability of the capillaries permits slight trauma to produce ecchymoses

Fever is common in the more acute and severe cases The spleen may be moderately enlarged particularly in the chronic type but abnormally small spleens are also re-

corded No other symptoms or signs occur except those attributable to hemorrhages or anemia

An acute and a chronic form of the disease are recognized

In the *acute type* the hemorrhages often begin abruptly without warning or after some days of debility In favorable cases the symptoms usually disappear within three weeks as inexplicably as they arose In others the course may be short and fatal The hemorrhages may persist for days and then cease only to recur after an interval of days or weeks and may thus render the disease *intermittent* for many months Such subacute conditions may become chronic and patients may live for years without much severe bleeding Other patients suffer more or less severe bleeding *continually* for weeks or months and become gradually exsanguinated or die from a cerebral hemorrhage or the like

The chronic type of the disease does not usually develop from the acute form At the time of a brisk hemorrhage the patient often states that for years he has bruised and bled easily, but not severely and often has had petechiae The platelet count usually remains below normal so that the patient continually shows some signs of hemorrhage The hemorrhages however may be so slight that for many years the individual gives little thought to the lesions More profound ones may occur intermittently particularly from the nose and vagina Rarely the number of platelets fluctuates markedly from well above to much below normal so that symptoms may be truly intermittent A pronounced drop in the platelets may occur only in association with menstrual periods

Diagnosis —Spontaneous hemorrhage from a mucous membrane and a paucity of platelets are sufficient evidence for a diagnosis of thrombopenic purpura and differentiate it from hemophilia The idiopathic disease is to be diagnosed after excluding a cause or conditions in which thrombopenia is a symptom *Aplastic anemia* is to be distinguished particularly by rather persistent leukopenia Bone marrow biopsy may be required to exclude myelosclerosis *Acute leukemia* even when in a nonleukemic phase seldom will be confused if a proper blood examination is carefully interpreted Rarely acute thrombopenic purpura occurs with blood pictures suggesting leukemia or infectious mononucleosis which does not necessarily herald fatality

The joint symptoms varying exudative skin lesions and visceral crises common to idiopathic purpura are rare in the thrombopenic forms while the characteristic blood pathology of the latter further serves to distinguish these two conditions *Hemorrhage from telangiectases easy bruising without spontaneous purpura* particularly in women and other hemorrhagic syndromes need cause no confusion as in these conditions there is no paucity of platelets The blood platelets are rarely involved in scurvy which presents quite a different symptomatology Their decrease however may occur in some individuals with a deficiency of vitamin C

Chronic cases of rare types of hemorrhagic disease are reported with increasing frequency Some cases such as *hereditary hemorrhagic thrombasthenia* (Glanzmann 1918) and *constitutional thrombopathy* (von Willebrand 1926) are hereditary appearing in both male and females These two conditions probably represent one disease entity In both the bleeding time is prolonged without alteration of the coagulation time or paucity of platelets The clot retracts except in some cases considered thrombasthenia The abnormal bleeding time may appear only intermittently The spleen is rarely enlarged Sporadic cases of this sort have been reported There also occur atypical hemorrhagic conditions without detectable blood abnormality instances of which may be associated with altered ovarian function These rare conditions should be distinguished from classic chronic thrombopenic purpura

Prognosis —Spontaneous recovery is not rare in acute cases If a given attack does not show signs of abatement within a few weeks an unfavorable outcome is probable but death or less often recovery may be delayed many months

The chronic type shows less tendency to permanent recovery than the acute The disease may last a lifetime but the condition tends to become gradually worse The above statements apply particularly to nonsplenectomized cases

Treatment —Any possible exciting agents such as drugs, should be removed and undesirable conditions such as hypersensitive states *should be alleviated* Cure may result following removal of an infectious process so that focal sepsis must be treated appropriately Surgery, however, except for splenectomy, should be undertaken cautiously when the blood platelets are few Iron and foods that enhance blood regeneration may aid in lessening anemia Sometimes, in subacute cases, the daily ingestion of large amounts of whole liver has been associated with rapid improvement Patients should follow a nutritious diet and avoid fatigue

Splenectomy because of its recognized influence in allowing the blood platelets to increase in the circulation and its possible effect in decreasing their abnormal destruction and enhancing capillary closure, has been shown to have a strikingly beneficial effect in *chronic* essential thrombopenic purpura but rarely in chronic cases with purpura hemorrhagica where the bone marrow is implicated The operation leads to symptomatic cure in about 70 per cent of cases In 30 per cent there is obvious improvement but episodes of mild bleeding recur Rarely there is no benefit sometimes because of existing liver disease or complications The operative mortality is slight The blood platelets usually increase in number very rapidly after removal of the spleen and are abnormally abundant After about a week the platelet count falls to remain usually for at least many months near the normal level The number of platelets tends, however to be low and in some patients they again become sparse The bleeding time may be more favorably affected than the number of platelets This suggests that removal of the spleen may favorably effect capillary closure There are splenectomized patients with few platelets who do not have serious hemorrhage They may give birth to children with very few platelets who bleed very little or not at all and who after some weeks have a normal number of platelets Great variation has been reported concerning the recovery of retractability of the blood clot The increased number of blood platelets appears to be only one factor in the arrest of the purpuric manifestations Exactly how extirpation of the spleen achieves at least temporary cure and the arrest of gross hemorrhage is not understood

If chronic purpura hemorrhagica is sufficiently disabling, splenectomy is indicated but this operation is not advised for the acute case If, however the acute case progresses or become subacute and of a few months duration, splenectomy may be desirable The postoperative mortality is considerably greater in acute than in chronic cases Splenectomy is, of course contraindicated in *symptomatic thrombopenia*, and it is wiser not to attempt the operation when the diagnosis is doubtful Each case must be considered individually One must not act hastily and should recall that many patients with the chronic form live for years with relatively insignificant symptoms and that spontaneous improvement may occur

Irradiation of the spleen or the body as a whole with roentgen rays sometimes increases blood platelets in essential thrombopenia but its effects are apt to be temporary Perhaps parenteral vitamin C therapy affects certain cases favorably but if so deficiency of cevitamic acid (scurvy) is probably the underlying defect

The most important method of checking hemorrhage is blood transfusion This may be resorted to when the bleeding or anemia is severe Transfusion of an adequate amount of blood relieves anemia and usually causes cessation of bleeding for from three to six days To control hemorrhage transfusion of 100 to 300 cc of blood at frequent intervals is more desirable than isolated large transfusions and although the platelets may be little altered the bleeding time is brought under control Repeated transfusions occasionally appear to have some unexplained specific effect but they often tide the patient over until his own platelets in the peripheral blood become normal Antivenin and snake venom have a hemostatic effect in some cases

Purpura fulminans, first described by Guillot is extremely rare The etiology is unknown It occurs chiefly in children and is characterized by very large symmetric ecchymoses on the skin The onset is sudden with high fever and death is usual within

a few days The platelet count is reported as normal and hemorrhage from mucous membranes is not a feature

HEMORRHAGIC DISEASE OF THE NEWBORN

(*Melena Neonatorum*)

Definition—Hemorrhagic disease of the newborn is a self limited disturbance occurring only in the newborn and characterized by spontaneous hemorrhages which may occur in any tissue of the body There is an exceedingly low prothrombin concentration in the blood as determined by the methods of Quick and Warner Brinkhaus and Smith and cure is prompt by the oral and parenteral administration of vitamin K

History—The disease was first adequately described by F Minot in 1852 In 1908 Lambert demonstrated the therapeutic effectiveness of injection of human blood while later J E Welch (1910) and Schloss and Commisky (1912) added further data to our knowledge The new knowledge concerning vitamin K has been added by various investigators since 1937

Etiology and Morbid Anatomy—The disease occurs in about 1 per cent of all newborn infants It is not recurrent and is usually manifest before the fourth day of life and does not develop after the tenth

The prothrombin concentration of the blood normally drops abruptly during the first few days of life but is soon restored spontaneously The recovery is probably brought about by the establishment of a bacterial flora in the intestines which can initiate the synthesis of vitamin K so that it becomes available to the infant for the production prothrombin A delay in restoration of the prothrombin of the blood occurs

in hemorrhagic disease of the newborn, with the result that the prothrombin content is exceedingly low The coagulation time of the blood is usually prolonged, the clot retractile, and the platelets present in at least normal numbers The bleeding time is rarely abnormal Except for extravasation of blood and the results of hemorrhage, postmortem examination is negative

Symptoms—Failure to nurse fretfulness subnormal temperature and even prostration may precede the hemorrhage Jaundice is often present The spontaneous bleeding causes ecchymoses which may be the only sign of loss of blood Bleeding often takes place from the umbilical stump and intestines Hematomata and bleeding from instrumental abrasions are common Less frequently there is intracranial hemorrhage or bleeding from serous surfaces kidneys or vagina The loss of blood from a single source may be slight but the total amount lost may be sufficient to produce symptoms of marked anemia

Diagnosis—In many cases of intracranial hemorrhage in babies following delivery it seems likely that the lowered prothrombin is a factor but trauma alone is probably the chief cause *Congenital fibrinogenopenia* which may cause bleeding is very rare At this age *melena due to ulcer* is seldom seen The usual forms of *idiopathic purpura* are very rare in infants but the *purpura and hemorrhages of syphilis or pyogenic infections though rare must be differentiated* from the manifestations of hemorrhagic disease of the newborn The hemophilic baby rarely bleeds during the first few weeks of life and melena a feature of hemorrhagic disease of the newborn is rare in hemophilia

Prognosis—The outlook for untreated infants is grave over 50 per cent die within a few days When human blood is injected early the prognosis is vastly better Treatment with vitamin K cures the condition promptly Once the manifestations of the disease have disappeared there is no recurrence

Treatment—The synthetic product 2 methyl 1 4 naphthoquinone may be given orally in fat soluble form or parenterally as a water soluble preparation for a few days An average daily dose is 0 75 mg, intramuscularly, or 3 mg of fat soluble material orally which requires good absorption Within eight hours the prothrombin time is shortened and bleeding ceases If the mother receives before delivery 1 to 2 mg intramuscularly for each of 2 days the infant s prothrombin time will remain normal There are many other synthetic and natural preparations with varying potency that are effective

Unless the hemorrhage is severe a blood transfusion (80 cc) need not be given Other treatment is symptomatic and depends on the needs of the individual case

HEMOPHILIA

Definition—Hemophilia is an hereditary disease in which the coagulation time of the blood is much prolonged The disease occurs practically only in the male but is transmitted only by the female A marked tendency to hemorrhage throughout life is characteristic Bleeding sometimes occurs spontaneously but usually follows trauma even when the injury is trifling

History—There are passages in the Talmud which indicate that the ancient Jews knew of the disease Consbrush in 1793 and Rave in 1796 described a case It was J C Otto of Philadelphia who brought attention to the condition by his excellent descriptions published in 1803 and 1805 Bulloch and Fildes monograph is a classic

Incidence and Etiology—The etiology of hemophilia is a mystery The disorder once

started is transmitted to males from generation to generation through the female Hemophilia is apparently a recessive sex character linked to a single male chromosome Its incidence follows the laws of mendelian inheritance The female conductor transmits the condition to about two thirds of her male offspring while about one third of the female offspring are not conductors Cases reported in females are usually proved unauthentic If a male hemophilic should marry a woman capable of transmitting the disease it would be possible for their female children to be hemophilic The fecundity of the females of bleeder families is peculiarly great, and among their offspring there is a predominance of males who never transmit the disease The children of hemophilic fathers are more often female than males

Morbid Anatomy —Custer and Krumbhaar have noted that the megakaryoblasts and megakaryocytes in the bone marrow may be markedly increased Postmortem examination otherwise shows that the organs are normal except for the results of hemorrhage

The Blood—The numerical counts of the formed elements are normal except after hemorrhage The number of blood platelets is never diminished The delay in coagulation time is typical but varies from time to time in the same case The cause of the delay in coagulation time has been the subject of much study and the multiplicity of terms used in discussing the problem has caused confusion It is evident however that there is a fundamental alteration in the physical chemistry of the coagulation factors this has been described as a shortage or qualitative defect of prothrombin an increase in the quantity of antiprothrombin changes in calcium ionization etc A qualitative defect of the platelets or their slow disintegration has also been considered of significance A defect in some factor of platelet free plasma however, must be considered to exist This is associated with the globulin f action of the blood and there may be a deficiency of plasma thromboplastin The blood may manifest the reclotting phenomenon but the clot once formed retracts normally

Symptoms —The essential symptom of hemophilia is hemorrhage following trauma which would not normally cause bleeding The injury may be very trivial spontaneous hemorrhage is rare The bleeding which often lasts many hours and sometimes days tends to be of a persistent oozing nature, and may lead to profound anemia or be fatal though death rarely results from the first loss of blood The condition usually becomes evident in early childhood but may not be apparent until later The tendency to bleed and the degree of bleeding vary in the same and different individuals The hemorrhage may be external internal or into joints Although pin pricks do not cause bleeding scratches may initiate serious hemorrhage Thus the veins and ears may be punctured with impunity indicating that the bleeding time is normal Obstinate epistaxis is frequent The cutaneous lesions are in the nature of bruises that is they are hematomata not purpuric spots Hemorrhages into and about joints are common and may do no lasting harm but they usually cause destruction of bone and lead to changes similar to those occurring in hypertrophic (degenerative) arthritis Internal hemorrhages including those into the muscles and joints may cause pain and fever

Diagnosis —Obstinate hemorrhage is more often due to local injury or disease than to abnormalities of the blood and the mere fact that bleeding persists does not justify a diagnosis of hemophilia The diagnosis depends on the family history the occurrence of repeated bleeding—usually protracted and from more than one location—joint manifestations and the coagulation time of the blood Mild atypical or sporadic cases are rare and may not be suspected until some accident or operation takes place

Hemophilia is to be sharply differentiated from *purpura hemorrhagica* especially from the chronic idiopathic form This latter disease occurs in either sex and is rarely congenital or familial but it may appear in hemophilic families The condition of the blood in these two diseases is very different In hemophilia the platelets are present in at least normal numbers the bleeding time is normal and the clot retracts in purpura hemorrhagica the number of platelets is much decreased the bleeding time is prolonged and the clot is nonretractile and

soft In the latter condition, the coagulation time is usually not far from normal instead of being prolonged as in hemophilia Purpuric skin lesions and truly spontaneous bleeding are evidences of purpura hemorrhagica, and not of hemophilia Rare cases of atypical and familial hemorrhagic disease exist, such as the hereditary thrombasthenia of Glanzmann and the constitutional thrombopathy of vonWillebrand Such conditions are to be distinguished from hemophilia

Hemorrhagic disease of the newborn is neither familial nor recurrent and develops only in the first few days of life—a time when the male hemophilic baby seldom bleeds *Melena* is rare in hemophilia The blood in *hereditary hemorrhagic telangiectasia* is normal and this condition as well as *scurvy* is readily distinguished from hemophilia

Prolongation of the coagulation time is not pathognomonic of hemophilia but occurs also in sepsis nephritis liver disease and jaundice among other abnormal states It is rarely as marked in these conditions however, as in hemophilia

Prognosis —Hemophilia tends to be fatal before the subject attains adult life Few patients reach adult life without suffering some disabling deformity of the joints If the manifestations are mild the condition will probably not become worse The tendency to bleed however, often varies greatly so as to suggest remissions and relapses of weeks to years in duration

Treatment —The *prevention* of hemophilia is a problem of eugenics The *course of the disease* cannot be fundamentally altered Hemophilic individuals and male children of tainted stock must be guarded from traumatism and must know of a suitable blood donor in case transfusion is necessary General principles of hygiene and nutrition should be carefully followed The *joints* should receive treatment similar to that for chronic arthritis in order to prevent deformity

The use of tissue protein extracts from the human placenta as described by Eley Green and McKhann is of some value particularly in children There is increasing evidence that ovarian and estrogenic substances have no important value

In case of hemorrhage the patient must have absolute quiet Morphine may be necessary The blood of hemophilic patients eventually clots and the hemorrhage tends to stop spontaneously, consequently treatment varies according to the severity and location of the bleeding The local application of thromboplastic or thrombic material may be of great value so that the patient should keep at hand such material for local use Rabbit thrombin is especially valuable as a local hemostatic It should be applied dry and kept in place by a firm dressing or pack It is rapidly effective and very serviceable when teeth are removed The desirability of transfusion varies in each case When loss of blood threatens life transfusion of enough blood (usually 800 cc) to restore the coagulation time and the plasma volume to approximately normal is necessary The effect of transfusion on the abnormal clotting mechanism and thus on the disease is only temporary, yet it is of great value in checking hemorrhage About four days after transfusion, the clotting time of the patient's blood returns to that before transfusion Small amounts of blood 25 to 100 cc can affect the coagulation time as much as large amounts (500 cc), but probably the clinical effect of large amounts on the cessation of bleeding is more dramatic and longer lasting However a single injection of a small amount is often effective and repeated every six to forty eight hours can check and prevent blood loss Hemophilics can undergo a surgical operation without serious hemorrhage if blood transfusions are appropriately used to hold the coagulation time near normal during operation and while the wound is healing

Sensitization to foreign protein offers a means of treating hemorrhage The patient can be sensitized to such a *substance* as sheep serum which requires about ten days Thereafter upon receiving *intradermally* a small amount of the same substance the coagulation time of capillary *blood* but seldom venous blood is temporarily decreased

ERYTHREMIA

(*Polycythemia [Rubra] Vera Splenomegalic Polycythemia Vaquez's Disease Osler's Disease*)

Definition—Erythremia is a chronic slowly progressive eventually fatal disease of unknown origin characterized by excessive erythroblastic activity of the bone marrow which induces a persistent polycythemia and splenomegaly The increase of erythrocytes usually leads to a red cyanotic appearance of the skin an erythrosis (Lundsgaard) an increase in the viscosity and in the total volume of the blood and distention and engorgement of capillary vessels

History—Vaquez in 1892 described a case but general knowledge of erythremia remained lacking until Osler drew attention to it in 1903

Incidence—Erythremia is rare It occurs in all races but especially in Jews born in eastern Europe It particularly occurs in individuals about fifty years old Some cases are familial The blood of members of the patient's family may contain an abnormally large number of red blood cells while the individuals remain free from symptoms

Etiology—The eventual level of the red cell count is controlled by the oxygen tension of the bone marrow, but a general anoxemia apparently is not operative in erythremia A localized anoxemia in the bone marrow may play a role Excessive gastric secretion cannot be considered seriously as a cause of erythremia because if this were the case polycythemia could be induced in any normal individual by continued administration of liver or stomach preparations such material however does not act in this way

Morbid Anatomy—There is a striking increase in the quantity of active red bone marrow which replaces the normal yellow marrow The microscope permits demonstration of hyperplasia of not only the red cells but also the white cells and megakaryocytes In the bone marrow vascular changes of a fibrotic nature are recorded by Reznikoff Foot and Bethea which are distinct from the medial fibrosis of general arterio or arteriolar sclerosis The basal metabolism is often high when the formation of blood is augmented Extramedullary formation of blood is unusual Actual myeloid transformation of the spleen and other organs may occur The splenic enlargement is usually caused by hyperplasia of the pulp and distention with blood Anemic infarcts are common and thrombosis is not rare a fact which may lead to such a condition as perforation of the stomach Peptic ulcer occurs in about 8 per cent of the cases Extreme vascular engorgement of all organs is characteristic The increased blood volume the physical character of the blood and the impeded circulation may lead to degenerative changes in the vascular system On the contrary changes in the vascular system of the bone marrow may be primary and lead to compensatory erythrogenesis and thus increased viscosity and impeded circulation

*The Blood**—The total volume of the blood in typical cases is much increased that of the plasma only slightly The hematocrit reading is important Haden has

* A colored plate of the blood of erythremia is shown in the Am J M Sc 166 469 1923

shown that the red cell mass per kilogram of body weight is constantly high in erythremia and not significantly changed in symptomatic polycythemia The red cell count bears no direct relationship to the blood volume The proportion of cells to plasma may be greatly increased This causes an increased viscosity so that grossly the blood, which is abnormally dark red appears thick and sticky and the corpuscles settle in the plasma very slowly This physical condition of the blood may delay coagulation and favor nonretractility of the clot

As a rule, the hemoglobin ranges between 20 and 40 per cent above normal As the need of the body is no greater than normal the venous blood is abnormally rich in oxygen The red cell count is usually 7 000 000 to 11 000 000 per cubic millimeter The color index is low sometimes strikingly so and achromia may consequently be marked The red cell count and amount of hemoglobin may vary considerably from time to time not only because of local conditions but also because of fluctuations in production and perhaps in destruction Anerythremic phases occur and anemia may develop when myeloid metaplasia is present

The abnormal activity of the marrow is reflected in the peripheral blood by the presence of abnormal and increased numbers of immature red cells bone marrow leukocytes and often platelets The abnormality of the red cells frequently consists in only a slight variation in size and the appearance of an occasional polychromatophilic cell Unevenness in the depth to which the cells stain is a feature The white cell count is often 15 000 per cubic millimeter sometimes much higher The blood may resemble that of myelogenous leukemia and polycythemia may rarely occur in leukemia (erythroleukemia) There may be an increased output of urobilin, microcytosis and certain alterations of the plasma and the red cell fragility which suggest that the increased destruction of blood is compensatory

Symptoms *—The *onset* of erythremia is insidious The symptoms which are largely directly referable to polycythemia often do not appear until engorgement has taken place in even the smallest vessels Some symptoms are attributable to increased metabolism Lassitude, increased sweating loss of weight headache vertigo tinnitus surging and congestive sensations dyspnea and various gastro intestinal symptoms sometimes associated with gastric achylia, are common The typical red cyanosis most obvious in the face and ears may be the patient s first complaint The peculiar color may be absent and the polycythemic patient may even be pale Changes in position external temperature and mood often cause striking fluctuations in color The vascular distention and engorgement is also shown in the capillaries of the nail fold by the bluish red color of the tongue and by congestion of the mucosae conjunctivae and retinae Irritability depression and forgetfulness are common Slight palsies of cranial nerves are not unusual Hemorrhages from or into any part are common so that apoplectic seizures are not rare The enlarged spleen often reaches to the umbilicus and may be associated with a dragging sensation as well as pain The liver is often increased in size and sometimes cirrhotic Neuralgia like pain in the extremities and muscular spasms are sometimes striking Swelling of joints is rare Cardiac failure may be manifest The heart is often not enlarged although slight hypertrophy and some increase in rate is not unusual The blood pressure is sometimes elevated Kidney function may be impaired usually temporarily by engorgement infarction or hemorrhage Pulmonary emphysema arterial degeneration and its varying results erythromelalgia and pigmentation of the skin sometimes occur

There are atypical cases of erythremia some of which are congenital and some of which begin in early life A benign familial form occurs Erythremia in elderly patients with high blood pressure usually with renal disease but without splenic enlargement has been described by Gaisbock and Hess Polycythemia of this type seems to be secondary

Diagnosis —The diagnosis depends upon the recognition of a persistent absolute polycythemia for which there is no obvious cause The appearance of the patient and

* A colored picture of a patient with this disease is shown in Fig 29 in Bedside Hematology by Gordon R Ward 1914 W B Saunders Co and in the 1939 Year Book of General Medicine p 328 The Year Book Publishers Inc Chicago

the splenomegaly should render diagnosis simple The *erythrocytosis* or *secondary polycythemia* which occurs with circulatory stasis from chronic cardiac disease—particularly congenital—and chronic pulmonary disease (emphysema) must not lead to confusion The cyanosis characteristic of these states as well as that due to methemoglobin and CO hemoglobin should be distinguished from the erythrosis of erythremia The saturation of the arterial blood with oxygen in polycythemia due to cardiac or pulmonary disease is less than in erythremia Confusion must not arise from the relatively slight increase of red cells that result from numerous causes such as residence at high altitude and from the administration of certain drugs exposure to some poisons and marked vasomotor instability

The gastro intestinal symptoms and those referable to the central nervous system heart kidneys and special sense organs may lead to an incorrect diagnosis of local primary disease

Prognosis —The course of the disease is chronic and there are spontaneous and prolonged remissions and exacerbations which necessitate a certain reserve in considering the results of therapy It is eventually fatal though death is often produced by other causes After the development of definite symptoms the *duration of life is seldom less than four years* Some patients live twice as long and others for even twenty years or more Death may occur during a sudden exacerbation or as the result of vascular complications *especially* thrombosis or hemorrhage Adequate treatment by modern methods permits a more favorable prognosis

Treatment —*The patient must lead a life* that does not cause intensification of symptoms He should avoid mental and physical strain extremes of temperature and over eating

Venesection relieves rapidly such symptoms as headache Its repeated use is an excellent form of treatment decreasing the red cell mass and reducing the color index The hematocrit level is an important guide to treatment The red cell level may become very high and the hemoglobin abnormally low but this state of affairs is relatively unimportant if the hematocrit *reading and* total red cell mass are approximately normal One may begin by removing 500 cc of blood twice a week and less often as the hematocrit reading approaches normal Later on the removal of 500 cc every one to two months is often sufficient

Irradiation of the long bones and any large mass of blood in the body with roentgen rays inhibits the formation of blood Such treatment can benefit many patients when given in adequate large repeated doses Spray x ray therapy seems to be valuable The effect may last for months or even years before repetition is necessary Serious depression of the white blood cell *forming tissue must be avoided by observations* on the peripheral blood Irradiation of the spleen alone is unsatisfactory and *splenectomy is contraindicated*

Phenylhydrazine hydrochloride because of its ability to destroy red blood corpuscles has been shown to be an efficient therapeutic agent in the treatment of erythremia Its use is less logical than irradiation Acetyl phenylhydrazine is perhaps less toxic than the hydrochloride Patients who have been adequately and carefully treated with these drugs have shown usually a decrease in the concentration of their hemoglobin and red blood cells and have been relieved of most of their symptoms The drugs must be given cautiously in doses determined by the needs *of the patient They are slowly eliminated* partly in the urine which may appear dark brown have a cumulative action and may cause severe anemia Too much is dangerous too little ineffective Following the administration of these substances the products of red blood cell destruction increase and may cause a rise of the bile pigments in the *plasma even jaundice and lead to increased* bone marrow activity When signs of such are present to a considerable extent the drug should be stopped The treatment should also be discontinued when the white blood cell count or the percentage of reticulocytes remains distinctly elevated Treatment guided by frequent blood examinations may begin with 0 1 Gm of actyl phenylhydrazine in capsules per day or every other day by mouth and continued until the red blood cell count has fallen definitely Thereafter at less frequent intervals *0 1 Gm should* be given until a maintenance effect is obtained The action of the

drug is cumulative and patients vary markedly in their response to it By proceeding slowly it is possible to obtain the maximum therapeutic effect with very little danger to the patient As time passes, increasing doses may be necessary In bed ridden patients or those with advanced arteriosclerosis or considerable visceral injury extreme caution should be observed in administering the drug Thrombosis may be precipitated by *phenylhydrazine therapy* The drug should not be given if thrombosis exists or has recently occurred Owing to the prevalence of thrombosis in erythremia effort should be made to keep the patient s circulation active by appropriate exercise and massage

Temporary remissions may be induced by full doses of solution of *potassium arsenite* (Fowler s solution)

Alteration of the type of treatment may be wise Combination of two types of treatment should be considered in resistant cases

ENTEROGENOUS CYANOSIS

The term "enterogenous cyanosis' was introduced in 1902 by *Stokvis who described* a syndrome of marked cyanosis severe enteritis and clubbing of the fingers in a man of thirty eight without evidence of cardiac or pulmonary lesions or of drug *poisoning* Spectroscopic *examination of the* blood showed the presence of methemoglobin Shortly after, Talma reported three other cases Since then an increasing number of similar cases have been described in which *a marked cyanosis has been observed in* association with methemoglobinemia or sulfhemoglobinemia

Etiology—The cause of this rare condition is unknown but the explanation for the methemoglobinemia or *sulfhemoglobinemia* at times has been attributed to the absorption of toxic products from the intestinal tract in association with the use of various nitrites of coal tar derivatives The reports of cases of methemoglobinemia *and cyanosis* occurring in association with the administration of bismuth subnitrate ammonium nitrate and similar preparations would seem to indicate that these drugs may occasionally be the cause of the *condition* in connection with a chronic gastro intestinal disturbance Instances of sulfhemoglobinemia appear to be associated with the intake of aniline derivatives acetanilid and the like According to *Healy* sulfhemoglobinemia may result from the use of aniline derivatives if there is an excessive amount of hydrogen sulfide in the gastro intestinal tract if insufficient hydrogen sulfide is present *then* methemoglobin will be formed An excellent discussion of the subject has been published by Vogel in his report of a case due to ingestion of sulfur and the absorption of nitrobenzene

Symptoms—The two characteristic clinical features are intense cyanosis and as a rule marked intestinal disturbances both of long duration *Dieckmann* has reported

such a case with methemoglobinemia of twenty seven years' duration Secondary symptoms are weakness dizziness headaches and occasional clubbing of the fingers Dyspnea may be present but usually is not a feature Diarrhea appears to have been noted more frequently than constipation in the cases with methemoglobinemia Patients with sulfhemoglobinemia are usually reported as suffering with marked constipation Moderate anemia may be present

Diagnosis —The diagnosis of the syndrome of enterogenous cyanosis depends largely on the demonstration of methemoglobin or sulfhemoglobin or a combination of both in the circulating blood The existence of cardiac or pulmonary lesions or polycythemia must be excluded If the term is to be correctly used acute cases of poisoning by drugs of the coal tar series potassium chlorate arseniureted hydrogen (sodium dichromate sulfanilamide) or other known causes of methemoglobinemia or sulfhemoglobinemia must be completely excluded Inasmuch as some cases occur without the existence of any known exposure to such compounds it may be that the term enterogenous cyanosis is justifiable As pointed out by Harrop in an excellent review of the subject differentiation between methemoglobinemia and sulfhemoglobinemia can usually be made by the use of a pocket spectroscope applied directly to the lobe of the ear which has been transilluminated by a small flashlight As a rule the cyanosis of methemoglobinemia appears to be more chocolate or brownish in color and affects the skin whereas the patients with sulfhemoglobinemia appear to have a more purplish or lavender color of the lips ears and nail beds with at times a waxy pallor of the skin At times methemoglobinemia and sulfhemoglobinemia are found together

Treatment should aim to improve the associated gastro intestinal disturbance Unlike the more acute cases due to poisoning from aniline dyes and the like no specific poison can be removed Constipation and diarrhea should be treated carefully although in the latter case probably it would be wise to use some preparation other than bismuth subnitrate Cases presenting methemoglobinemia are said to be improved by a diet high in carbohydrate and low in protein A report by Steele and Spink on the use of methylene blue in acute methemoglobin poisoning suggests that such a form of treatment might be applicable in the treatment of enterogenous cyanosis along with measures directed toward improvement of an underlying gastro intestinal condition

THE LEUKOPENIC STATE

Introduction —Leukopenia may be defined as a lowering of the total white cell count to a value less than that normally observed It is seen in a variety of pathologic conditions and is usually though not invariably accompanied by distinct alterations in the differential count Only rarely does it indicate what is now called agranulocytic angina This fact is frequently overlooked Any one of the constituent types of white cells may be primarily affected but diminution or absence of polymorphonuclear neutrophils is the commonest and most important deviation from the normal

Leukopenia may occur as an incidental though significant finding in certain infectious states such as typhoid typhus Rocky Mountain spotted fever influenza virus pneumonia measles malaria and overwhelming sepsis Thus leukopenia is sometimes a valuable diagnostic aid in sepsis it may be of great prognostic value and may require energetic therapy with such agents as are reported to raise the total white cell count Unquestionably the prognosis of a case with generalized infection due to pyogenic organisms is very grave if the total

count falls below 2000 irrespective of other existing factors unless there be a specific therapeutic agent capable of overcoming the sepsis and thus relieving the leukopenia The leukopenia accompanying sepsis due to pyogenic organisms may show the following types of differential white cell counts (1) a preponderance of mature polymorphonuclear neutrophils, many of which may show the so called toxic granules' (2) a leukemoid picture with many myelocytes and an occasional myeloblast (3) an absence of granulocytes This last type is the most serious and obviously simulates most closely agranulocytic angina In the other diseases mentioned there are no characteristic alterations in the differential count

Leukopenia may also be found in association with certain well defined blood dyscrasias In untreated pernicious anemia a moderate leukopenia is the rule rarely it may become extreme The diagnosis and treatment of such cases is usually clear and the leukopenia itself of little moment Aplastic anemia is characteristically accompanied by a low white cell count and it is important to remember that this sign may occasionally precede all others so that for several weeks the true diagnosis may be in doubt The life of the white cell in the peripheral blood stream is measured in days that of the red cell in weeks Cessation of bone marrow function from whatever cause if all inclusive is therefore first manifested by leukopenia and only later does the more definitive and diagnostic anemia make its appearance

Finally, we are so accustomed to think of leukemia as associated with extremely high white cell counts splenomegaly, and lymphadenopathy that one is prone to forget that this formidable disease may first manifest itself only by vague constitutional symptoms and that the peripheral blood in the initial stages at least may show a moderate or even an extreme leukopenia The diagnostic and therapeutic implications of this fact are obvious It is particularly in children that one is apt to see this atypical onset Other signs of leukemia—myelocytes stem cells (blasts) thrombocytopenia hemorrhagic diathesis increased basal metabolism and changes in the long bones—should be sought for

Leukopenia not infrequently accompanies certain definite pathologic states only indirectly affecting the bone marrow, such as Banti s disease kala azar tuberculosis sarcoid and Hodgkin s disease Banti s disease is one of the commonest causes of marked leukopenia extending over a period of years This fact is of considerable diagnostic value In kala azar the total white cell count occasionally falls to such levels (500-1000) that it becomes in itself of prognostic importance for under these circumstances, as with agranulocytic angina, the patient is particularly susceptible to pathogenic bacteria and death may ensue not by reason of the fundamental disorder but because of these secondary invaders In widespread tuberculosis of the bone marrow there may develop extreme leukopenia and neutropenia, and cases are on record that have closely simulated true agranulocytic angina Curiously enough these hematologic changes may be of a recurrent relapsing type, and I have seen several in which repeated bouts of extreme leukopenia have succeeded each other at irregular intervals and have been followed by the secondary bacterial invasion so commonly seen in agranulocytic angina so that only at autopsy was the true condition discovered Without sternal marrow biopsy it is doubtful if the correct diagnosis can be made under such circumstances In an occasional case of Hodgkin s disease an extreme leukopenia may ensue but in this disease the lymphocytes rather than the polymorphonuclear neutrophils are likely to disappear from the peripheral blood so that one has primarily a lymphopenia

It is well known that a variety of chemical agents some used in therapeusis others in industry may cause leukopenia and neutropenia Chief among these are benzol arsphenamine dinitrophenol gold salts bismuth and sulfanilamide It has long been taught that benzol poisoning was accompanied by an aplastic anemia or pancytopenia and that leukopenia was the first reliable sign of impending trouble From the recent studies of Hunter and his associates however it is apparent that industrial benzol poisoning may bring about the most diverse hematologic pictures and that neither leukopenia nor anemia is an invariable accompaniment When the other chemicals

mentioned affect the bone marrow adversely there usually results an anemia together with thrombocytopenia and leukopenia However dinitrophenol arsphenamine and the sulfonamides *may produce a relatively* pure leukopenia and it behooves all who use these drugs to bear this fact in mind and to watch carefully for its appearance Should leukopenia develop following such medication, it is obvious that the offending drug must be immediately discontinued In the case of poisoning with one of the sulfonamides however the situation is extremely complicated for on the one hand the drugs may cause neutropenia and leukopenia, and on the other they may overcome the sepsis so dangerous to the patient The continuance or withdrawal of the drug and the institution of measures designed to stimulate the bone marrow must therefore be decided in each individual case

HENRY JACKSON JR

AGRANULOCYTIC ANGINA
(*Agranulocytosis*)

Definition.—Agranulocytic angina is an acute fulminating disease characterized by an extreme leukopenia and neutropenia accompanied by ulcerations of the mucous membranes skin or gastro intestinal tract and when untreated leading to death in the great majority of cases

Etiology—This condition was at first not unnaturally presumed to be simply a manifestation of overwhelming sepsis It was not long however before it was noted by Kracke and others including myself that the characteristic hematologic changes preceded the constitutional symptoms and local ulcerations by a matter of several days and it thus became clear that the sepsis was the result rather than the cause of the condition Even so the etiology of the disease remained obscure In 1932 however Kracke noted that most patients had a history of previous medical care or treatment with various drugs containing the modified benzene ring and suggested that agranulocytic angina might well be due to these chemicals This suspicion was amply confirmed by Madison and Squier on clinical grounds and it soon became obvious to all through whose hands any considerable number of these cases had passed that aminopyrine the use of which did not become widespread until 1922, was indeed a very real and perhaps *the commonest cause of this dread* malady In a series of personally collected cases 109 followed the use of some drug Thirty four followed sulfanilamide, eight sulfapyridine thirty nine aminopyrine seven allonal, four causalin In decreasing frequency the following drugs were apparently causative acetanilid amidophen midol cinchophen amytal compound cibalgin bismarsen and neocinchophen It is probable that any of the sulfonamide compounds may cause agranulocytosis and the fact that a disproportionately large number are reported is perhaps the result of the wide use which these drugs have enjoyed Hadler reports a case apparently due to allurate The patient recovered following the use of pentnucleotide and reticulogen This case report raises the serious question of whether agranulocytosis may not be brought on by barbiturates heretofore considered blameless It is important to remember as Rinkoff and Spring point out that fatal agranulocytosis may follow even small doses of any of these drugs and all incriminated should therefore be used with the greatest caution I agree with these authors that such therapeutic agents should seldom be used prophylactically and it may seriously be questioned whether aminopyrine should ever be used except as an analgesic in patients suffering from incurable disease In certain cases the physiologic events of menstruation would appear to be of etiologic importance in this condition but it is well to remember that at such times self medication with coal tar derivatives is common and is often overlooked as an etiologic factor by both patient and physician In a considerable percentage of cases the etiology is still unknown

Women are far more liable to contract the disease than are men Plum found that 80 per cent of his eighty eight patients were women and in my own series of 104 cases almost precisely the same percentage obtained

Agranulocytic angina as we know it at present is a disease of adult life Plum found that it was extremely rare in childhood and

that the incidence rose steadily after the age of twenty five My experience is in agreement with this finding In view of the fact that acute leukemia is a disease chiefly of childhood and that it may at times be most difficult to distinguish from agranulocytic angina these facts relative to age incidence are not without practical diagnostic value

Pathology—The pathologic changes in the bone marrow appear to reflect a maturation arrest at the stem cell (myeloblast) stage In rapidly fatal cases there is an anakmesis of the granulocyte series and a moderate hyperplasia of the precursor stem cells When death occurs after a longer period of illness (eight to fourteen days) there is found hypoplasia of the myeloid tissue, with the coincident appearance of plasma cells and lymphocytes in abnormal numbers Neither the red cells nor the megakaryocytes appear to be materially affected

Symptoms and Signs—It has been repeatedly demonstrated that the first stage of agranulocytic angina is characterized by an extreme leukopenia and neutropenia Thereafter follow the symptoms and signs so familiar to all For obvious reasons this initial asymptomatic leukopenia is rarely recognized The usually observed onset is rapid or sudden with marked prostration high fever headache chills malaise and sore throat When first seen the patient commonly shows a markedly injected and often greatly ulcerated throat There is frequently a brawny edema of the neck and the cervical lymph nodes are usually enlarged and tender, sometimes exquisitely so The temperature is elevated, reaching 100° 103° or even 106° F The spleen is rarely enlarged never greatly so There is no lymphadenopathy not readily accounted for by adjacent infection Jaundice was once considered a *sine qua non* but further clinical experience has shown that this symptom is rare and is to be regarded in all probability as the result of hemolysis or hepatitis due to secondary bacterial invasion

The peripheral blood shows characteristically an extreme leukopenia and neutropenia It is not unusual to find the total white cell count 500 or even less and if the count is above 2500 it is very questionable whether agranulocytic angina is the disease at hand The polymorphonuclear neutrophils are always greatly reduced, and indeed they are frequently absent Eosinophils are virtually never seen at the height of the disease and they may be absent for many months after the acute attack has subsided and the patient has returned to apparent health It is obvious that with a total white cell count of 1000 or less the lymphocytes are also reduced in number This fact is only too often overlooked At the height of the disease it is not unusual to find that 98 or even 100 per cent of the remaining white cells are lymphocytes and in the majority of cases these are of the small normal adult type Occasionally a considerable proportion of the remaining white cells are monocytes It has been said that under such circumstances the prognosis is favorable There is but slight evidence to support this view There is little or no material alteration in the red cell picture though it must be remembered that for various reasons a moderate degree of anemia is not uncommon in middle aged or elderly persons and therefore may well be an incidental finding in true agranulocytic angina However th presence of marked anemia unless explainable upon other grounds strongly militate against the diagnosis of the disease under consideration

Sepsis and ulcerations in and around th throat are so much a part of the usual clinical picture that these findings can hardly be classed as complications In certain cases the ulcerations may become so extensive that the great vessels of the neck are invaded and fatal hemorrhage may result The brawny edema of the neck may cause extreme stenosis of the upper air passages and death by asphyxia Multiple septic infarcts of the lung are occasionally seen Necrosis of the gastro intestinal tract occurs and may be fatal Infection of the skin is common particularly about the face and in rare cases a pemphigus like lesion may result in almost complete dermatolysis in an incredibly short time It should be constantly borne in mind that the patient harbors bacteria throughout his body and that almost any pyogenic complication may therefore result It is further important to remember that during the leukopenic stage foci of infection may give little or no evidence of

their existence but that with the return of the white cell count to relatively normal levels the most diverse manifestations of sepsis may become evident often with surprising rapidity In one case the patient complained throughout the early stages of her disease of pain in the rectum No lesion could be found On the return of the white cell count to 4000 a large ischiorectal abscess developed in the course of forty-eight hours In another case an orbital abscess and cellulitis developed the white cell count rising to 80 000 Autopsy revealed the characteristic findings of agranulocytic angina Such complications developing as the white cell count is rising should be regarded as a sequel to renewed bone marrow activity Pus can not develop during the leukopenic stage Suppuration is the laudable pus of our forebears

Differential Diagnosis—Agranulocytic angina must be distinguished from aplastic anemia, aleukemic leukemia, overwhelming sepsis and diphtheria It is rare that other conditions accompanied by extreme leukopenia (such as Hodgkin's disease) are a source of confusion provided careful attention is paid to signs and symptoms other than the leukopenia Miliary tuberculosis of the bone marrow is an exception to this general rule

Aplastic anemia (pancytopenia) is of course sooner or later accompanied by a marked decrease of the red cell count and a thrombocytopenia These features together with the insidious onset are usually sufficient to differentiate this condition from agranulocytic angina Rarely however aplastic anemia may begin with comparative abruptness and its first hematologic sign may be only leukopenia with relative lymphocytosis Under such circumstances the diagnosis may be difficult until anemia develops It should be remembered that aplastic anemia is common agranulocytic angina extremely rare in childhood

Aleukemic leukemia may be very difficult to differentiate from agranulocytic angina The following points should be borne in mind Acute leukemia is usually a disease chiefly of childhood and early adult life though it may occasionally be seen at any age Agranulocytic angina is practically never seen under the age of fifteen years and is commonest in the older age groups In acute leukemia there are thrombocytopenia progressive anemia and very immature white blood cells (myelocytes myeloblasts lymphoblasts monoblasts) in the peripheral blood A hemorrhagic diathesis is common Marked splenomegaly and generalized lymphadenopathy may occur especially later in the disease In agranulocytic angina the platelets are normal in number anemia of moment does not occur unless occasioned by other causes and the remaining white cells are usually normal appearing lymphocytes though during the stage of recovery immature granulocytes (myelocytes) characteristically appear in considerable percentage The spleen is seldom enlarged never greatly so Lymphadenopathy is found only in association with obvious adjacent sepsis Cases are on record in which what appeared to be true agranulocytic angina has been followed after a period of several months of complete remission by obvious and fatal acute leukemia This fact should make one especially cautious in those cases of apparent agranulocytic angina not preceded by medication with aminopyrine or allied drugs

It may be impossible to distinguish overwhelming sepsis from agranulocytic angina particularly when the polymorphonuclear neutrophils are greatly depressed or absent Commonly however the sepsis is apparent prior to the neutropenia and it is rare to see the extreme neutropenia characteristic of agranulocytic angina

Agranulocytic angina is frequently erroneously diagnosed as diphtheria The mistake is easily avoided if appropriate blood studies are done

Treatment—A number of remedies have been advocated as specific or at least beneficial in this condition In the hands of some physicians good results have followed the parenteral use of liver extract Griffin and Watkins have recommended 300 to 500 Gm of desiccated yellow marrow taken by mouth This method of treatment is definitely limited by the fact that many patients can swallow only with difficulty or not at all Marberg and Wiles have treated patients with extracts of bone marrow It is impossible to draw any concrete conclusions from the small series of cases so treated but the apparent success of this latter method of

therapy should stimulate its further study Other authors notably Forkner, appear to regard any and all forms of therapy as useless Such pessimism does not favor the acquisition of further data regarding the therapeusis of a disease admittedly fatal in some 70 per cent of the cases On the other hand, Goldhamer, Sturgis and Bethel write 'We do not agree with Forkner in labelling as useless all forms of treatment which have been suggested for agranulocytosis It is our opinion that there does exist evidence which suggests strongly that pentnucleotide and blood transfusions are superior to other forms of therapy and should be employed in all cases' Dreverman recommends pentnucleotide and yellow bone marrow both of which agents in his opinion play a role in the maturation of the white cells Strong discussing 'three cases of granulopenia apparently due to infection' says Although the discontinuance of the therapeutic agent (sulfonamide compound) is probably the only measure necessary when the granulocytes reach a low level pentnucleotide appears to accelerate the rate of recovery of the bone marrow and this drug may prove to be a useful therapeutic addendum for us with young patients A combination of attempts to control the infection, discontinuance of drugs which may affect [adversely] the bone marrow, the use of frequent transfusions and the administration of pentnucleotide seems the logical form of treatment Pentnucleotide was first suggested as a form of therapy in 1931 The mortality in a comparatively large series of cases treated with this drug only has been shown to be approximately 35 per cent Ten centimeters of pentnucleotide should be administered intramuscularly four times a day Smaller amounts are ineffective The treatment should be continued until the white cell count has reached a level of at least 5000 and immediately resumed if it should fall again Occasionally unpleasant side affects such as precordial distress nausea or abdominal cramps are seen If the diagnosis of agranulocytic angina seems clear these need not interfere with adequate therapy Only very rarely are the reactions sharp enough to require discontinuance of the drug which at present seems to be the most promising form of specific therapy

The ulcerations in the mouth should be treated with irrigations of saline or glucose The skin should be kept scrupulously clean Fluids must be forced parenterally if necessary

Obviously all drugs suspected of causing the disease must be immediately withdrawn The question of the administration or continuance of the sulfonamide compounds in the presence of extreme leukopenia must be a matter to be decided in each individual case Three points however seem clear First if the agranulocytosis is patently or probably due to the drug the latter should be summarily stopped Second if the agranulocytosis is obviously due to an infection ordinarily amenable to treatment with the sulfonamide compounds (e g pneumococcus pneumonia) these therapeutic agents should immediately be started together with such other measures as the physician in charge believes may help restore the white count to normal levels Third the mere withdrawal of the offending drug does not suffice to restore the white blood cell picture to normal especially if the leukopenia and granulocytopenia has been extreme in spite of a rather general belief that withdrawal is sufficient Such optimism is based largely on reports of cases with moderate leukopenia (e g 3000 white cells of which 20 per cent were polymorphonuclear neutrophils) In any event daily white counts should be done on all cases suspected of having agranulocytosis and energetic measures immediately started if the diagnosis is established If one has faith in any of the therapeutic measures advocated the importance of prompt diagnosis cannot be overemphasized If one maintains a robust pessimism the acquisition of hematologic data is purely of academic interest It is my own belief—and it is shared by others—that all patients under treatment with any drug which has been incriminated should have frequent blood counts and differentials and that if the total granulocyte count should be found very low immediate treatment should be instituted—whether one chooses frequent transfusions yellow bone marrow or pentnucleotide or a combination of one or more of these agents The same holds true of patients with a severe sore throat perhaps the most common initial symptom of agranulo

cytosis It is furthermore imperative that treatment should be intensive—in the case of pentnucleotide no less than 40 cc a day should be given and continued until a favorable response has occurred or until it is apparent that no benefit will accrue

If an analgesic is necessary, codeine will usually suffice to make the patient comfortable morphine may be necessary but should not be used if it can be avoided Complications which would call for surgical intervention in a patient without agranulocytosis should be treated exactly as if the blood picture were normal and just as vigorously

Prognosis—The mortality of the untreated or inadequately treated disease is approximately 70 per cent Death may occur as soon as twenty four hours after the apparent onset or may be delayed as long as three weeks A sustained unremitting high temperature and increasing drowsiness are unfavorable prognostic signs It is obvious that the character and extent of the complicating sepsis play an important role in the prognosis There are few diseases however in which it is more difficult to foretell the outcome I have seen patients recover who on admission were unconscious and had temperatures of 106° F on the other hand patients with but slight elevation of temperature and with white cell count above 1000 have died in spite of all that could be done In general it may be said that once the white cell count has risen to a level of 4000 or more a favorable outcome can be expected while if no hematologic improvement has occurred ten days after the initiation of supposedly remedial measures death is almost certain

THE LEUKEMIAS

Definition—Leukemia is a fatal disease considered by many to be neoplastic in nature which arises primarily in the blood forming organs and is characterized by an extensive and abnormal proliferation of the leukocytes and their precursors Almost invariably at some time during the disease immature white corpuscles appear in the circulating blood frequently in great numbers in most cases there is an associated anemia often of a severe degree

Types of Leukemia and Allied States—For practical purposes it is convenient to discuss the various types under the following divisions

1 Chronic myelogenous leukemia
2 Chronic lymphogenous leukemia
3 Acute leukemia
   (a) Myelogenous
   (b) Lymphogenous
   (c) Monocytic

4 Chronic and subacute *monocytic* leukemia
5 Other varieties and allied pathologic states
 (*a*) Subleukemic leukemia
 (*b*) Lymphosarcoma cell leukemia
 (*c*) Leukemoid reactions
 (*d*) Chloroma
 (*e*) Plasma cell leukemia
 (*f*) Multiple myeloma
 (*g*) Myeloid metaplasia of the spleen of unknown etiology

History —Credit for first establishing the condition as a new clinical syndrome must be given to Hughes Bennett and to Rudolf Virchow In the autumn of 1845 these observers independently and almost simultaneously described in patients after death the greatly enlarged spleen and the increase in white corpuscles in the blood Fuller in 1846 recognized the first case during life The disease was called leukocythemia by Bennett and leukemia by Virchow With the introduction of differential staining methods by Ehrlich in 1891 it became apparent that splenic and myelogenous leukemia were the same The first case of acute leukemia was described by Friedreich in 1857 Lissaurer in 1865 was among the first to employ arsenic in its treatment and observed symptomatic improvement but it was not until 1878 that G E Cutler and E H Bradford made the first careful study of the effect of this drug on the blood Pusey in 1902 introduced roentgen rays in the treatment of leukemia this was followed in 1903 by the observations of Nicholas Senn and in 1904 by those of George Dock on the same subject O Naegeli in 1900 identified the myeloblast and emphasized its importance in relation to the leukemic states *Monocytic leukemia* was first described by H Reschard and Schilling Torgau in 1913

Etiology —There are two principal views concerning the nature of the leukemic process one that the condition is an infection the other that it is a malignant neoplasm The latter is the more commonly accepted theory at present Certainly the condition is an invariably fatal, invasive pathologic process Banti s conclusion in 1904 in regard to the cause of *lymphatic leukemia* epitomizes the most rational present day tentative opinion concerning the etiology of leukemia in general His statement is as follows "A tissue with atypical structure that has a tendency to spread locally from the involved to neighboring organs that forms hematogenous metastases cannot be called hyperplastic it belong instead, in the group of new growths

Those who argue for the infectious *etiology* are influenced to do so because some of the striking features particularly in the acute leukemias, such as chills fever and leukocytosis are also present in diseases of a known infectious nature Infection, especially about the mouth and throat is commonly present, and septicemia may be observed On the other hand it has not been possible to produce leukemia in animals with any organisms which have been isolated from a patient there is no evidence to indicate that the disease is transmissible from man to man, and it is not communicated to the fetus by a mother who has leukemia It is a more logical conclusion that the organisms which have been isolated from patients with leukemia are present in the role of secondary invaders rather than as primary etiologic agents

Additional evidence in favor of the neoplastic theory other than that emphasized in *Banti s statement* given above is as *follows* The disease so far has been produced in mice and guinea pigs only by the actual transference of malignant cells Fowl leukemia is apparently a filtrable form but this is also true of certain types of neoplasms such as sarcomas Maude Slye maintains that spontaneous leukemia in mice follows *the laws of heredity* and is inherited as a simple mendelian recessive characteristic as are other neoplasms

Age and Sex Incidence —Leukemia of various types may be observed in either sex at any age The greatest number of cases of chronic myelogenous leukemia is observed in the decade from thirty five to forty five years whereas the maximum incidence of chronic lymphatic leukemia is between the ages of forty five and fifty four some observers however place its greatest incidence somewhat later namely fifty to sixty nine years It is unusual to observe *chronic leukemia* of either type in patients younger than ten years and it is not likely to occur before the age of twenty five years Acute leukemia occurs *most* frequently in persons younger than twenty five years and has its greatest incidence in children under five years it is very rare in patients older than fifty years but it does occur at any period of life and has been reported in old age

Chronic myelogenous leukemia develops more frequently in males than females in the ratio of 60 40 and chronic *lymphatic*

leukemia is three times as common in the male sex Acute myelogenous leukemia of childhood appears to occur about equally in the two sexes There is no evidence to indicate that leukemia of any type pursues a different course in either sex

Pathology of Various Types of Leukemia—The fundamental pathologic change in any type of leukemia is an extensive proliferation of cells of the myeloid lymphoid or monocytic group which is usually associated with the presence of large numbers of these cells in various tissues of the body and the blood stream

In chronic myeloid leukemia the bone marrow most frequently of the sternum and the long bones is replaced by myeloid cells in which the myelocytes and metamyelocytes predominate although a few myeloblasts may be present A quantitative reduction of the red blood cell forming marrow is the explanation of the commonly associated anemia of the disease The spleen is usually grossly enlarged and there may be a great increase in the myeloid cells of the splenic pulp with often a fibrous thickening of the capsule infarcts are commonly present The liver is usually moderately increased in size and myeloid metaplasia is frequently present in that organ

In chronic lymphogenous leukemia the characteristic pathologic change consists of a replacement of the normal architecture of the lymph glands spleen liver bone marrow and other tissues by lymphoid cells Similar changes may be observed in the tonsils lymphadenoid tissue of the pharynx bronchi esophagus stomach solitary lymph follicles Peyer s patches the bladder and urethra The spleen is usually moderately enlarged due to the lymphocytic infiltration and there may be infarction perisplenitis and thickening of the splenic capsule The bone marrow is almost always involved with a similar lymphoid infiltration which eliminates most of the fat and normal marrow cells

In the acute forms the leukemic infiltrations occur in various tissues throughout the body in a manner similar to that observed in the chronic leukemias In the former however the abnormal collection of infiltrating cells consists almost entirely of myeloblasts lymphoblasts or monoblasts In addition there is commonly a widespread and severe tendency to bleed due to the secondary thrombocytopenic purpura

Symptoms and Signs—The onset is usually insidious and frequently the disease is well advanced when the patient is first examined Definite and pronounced leukemic changes may exist in the blood for several years before the patient complains of symptoms

Frequently the initial complaints are weakness pallor, palpitation and dyspnea which are due to the associated myelophthisic type of anemia In some cases there are no symptoms other than a dull dragging sensation in the left side of the abdomen or a bulging in the left upper quadrant which results from splenic enlargement Fever of an intermittent or remittent type rising as high as 101° or 102° F is commonly observed and this sometimes associated with chills may be an early complaint As an increased basal metabolic rate is commonly encountered in the condition the symptoms due to this such as increased sweating intolerance of warmth loss of weight and tachycardia are frequently present During the acute exacerbations of the chronic form and as a terminal event there may be an abnormal tendency to bleed which manifests itself as epistaxis hemorrhages under the skin from the uterus kidneys bowels or into the retinas or middle ear Cerebral hemorrhage is an occasional complication The hemorrhagic tendency is usually associated with a diminution of platelets in the circulating blood Priapism although always mentioned is an exceedingly rare complication Symptoms associated with an increasingly severe anemia fever and abnormal bleeding are likely to become more pronounced as the disease progresses

The general appearance of the patient varies widely depending largely on the degree of anemia which is present When this is advanced the patient has the aspects of a chronically ill person with pronounced pallor and emaciation In the earlier stages when the red blood cell count and hemoglobin are within normal limits the appearance may be that of a robust person in good health although even then the white blood cell count may be several hundred

thousand per cubic millimeter and the spleen greatly enlarged

Splenic enlargement, sometimes to a degree which causes this organ to occupy a greater portion of the abdominal cavity is characteristic of the disease The lower edge commonly reaches below the umbilicus The absence of a palpable spleen is strong evidence against the diagnosis of chronic myelogenous leukemia The organ is firm and is not tender unless perisplenitis develops The liver is usually palpable and may attain an enormous size

Characteristically the lymph nodes are not enlarged as they are in the lymphatic type and this assists in differentiating the two types of the disease Occasionally there may be a moderate increase in size of some of the lymph glands due to an infiltration with myeloid cells similar to that which occurs in other tissues of the body

Skin lesions other than the purpuric manifestations are not a commonly encountered complication In some instances there is an infiltration of the skin with myelocytes and myeloblasts which causes the formation of bluish gray, elevated nodules varying in size from a pin head to a walnut They most frequently appear on the trunk although they have been observed elsewhere on the body Ordinarily they are not associated with itching or pain

As leukemic infiltrations may be present in almost any tissue of the body the possible complications are many In addition to those already mentioned the following may occur the retinae may show hemorrhages and leukemic infiltrations there may be destructive lesions of bone with pathologic fracture deafness can occur due either to hemorrhage or leukemic infiltrations in the inner or middle ears various lesions of the nervous system may be observed which are due either to hemorrhages thromboses or tumor like infiltrations hematuria associated with infiltration of the kidneys may be encountered, myeloid changes may occur in the gastro intestinal tract resulting in hemorrhage but this is more frequently observed in lymphatic leukemia

Blood Examination—The typical blood picture is an increase in the total number of leukocytes to 100 000 or more per cu mm of which from 20 to 60 per cent are myelocytes chiefly in the later stages of development and from 30 to 70 per cent are polymorphonuclear neutrophils with segmented nuclei An occasional myeloblast may be seen As the disease progresses the proportion of myelocytes and myeloblasts increases and in the advanced or terminal stages 70 per cent or more of the cells may be of the latter type The total white blood cell count usually ranges between 100 000 and 500 000 per cu mm although as many as 1,000 000 or more leukocytes per cu mm have been observed It is not rare for the leukocyte count to become normal or for a leukopenia to develop either spontaneously or following treatment This is discussed in the section on Subleukemic Leukemia An almost constant finding is an increase of from 2 to 10 per cent of basophils and occasionally these cells may comprise 50 per cent or more of all the leukocytes (basophilic leukemia) Likewise the numbers of eosinophils and eosinophilic myelocytes are frequently increased to 5 or 6 per cent of the total leukocytes and in some instances these types of cells are the predominating ones in the circulating blood (eosinophilic leukemia) Monocytes are usually present but rarely exceed 3 per cent of the total number of leukocytes There is characteristically a decrease in the percentage of lymphocytes but their absolute number may be normal or actually increased Care should be used in differentiating between lymphocytes and myeloblasts

Most frequently there is a slight increase in the blood platelets above normal but this may be excessive or in some instances the numbers may be reduced sometimes to a marked degree The latter change usually prevails in the more acute and terminal stages of the disease and is often associated with a hemorrhagic tendency Occasionally an experienced observer may detect megakaryocytes in the blood

An anemia is an almost constant finding at some stage during the course of every case of leukemia It is usually normocytic in nature as almost always the mean corpuscular volume mean corpuscular hemoglobin and mean corpuscular hemoglobin concentration are within normal limits At the onset or following spontaneous or therapeutically induced remissions it is often mild

or may be absent The general condition of the patient usually parallels the level of the red blood cell count and hemoglobin percentage It is generally accepted that the anemia is of the myelophthisic type which results from the encroachment of the hyperplastic myeloid tissue in the bone marrow on the red blood cell forming elements causing a diminished rate of erythrocyte production In the bone marrow there often remain areas of erythrocytic activity which as a compensatory mechanism may account for the presence of reticulocytes and nucleated red blood cells in the circulating blood

Prognosis —There are no authentic cases on record in which a patient with myelogenous leukemia has recovered It is generally agreed among authorities that the average duration of life is between two and one half to three and one-half years after symptoms appear and that irradiation will prolong life for an average of only about six months at the most Undoubtedly the characteristic blood changes precede the onset of symptoms in some cases by a period of several years Although the average duration of life is short over 10 per cent of the cases survive for a period of five to ten years after the onset of symptoms and instances are known of patients who have survived as long as sixteen years

The great benefit derived from treatment is not the prolongation of life but the improvement of symptoms and the temporary restoration of a patient to apparent health for considerable periods of time A study of the natural course of the disease indicates that spontaneous remissions occur in less than 10 per cent of the patients The proper use of irradiation however will improve the patients markedly in fully 50 per cent of the cases and permit them to lead efficient lives for 50 to 75 per cent of the period between the beginning of treatment and death The results attained are much better when treatment is applied as soon as the earliest indications for it appear the effect when used later in the course of the disease however is worth while Judging by the improvement in the anemia the response in chronic myelogenous leukemia is better than it is in the chronic lymphatic type

Regardless of the method with which irradiation is used there inevitably comes a time when it produces little improvement in the blood or the clinical condition of the patient Emaciation develops fever is often a prominent feature the anemia becomes progressively worse a hemorrhagic tendency may develop and death usually ensues in from four to six months after the onset of the period of decline

CYRUS C STURGIS

CHRONIC LYMPHOGENOUS LEUKEMIA

The onset is insidious usually with one or two types of complaints namely the patient observes either a painless nontender lymph node in the neck axillae or groin or the symptoms of an anemia develop such as pallor weakness ease of fatigue dyspnea and palpitation Less frequently the initial symptom may be the occurrence of an abnormal tendency to bleed as indicated by hemorrhages from the mucous membranes or excessive bleeding following trauma Occasionally an early symptom may be associated with a leukemic infiltration of the skin which causes itching and redness In some instances the disease has been discovered as an incidental finding of a lymphocytosis when a routine blood examination has been done

The commonly encountered findings on physical examination are associated with the anemia the enlarged lymph glands and splenomegaly Usually the patient appears pale and gives a history of recent increasing pallor and loss of weight Evidences of abnormal bleeding are not ordinarily observed except during acute exacerbations of the disease and as a terminal event The lymph nodes are most frequently enlarged in the cervical axillary and inguinal regions They vary in size from a pea to a hen s egg and are nontender smooth moderately firm and are not adherent to each other Usually they increase slowly in size unless reduced with radiation therapy it is not common to have them diminish in extent spontaneously although it has been claimed that this may occur following an intercurrent infection Roentgenograms may disclose an increase in the extent of the mediastinal lymph glands

but rarely is it possible to palpate enlarged abdominal glands Occasionally cases have been reported without enlargement of the lymph glands but such a situation is exceedingly rare The firm nontender edge of the spleen is most often palpable 7 to 8 cm below the left costal margin but never is a huge size attained The liver is usually moderately enlarged

Blood Examination —It is ordinarily not difficult to conclude, from the blood examination alone that a patient has chronic lymphatic leukemia This is because usually the total leukocyte count is increased to from 30 000 to 100 000 per cu mm and from 60 to 90 per cent of the cells resemble the normal small lymphocytes In the early stages the red blood cell count and hemoglobin percentages are normal but eventually a normocytic anemia will develop and as the disease progresses it almost always reaches a severe degree The number of blood platelets is characteristically decreased to a moderate extent, although they may at times show a slight increase The difficulty in recognizing the disease arises when the total white blood cell count is normal or below normal and the diagnosis from a study of the blood depends primarily on the recognition of the immature forms of lymphocytes This is also puzzling in the acute phases when a very large percentage of the cells are immature as even experienced observers in hematology cannot always agree upon the criteria for differentiating immature lymphocytes from myeloblasts Although the various stages of the myeloid cells are easily recognized, this is not true of the lymphocyte series In general the immature lymphocyte differs from the fully developed form in that the former is more commonly a large cell with comparatively large nucleus some believe that the nuclear pattern serves to differentiate it from the myeloblast It is generally accepted that the degree of basophilia of the cytoplasm parallels the age of the lymphocyte series and that young lymphocytes and lymphoblasts have a more basophilic cytoplasm

There is a marked diminution or almost complete absence of monocytes polymorphonuclear neutrophils eosinophils and basophils

The Basal Metabolic Rate in Chronic Leukemia —The basal metabolic rate in untreated patients with either chronic myelogenous or lymphogenous leukemia may be elevated above normal limits although the increase is moderate usually varying between +20 and +30 occasionally the elevation may be more extreme reaching levels as high as +70 or +80 It should be recognized that some of the important manifestations of the disease depend on an increased basal metabolic rate These are dyspnea tachycardia sensation of increased body warmth excessive sweating intolerance to heat and loss of weight These symptoms however, are never as conspicuous as they are in patients with toxic goiter who have a similarly elevated basal metabolic rate Often in leukemia the level of the basal metabolic rate is a more accurate index of the clinical condition of the patient than either the white blood cell count or the percentage of immature myeloid cells in the circulating blood High estimations which persist despite irradiation suggest a poor prognosis

The cause of the increased basal metabolic rate is not definitely known but it is considered to be due in large part to the increased consumption of oxygen by the leukemic cells throughout the body An accelerated rate of destruction of these cells may also be a factor of importance in this connection

Prognosis —Chronic lymphatic leukemia resembles other types of the disease in that it is an invariably fatal condition The average duration of life is about three and one half years If the period of survival is considered in a large group of patients either treated or untreated it will be found that about two thirds of them die between one and four years from the onset of symptoms one fifth in four to six years and one tenth in six to eight years a few succumb in less than a year Irradiation even when efficiently employed early in the course of the illness does not materially prolong the life of the patient Although the beneficial results in this form of leukemia are not as striking as they are in the chronic myelogenous form they are distinctly worth while About one half of the patients show moderate and 10 per cent striking improvement following irradiation The failure of response of a patient to x ray is a reliable but unfa

vorable aid in prognosis for it usually indicates that a fatal outcome is to be anticipated in a matter of months In such patients often over 50 per cent of the circulating white blood cells are immature lymphocytes and when this occurs it is strongly suggestive evidence that the patient will not survive for a longer period than six months

Treatment of Chronic Leukemia.—It is generally accepted that leukemia is an invariably fatal disease but that the roentgen rays may produce worth while benefit when employed as a symptomatic form of treatment Arsenic especially in chronic myelogenous leukemia is of use but less effective Benzol and splenectomy are no longer considered to be of value radium although it produces beneficial effects is ordinarily less convenient to apply and possesses no advantages over the x ray blood transfusions are of limited value but are desirable in certain phases of the disease

Treatment with the Roentgen Rays—It should be emphasized that this therapeutic agent should be applied *only* when important symptoms warrant its use The most commonly encountered indications are as follows pressure symptoms resulting from enlarged glands or the spleen loss of weight which is frequently associated with fever and a persistently elevated basal metabolic rate symptoms referable to an increasingly severe anemia of which the most significant are weakness and ease of fatigue involvement of important regions of the body with leukemic infiltrations and the occurrence of purpura and spontaneous bleeding from the mucous membranes

The *contraindications* which should be carefully evaluated before irradiation is employed are now well recognized It is known that in acute leukemia of any type or in an acute exacerbation of chronic leukemia x ray therapy is valueless and commonly does more harm than good While the presence of as many as 50 per cent of myeloblasts or lymphoblasts is not in itself enough to deter treatment with x ray it should be applied with caution when these circumstances prevail and probably little benefit will result Following the appearance of a hemorrhagic tendency or a leukopenia which arises spontaneously the x ray should be used with extreme care if at all and then it is unlikely to improve the condition of the patient If either of these situations develops during the course of treatment it is a definite indication to stop immediately all roentgen ray therapy The presence of a severe anemia does not prohibit the use of x ray therapy but it is advisable in such patients to precede the x ray exposures with several blood transfusions and to discontinue further roentgen ray therapy if the anemia becomes more severe

The usual form of therapy has been to employ the following physical factors 200 kilovolts (peak) filtration of 0.5 mm copper plus 1 0 mm aluminum (H V L 0 9 mm copper) distance of 50 cm, and a dose of 100 to 200 r measured in air to parts ranging from 10 × 10 to 15 × 15 cm per treatment Such an exposure is given each day usually for eight to twelve days Caution should be used in the application of roentgen therapy as not all patients will tolerate the maximum treatment outlined above and the reaction is often unpredictable It is advisable that the initial treatments should consist of smaller doses applied to more limited fields

A valuable guide to roentgen ray dosage is the level of the leukocyte count Rarely is it advisable in a patient who has pronounced leukocytosis at the beginning of treatment to continue the therapy after the count falls to 25 000 or 30 000 per cu mm The maximum effect of therapy often does not become apparent until several days after exposure Patients who have an initial leukocyte count of less than 20 000 per cu mm should be given a decreased dosage the interval between the treatments should be lengthened and the white blood cell count made daily as a guide to treatment

Treatment with Arsenic—Recently Forkner has revived an interest in the use of arsenic and believes that it has a distinct value in chronic myelogenous leukemia It may also be of benefit in the lymphatic form but does not cause improvement in the acute types of the disease even though it may produce a reduction in the total leukocyte count Apparently the drug fails to act in patients who have become refractory to irradiation It is worthy of a trial however when high voltage x ray is not available

and it has the advantage of being less expensive Forkner* recommends that arsenic in the form of Fowler's solution be given as follows "Begin with doses of about 5 minims (0 3 cc) three times daily for two days, preferably in orange juice immediately after or with meals On the third and fourth days give 6 minims three times daily and continue increasing in this manner to about 10 minims three times daily, thereafter increasing by 1 minim per day until toxic symptoms are pronounced or until the leukocyte count approaches normal Thereafter omit medication for from two to five days and then decrease the dose from the maximum by 1 minim per day down to a maintenance dose of from 5 to 8 minims three times daily Continue this dosage indefinitely' All toxic manifestations of the drug such as anorexia nausea vomiting and diarrhea disappear in forty eight hours after it is discontinued and it may then be given again in slightly smaller doses

Treatment with Radio active Phosphorus—This is the most recent form of treatment employed in patients with various types of leukemia Although experience with it is limited it is possible to make the following tentative statements (1) it is effective therapeutically when given orally as sodium phosphate dissolved in water and does not produce important untoward symptoms (2) it is effective in both myelogenous and lymphogenous leukemia but some claim that better results are attained in the former, (3) the indications and contraindications for the use of radio active phosphorus in leukemia are the same as those commonly accepted for roentgen ray therapy (4) although the optimum dosage has not been finally determined an average course of treatment for a patient weighing 70 kg would total approximately 25 to 50 millicuries divided into six or seven equal doses given at weekly intervals As in roentgen ray therapy however it is essential that the amount of treatment be guided by frequent blood examinations with particular reference to the leukocyte count and the total number of immature cells

The Use of Blood Transfusions—The transfusion of blood should be considered as a palliative measure in all patients with a severe anemia or those in whom purpuric manifestations are present Temporary improvement may follow in those who have not responded favorably to roentgen ray or arsenic therapy Furthermore, in the presence of a severe anemia several transfusions of from 400 to 600 cc of blood should be given before these forms of therapy are employed

ACUTE LEUKEMIA

At least three varieties of the acute type of the disease undoubtedly do occur Frequently however the mode of onset, the signs and symptoms the course of the disease the changes in the circulating blood and the pathologic findings at necropsy, are so similar that recognition of the particular type in any given case may be impossible This is because almost all of the circulating leukocytes may be of the very immature type and as a result difficulty arises in classifying them as either myeloblasts lymphoblasts or monoblasts

Symptoms and Signs—The onset of acute leukemia is usually rather abrupt with the development of symptoms which are often considered to be due to a cold or upper respiratory infection an ulcerative stomatitis or acute tonsillitis There is ordinarily no suspicion as to the serious basis for the complaints until attention is directed toward the rather sudden appearance of pallor indicative of a rapidly developing anemia or an unusual degree of prostration which is out of proportion to the minor nature of the initial symptoms Fever which may be associated with outspoken *chills o* chilly sensations is almost invariably present in the advanced stages but an increase in body temperature may also occur early

A spontaneous hemorrhagic *tendency* is commonly present and is usually a manifestation of a secondary *thrombocytopenic* purpura with the characteristic decrease in *blood platelets* It may be one of the early indications of the sinister nature of the patient's illness Bleeding occurs into the skin and from the mucous membranes of the mouth the gums or the nose into the

fundi of the eyes and the brain from the gastro intestinal tract and the uterus The first evidence of the disease may be profuse hemorrhage following the extraction of a tooth removal of the tonsils or from minor injuries Although a slight tendency to bleed may be noted early in the illness the more extensive hemorrhagic manifestations occur late as a rule and their appearance is usually an ominous sign

Blood Examination —The characteristic change in the blood is the presence of a large number of mononuclear, nongranular cells which are usually either myeloblasts or lymphoblasts rarely are they monoblasts Frequently almost all of the cells are of a uniform immature type and confusion arises as to their exact identity Very few, if any intermediate cells representing stages between the mature and the primitive forms may be present a fact which makes difficult the recognition of the predominant primitive cell type It then becomes necessary to depend upon the cytologic characteristics of the myelocyte lymphocyte and monocyte in order to classify the type of acute leukemia from which the patient is suffering This is not possible in all instances even by experienced hematologists in such cases therefore it is necessary to be content with the diagnosis of acute leukemia of undetermined type The total number of leukocytes in the various types of the disease is most frequently between 15 000 and 30 000 per cu mm rarely does the count exceed 100 000 per cu mm At the onset it is commonly below 8000 per cu mm and it may be 2000 to 3000 per cu mm or less

The characteristic alteration in the circulating blood in acute myelogenous leukemia is the presence of immature cells of the myeloid series As previously mentioned almost all of the white corpuscles may be of the myeloblast type which closely resembles both the lymphoblast and the monoblast There is a parallelism between the number of myeloblasts and the acuteness of the disease In the subacute myelogenous variety the intermediate cell stages promyelocytes and myelocytes are present and classification can be made without difficulty In acute lymphatic leukemia some of the cells may be in the intermediate stage between the lymphoblast and the mature lymphocyte As the large cells represent the more immature lymphocyte it is this type that predominates in acute lymphatic leukemia whereas the small lymphocyte is the commonly encountered cell in chronic lymphatic leukemia

A severe anemia almost always develops in the acute leukemias in which the red blood cells may fall to 1 000 000 per cu mm or less in some cases there may be nucleated red blood cells and an increase in reticulocytes The blood platelets are almost always reduced in number

Prognosis —The disease frequently has a fulminating course and terminates fatally within a relatively brief interval More than three fourths of the patients succumb within eight weeks after the appearance of the initial symptoms and about one fifth die after an illness of two or three weeks There is no authentic record that a patient with true acute leukemia has ever recovered Occasionally the disorder will change spontaneously from the acute to the subacute or chronic phase but this is rare and even then the duration of life is ordinarily not greater than six months

Treatment —The treatment of the acute leukemias is ineffective Irradiation usually produces more harm than benefit and is contraindicated except in exceedingly small doses Repeated blood transfusions may cause some transient improvement by increasing the red blood cell count and hemoglobin percentage and in rare instances the acute phase may change to the chronic type which is more amenable to irradiation transfusions may also control temporarily the tendency to bleed through the introduction of platelets into the circulating blood

CYRUS C STURGIS

MONOCYTIC LEUKEMIA

Within recent years it has been recognized that a leukemia may occur which differs from other types in that there is a significant increase in the cells of the monocyte series in the circulating blood The characteristic pathologic change is an infiltration of the organs of the body especially the spleen and the liver with monocytic cells resembling those of the blood

There is no agreement concerning the origin of the monocytes but there is strong evidence that they are an independent strain of cells Undoubtedly a leukemia does occur which has acute, subacute chronic and aleukemic phases and in which the chief characteristic in common is the presence of an increased number of monocytes in the blood some of which may be immature in type Distinctive clinical features appear to be the frequent occurrence of oral lesions such as gingivitis and angina and a tendency for the patients to develop purpura and bleeding from the mucous membranes Enlargement of the liver and spleen may be observed but it is uncommon and when present is usually of slight extent The course is usually rapid and a fatal termination commonly occurs within a period of months

Downey recognized two varieties of monocytic leukemia—the Schilling type in which the monocytes are derived from the reticulo endothelial system and the Naegeli type in which the monocytes are supposed to develop from the myeloblasts, thereby making this form a variant of myelogenous leukemia Although the mature monocytes are identical in both varieties their origin is entirely different There are no significant differences in the clinical picture between the types of the disease or other forms of leukemia The recognition of the two types of monocytic leukemia is based solely on hematologic grounds In the Naegeli variety the peripheral blood contains a predominance of monocytes in various stages of development in association with a number of myeloblasts and young myelocytes In the Schilling type, monocytes usually fairly mature predominate and larger histiocytes may be found Myeloblasts are absent from the peripheral blood but an occasional myelocyte may be present

Blood Examination—The white blood cell count is usually between 25 000 and 100 000 per cu mm although extreme variations may be from 2000 or 3000 to several hundred thousand The monocytes usually make up 50 per cent of all white blood cells occasionally 90 per cent In patients with the chronic form of the disease almost all of the monocytes resemble the normal adult form The monoblast is described as a cell having a nucleus with a density similar to the lymphoblast and myeloblast As the cell develops the bluish shade of the cytoplasm in films becomes less deeply stained and finally resembles the light blue mottled cytoplasm of the mature cell

CYRUS C STURGIS

UNCOMMON VARIETIES OF LEUKEMIA AND ALLIED PATHOLOGIC STATES

Subleukemic (Aleukemic) Leukemia—Confusion in regard to this condition is in part due to the many names applied to it In the past it has been designated pseudo leukemia aleukemic myelosis aleukemic lymphadenosis aleukemic monocytic leukemia pseudoleukanemia aleukemic erythroblastosis and many others These should all be superseded by the term subleukemic leukemia'

In order to clarify the situation it should be emphasized that there may be a stage of either chronic subacute or acute myelogenous lymphatic or monocytic leukemia in which the white blood cell count is either normal or actually below normal Almost always there are a variable number of immature white blood cells in the circulating blood and often by sternal puncture it is possible to demonstrate a characteristic leukemic change in the bone marrow In some cases the leukocyte count remains apparently normal or below throughout the illness more commonly there have been transient or prolonged increases to 30 000 or 50 000 per cu mm or higher This may occur at any time during the course of the disease but it is more likely to be observed as a terminal event These spontaneous increases in the number of leukocytes are the most convincing evidence that subleukemic leukemia is a variety of the more commonly encountered type and varies from it chiefly in the changes observed in the circulating blood Occasionally leukemic changes have been demonstrated at necropsy in patients in whom it has been claimed that immature white blood cells have not been present in the circulating blood and that the total leukocyte count has never been elevated

This situation may be exceedingly rare and in such reported cases one suspects that if the circulating blood had been examined more frequently during life, immature white blood cells would have been noted

The clinical picture in such patients depends to a certain extent upon the variety of subleukemic leukemia which is present There are variable degrees of splenomegaly and lymphadenopathy but in some cases these findings may be absent The most common clinical features are as follows (1) A progressive normocytic normochromic anemia often reaching a severe grade associated with this are the customary complaints of weakness ease of fatigue dyspnea and palpitation on exertion Aplastic anemia is the condition most commonly confused with subleukemic leukemia but it is necessary also to distinguish from it pernicious anemia Hodgkin s disease myelophthisic anemia resulting from metastasis in bones and achrestic anemia (2) The anemia of this disease is refractory to all forms of treatment Aside from the temporary improvement following blood transfusions none is observed except that associated with rarely occurring spontaneous remissions (3) The total white blood cell count is frequently below 4000 per cu mm and may be as low as 1000 or 2000 per cu mm In almost every instance there are immature white blood cells present in the circulating blood but as they are scarce and the total white blood cell count is usually diminished they may be easily overlooked even by the expert hematologist It is not uncommon for the less experienced to regard the myeloblasts which may be present as lymphocytes It should be emphasized that careful examination in almost all instances will show that the differential formula is abnormal (4) Sternal puncture may assist in the diagnosis as it may show the predominating cells of the marrow to be myeloblasts lymphoblasts or monoblasts Unfortunately from a diagnostic standpoint the sternal marrow is not infiltrated with abnormal cells in all cases of subleukemic leukemia The examination is of greatest value in demonstrating positive evidence of the disease a normal sternal marrow does not eliminate it as a diagnostic possibility (5) It is important to emphasize that there is commonly a decrease in the circulating blood platelets which may or may not be associated with purpuric manifestations such as bleeding from the mucous membranes retinal hemorrhages and petechiae

One should always consider the diagnosis of subleukemic leukemia in the presence of any one or a combination of the following (1) a leukopenia with or without an associated normocytic or macrocytic anemia (2) an unexplained lymphadenopathy or splenomegaly (3) fever without obvious explanation (4) tumefaction of the gums (5) a hemorrhagic tendency (6) certain characteristic skin lesions (7) vague pain in the bones and about the joints and (6) bone tenderness especially if it involves the sternum

Lymphosarcoma Cell Leukemia.—Lymphosarcoma cell leukemia is a definite clinical entity characterized by the presence of lymphosarcoma cells in the blood stream These vary in size from 12 to 14 microns in diameter and have a sparse but deeply basophilic cytoplasm The most striking identifying feature of the cell is the nucleolus which is usually single eccentrically placed and light blue in color When stained with cresyl blue and Wright s stain it is surrounded by an intensely staining conspicuous blue black rim

Such a type of leukemia arises when lymph tissue undergoes sarcomatous change which at first is a localized new growth Eventually the neoplastic cells escape from the confines of the surrounding tissue and appear in the blood stream The earliest evidence of the disease is usually enlargement of the lymph glands or spleen or symptoms referable to the anemia Throughout the course of the disease anemia fever hemorrhage and infection are the most conspicuous features The condition occurs most commonly in males it may appear at any age Frequently the condition manifests itself at a time when the blood does not exhibit abnormal changes It may be months or even several years before the lymphosarcoma cells invade the blood stream When this occurs the course is usually rapid although beneficial effects may follow the cautious employment of roentgen therapy About one half of the patients die within one year after onset of symptoms or

discovery of the tumor Patients with this condition are usually regarded as suffering from lymphatic leukemia, the careful exclusion of such cases will extend the average duration of life of patients with lymphatic leukemia to four or five years which is longer than usually stated

Leukemoid Reactions —It is now appreciated that there are a considerable number of conditions, in addition to true leukemia in which immature white blood cells may appear in the circulating blood in association with a normal, increased or decreased leukocyte count Such a blood picture is called a *leukemoid reaction* This highly important differentiation can usually be accomplished by continued clinical observation repeated blood examinations and a study of the sternal marrow

As the hematopoietic tissues in infancy and childhood are more likely to react abnormally to various stimuli especially infections caution should be used before concluding that the hematologic changes in the blood of a young person are of a leukemic nature Confusion is more likely to arise with the alterations observed in the acute leukemias In this condition three important and almost constantly occurring changes are helpful in differentiating it from a leukemoid reaction (1) 60 to 70 per cent or more of the circulating white blood corpuscles are of the uniformly large immature blast" type (2) a normocytic or slightly macrocytic anemia often of severe grade usually develops during the course of the disease (3) the blood platelets are almost always reduced in number

Lymphatic leukemoid reactions are observed in a number of diseases including pertussis typhoid fever and infectious *mononucleosis* The latter condition which is characterized by complaints referable to the upper respiratory passages fever lymphadenopathy a palpable spleen in 50 per cent of the cases and atypical lymphocytes in the circulating blood, should receive most careful consideration in all young persons in whom the diagnosis of leukemia is a possibility Of considerable assistance in the differential diagnosis is the heterophile antibody reaction which is usually positive in infectious mononucleosis and negative in leukemia

Leukemoid reactions of the myeloid type are observed occasionally in almost any type of pyogenic infection A pyonephrosis in which the infected kidney may be mistaken for the spleen when it is on the left side if associated with a leukemic blood picture may present a most puzzling diagnostic problem Immature leukocytes may also be present in nonpyogenic infections such as subacute bacterial endocarditis and tuberculosis Similar changes may be observed in various hemolytic anemias of which congenital hemolytic icterus sickle cell anemia and Lederer s anemia are examples Other blood dyscrasias including pernicious anemia especially at the beginning of a remission polycythemia vera erythroblastic anemia and anemia following hemorrhage may be associated with such blood changes A special group in which a leukemoid blood picture may be present consists of pathologic processes which involve the bones and bone marrow Examples of such conditions are metastases from malignant processes multiple myeloma and osteosclerosis Lastly immature white blood cells may be noted in the blood stream of patients in diabetic coma in poisoning with mustard gas mercury, and phenylhydrazine and occasionally in cases in which the cause cannot be ascertained

Chloroma —*This disease is a rare variety* of leukemia characterized by an invasive tumor like growth of greenish color in various organs and tissues of the body and by changes in the blood simulating closely those seen in acute myelogenous *leukemia Often* many of the white blood cells are of the mononuclear nongranular type which so commonly occur in acute leukemia and the same difficulty arises in classifying these changes into the lymphatic or myelogenous variety Most present-day observers believe that they are myeloid cells

The greenish tumors may be observed in any tissue in which leukemic infiltrations are known to occur The bones of the skull are involved with relative frequency a tumor of the orbital fossa causing exophthalmos was present in 11 of 18 cases collected by Dock and Warthin Tumors may occur in the lymph nodes spleen kidneys and many other organs and tissues The bone marrow may have a uniformly greenish color or circumscribed areas of pigmentation

The condition is observed more frequently in males than in females and has its greatest incidence in childhood adolescence or young adult life It is similar to acute leukemia in that it has a brief course which usually terminates fatally in a few weeks or months All types of therapy which have been employed are ineffective

Plasma Cell Leukemia —A statement concerning this exceedingly rare condition is included for the sake of completeness Plasmacytomas or tumors in which the type cells are plasma cells are regarded as neoplasms which may be localized or metastasizing new growths They are observed in the bones the upper respiratory passages the conjunctiva the cornea the pleura and elsewhere In contrast to this type of plasmacytoma there is a diffuse form which is characterized by an extensive infiltration of plasma cells into the bone marrow the lymphoid tissue and the liver and spleen Such an alteration simulates closely the characteristic changes in tissue which are seen in the well known varieties of leukemia except that the infiltrating cells are plasma cells

In some instances these pathologic changes are not associated with the presence of plasma cells in the blood in others small numbers are observed in some which may be regarded as true plasma cell leukemias the total white blood cell count may be greater than 50 000 per cu mm of which 25 to 50 per cent are plasma cells

Multiple Myeloma.—*Definition.*—Multiple myeloma is a neoplastic like growth which involves the skeletal trunk with destructive lesions causing pain pathologic fractures and anemia It is usually associated with the presence of Bence-Jones protein in the urine and blood

Although it has not received general acceptance the most satisfactory tentative view is to consider multiple myeloma as a neoplastic process in which the myeloid cells are derived from the hematopoietic system If this is true the condition bears a close relationship to leukemia The cells making up the tumors have been most commonly regarded as plasma cells although their identification is by no means definite Possibly myeloma cells are a distinctive type varying from all other forms

Symptoms and Signs—The condition is observed twice as commonly in males as in females Almost all cases occur after the age of forty years Pain of a vague intermittent shifting type often referable to the spine is commonly the earliest evidence of the disease As the condition progresses this frequently is a severe and dominant symptom Tumors and pathologic fractures usually in bones containing red marrow are common Changes in the spine causing compression of the spinal cord with its resultant neurological manifestations is not a rare complication

Blood—A moderately severe normocytic or slight macrocytic normochromic anemia is almost always present The leukocyte count is ordinarily normal slightly elevated or diminished and the differential formula is usually not disturbed or may reveal only an occasional abnormal white blood cell. Rarely have many plasma cells been observed in the blood stream but these when present have caused the condition to be regarded as a plasma cell leukemia

A finding of great diagnostic importance is the presence of Bence Jones protein in the urine which appears in about two thirds of the cases It is said to occur occasionally in the urine of patients with leukemia and polycythemia This protein precipitates at temperatures of 50° to 60° C, further heating causes it to go into solution at about boiling and on cooling it reappears Its presence appears to be limited to pathologic conditions attacking the bone or bone marrow There may be a pronounced hyperproteinemia as indicated by plasma protein determinations which are often found to be 10 Gm per 100 cc of plasma or above figures twice as high as this have been reported This is due entirely to an increase in the globulin fraction Autohemagglutination or spontaneous clumping of the erythrocytes occurs in some cases This accounts for the tendency to striking rouleau formation and an accelerated sedimentation rate Serum calcium is frequently elevated to levels of 12 to 16 mg per cent but the serum inorganic phosphates are usually normal

In addition to those mentioned above there are two diagnostic procedures which are of great importance (1) sternal puncture which usually reveals the presence of

typical myeloma cells, and (2) roentgen ray examination which demonstrates the characteristic punched out areas, without evidence of bone regeneration in the ribs spine, clavicles skull and the shoulder and pelvic girdles

Prognosis and Treatment —The disease is uniformly fatal after an average duration of life of between two and three years Occasionally the course is prolonged with remissions and exacerbations Roentgen ray exposures should be employed in all cases as it frequently gives worth while symptomatic relief and may prolong life in some instances This with blood transfusions is the only known therapeutic agent of recognized value Otherwise the treatment is symptomatic

Myeloid Metaplasia of the Spleen of Unknown Etiology —This condition has been described by Henry Jackson Jr and his collaborators as one which closely simulates chronic myeloid leukemia It is characterized by weakness abdominal distress a hemorrhagic tendency and a slowly progressive enlargement of the spleen due to the myeloid metaplasia The hematologic picture is almost identical with that of myelogenous leukemia but it may resemble chronic hemolytic jaundice Usually there is a moderate elevation or slight depression of the white blood cell count, immature white and red blood cells are present in the blood stream The changes in the spleen and bone marrow differentiate the condition from myelogenous leukemia In the former, the malpighian corpuscles are preserved infarction is absent, and the marrow may appear normal aplastic hyperplastic or fibrotic but never resembles the alterations observed in leukemia The diagnosis of myeloid metaplasia can only be made during life by the finding of myeloid cells in the splenic puncture with histologic evidence obtained by sternal puncture that the bone marrow has not undergone leukemic changes When these alterations are present in a patient with the picture of myelogenous leukemia in the circulating blood the diagnosis is suggested Irradiation and splenectomy are said to be of no benefit and may be harmful If one is certain of the diagnosis only symptomatic and supportive treatment is indicated The duration of life from the onset to the date of death was almost eleven years in Jackson s cases

HODGKIN S DISEASE

Definition —Hodgkin s disease is an affection characterized by painless progressive enlargement of the lymph nodes Frequently the spleen is enlarged and the lymphoid tissue of other organs involved In the late stages fever anemia and cachexia are often important symptoms

History.—Hodgkin in 1832 described for the first time a peculiar group of cases presenting multiple swelling of lymph nodes Somewhat later similar cases were recognized in France and Germany and in 1865 Wilkes named the condition "Hodgkin s disease" A formidable list of names has been given to the disease among which are pseudoleukemia," "ademie generalized lymphadenoma, "malignant lymphoma, lymphomatosis granulomatosa malignant lymphogranuloma lymphoblastoma and chronic lymphomatosis The most common designation at the present time is Hodgkin s disease

Incidence —The ailment is comparatively common is widely spread throughout Lu rope and the Americas and is thought to be on the increase The malady attacks the young and tends to appear in the second or third decade but old age is not immune and patients have been reported up to eighty years of age Men are more likely to be affected than women

Etiology.—At present the cause of the disease remains unknown There are two principal theories as to its origin (1) that the changes in the lymphoid tissue are the result of some infection the disease thus conforming to an infectious granuloma (2) that the alterations in the lymph nodes are neoplastic in nature the disease thus belonging to the category of true tumor growths All efforts to transmit the disease to animals including apes have failed The etiology has been ascribed from time to time to a number of different bacteria Sternberg considered the disease to be a form of tuber culosis This view was upheld by Frankel and Much who found gram positive gran ular rods in the lymph nodes believed by them to be a form of tubercle bacillus Recently the disease has been ascribed to the action of avian tubercle bacilli Though the tuberculous origin of Hodgkin s disease is to some extent, still under discussion it is not an acceptable explanation to most in vestigators Other bacteria such as diph theroid bacilli described as etiologic agents have not withstood the test of time The observation that *Brucella* organisms can be cultivated from the affected lymph nodes still leaves in doubt their etiologic relation ship to the disease It is now generally thought that the encephalitis obtained by Gordon as a result of the intracerebral in oculation of emulsions of lymph nodes into rabbits is not due to a filtrable virus as he first suggested but is caused by a chemical substance derived most probably from eosin ophilic leukocytes The so called Gordon reaction is however almost never observed with any lymph nodes except those affected by Hodgkin s disease

Arguments in favor of the neoplastic origin of Hodgkin s disease have been based largely on the observation that in rare instances the process may invade neighboring tissues and assume the character of sarcoma

The view which is most widely adopted however is that Hodgkin s disease is an in fectious granuloma of unknown etiology

Morbid Anatomy —*Lymph Nodes* —The process generally makes its appearance in the cervical region on either or both sides but any group of nodes may be involved first. The order of frequency is roughly as follows cervical axillary inguinal medias tinal mesenteric and retroperitoneal At first the affected nodes are small and isolated but sooner or later they increase in size and numbers so that great collections of tumors appear in any of the locations mentioned Chainlike masses of glands sometimes ex tend from the neck into the chest and under the pectoral muscles When large groups of nodes form in the mediastinum the trachea is displaced and the esophagus and blood vessels are compressed Less often the tumors press on the spinal column or lumbar and sacral nerves rarely the cord itself is injured either by pressure or infiltration Mesenteric nodes sometimes form astonish ingly large swellings in the abdomen they have been known to obstruct the common bile duct as well as the vessels in the iliac region The tumor masses wherever found are strikingly similar Each node is round oval or slightly irregular with a smooth surface As the capsule is seldom involved the nodes are held together by loose con nective tissue The color is whitish pink semitranslucent gray or cream The con sistency varies—some of the nodes are hard others elastic or even soft In rare cases where the capsule is infiltrated the masses become much more compact

The literature contains only a few refer ences to primary enlargement of the spleen Secondary enlargement occurs in about 60 per cent of the cases Rarely if ever does the splenomegaly suggest the enormous spleen of leukemia When cut the red pulp shows many irregular pearly white or yellowish masses that vary in shape and size Infarctions also occur The liver and kidneys are less often the site of secondary deposits Any organ or structure that contains collec tions of lymphoid tissue is a target for this disease The lung is frequently invaded Growths have been described in the peri cardium pleura thymus thyroid muscles bone marrow periosteum skin central ner

vous system and gastro intestinal tract Hodgkin s disease rarely involves the tonsils a situation frequently affected in lympho sarcoma

Histology —The first well marked micro scopic changes consist of hyperplasia of the lymphoid cells with active proliferation of the germinal centers of the lymphoid fol licles There is also increased vascularity with proliferation of the reticulo endothe lium, while the reticulum itself is prominent The lymph sinuses are dilated and partially filled with cells among which there are numerous endothelial cells leukocytes, and

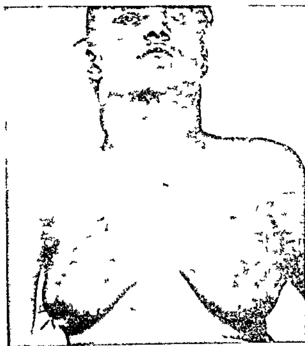

Fig 115—Hodgkin s disease in a patient thirty-six years of age Duration two and a half years In this patient the disease started with enlargement of the lymph nodes in the neck and axilla

eosinophils Karyokinetic figures are infre quently found in the endothelial cells lining the reticulum

As the disease advances the normal struc ture of the node is entirely lost and the microscopic picture shows a reticular network in the meshes of which lie lymphocytes plasma cells many eosinophils epithelioid cells and mononuclear and poly nuclear giant cells in varying proportions The most constant and striking feature is the polynucleated giant cell described by Dorothy Reed The tumor at this stage rep resents the soft type of lymphoma

In the late stage the predominating feature is the great increase in the connec tive tissue Sometimes areas of necrosis are noted and rarely hyaline degeneration is seen At this stage the tumors are much harder than in the earlier phases of the disease

Symptoms —The onset is sometimes pre ceded or accompanied by infections about the teeth or of the tonsils It remains to be proved however, that the enlargement of the cervical lymph nodes is directly associ ated with these infections

In about three fourths of the cases the disease starts with a painless enlargement of one or more groups of *superficial lymph nodes* and later pursues a fairly character istic clinical course In the remaining quarter the disease presents a much more varied clinical picture and it is possible to differentiate roughly as Ziegler has done (1) an acute form (2) a localized form (3) a generalized form, (4) a mediastinal type (5) a larval or abdominal form (6) a splenomegalic form (7) an osteoperiostitic form and to these may be added (8) a gastro intestinal form

Usually the patient first notices a gradual enlargement of the *cervical lymph nodes* The swelling is often unilateral but there commonly follows enlargement of the glands on the opposite side or the enlargement may affect both sides simultaneously In rare instances the enlargement of the axil lary or even the inguinal nodes first attracts the attention of the patient The nodes are not painful or tender nor is the skin red The swelling increases slowly and the dis ease often progresses for several months without producing constitutional symptoms *Pruritus* which sometimes appears early is often persistent and severe Occasionally the disease is limited almost entirely to the cervical region but as a rule the enlarge ment proceeds from one group of nodes to another spreading from the cervical or supraclavicular region to the axillary sub pectoral mediastinal or even retroperit oneal mesenteric and inguinal nodes The epitrochlears often escape and are seldom as large as those seen in lymphatic leukemia Glands have been known suddenly to crop up in bizarre locations such as below the clavicles over the posterior aspect of the fore-

arm or over the occiput As a rule the enlargements are not uniform in size for the nodes first affected may attain huge proportions while those involved later are comparatively small Throughout the disease the separate nodes even though in large groups may be felt as fairly well isolated masses for unless they become secondarily infected or are exposed to radium or the x ray they do not tend to adhere to the skin or surrounding tissue The *spleen* is often large but rarely reaches a great size The *liver* is usually palpable The lungs and pleurae are frequently infiltrated and large areas of solidification extend out from the roots into the lobes of the lungs The disease not infrequently affects the bone marrow and periosteum Several bones may be affected and give rise to areas of rarefaction visible in the x ray film When the vertebrae are affected the disease may extend to the spinal cord and cause paraplegia Instances are described in which the disease involved the brain Among thirty five cases of Hodgkin s disease at the Johns Hopkins Hospital the spinal cord was involved in one the cranial and sympathetic nerves in two and the cerebrum in one As the process advances the patient *loses weight* and presents a cachectic appearance The *blood pressure* is low

The enlarged regional lymph nodes may compress various structures and thus give rise to an important series of secondary symptoms Pressure on the trachea or surrounding structures causes *dyspnea dysphagia* or *laryngeal paralysis* When the brachial lumbar or sacral nerve plexuses are interfered with pain often results *Edema* of an extremity and *effusions* in the chest or peritoneal cavity may be similarly produced The fluid in sometimes bloody If the pressure is sufficient general *anasarca* may appear The clinical picture has been complicated by an obstructive jaundice Tumors sometimes compress the ureters producing bilateral pyelonephrosis or invade the brain and give rise to symptoms of tumor or diabetes insipidus

A second series of important symptoms are suggestive of infection or intoxication *Fever* is a frequent and significant accompaniment of the disease It varies considerably in its character At times it is continuous and irregular though the temperature rarely exceeds 101° F At other times there are wide daily variations The most characteristic form is the relapsing type described by Pel and Ebstein After an afebrile period lasting perhaps for weeks months or longer the temperature suddenly rises more or less abruptly to 102° or 104° F With only slight variation the fever remains high for from a few days to several weeks then recedes again to normal The afebrile period lasts for days or weeks and again the strange cycle is repeated these bouts of high temperature may occur over and over again One of our patients had ten relapses of fever during fifteen months This type of fever is more likely to appear when the mediastinal and abdominal glands are involved it must always be regarded with alarm and frequently indicates that the disease is advancing rapidly

Of all the distressing symptoms none is more bitterly complained of than *itching of the skin* It is common and often occurs early in the disease Patches of *pigment* a peculiar bronzing of the skin urticaria and crops of small erythematous nodules are sometimes present Even *ulcers* and small *superficial granulomata* have been reported We have seen patients in whom the skin looked dry but otherwise normal yet the numerous deep scratch marks bore only too eloquent evidence of the itching Herpes zoster may appear Its relation to the disease is obscure

Alterations in the blood are important though not distinctive During the early stages the total number of leukocytes may not vary from normal There is sometimes a lymphocytosis with an increase of monocytes In the later stages a polymorphonuclear leukocytosis is common Occasionally there is an eosinophilia sometimes reaching figures as high as 60 to 80 per cent In advanced stages particularly in the abdominal forms there may be a pronounced leukopenia There is rarely anemia in the early stages but as the disease progresses anemia is a distinctive feature It is usually normocytic but in some instances may be simple microcytic hypochromic microcytic or in rare cases even macrocytic in type Periods of hemolytic anemia sometimes occur accompanied by jaundice and urobi

linuria When there is widespread involvement of the bone marrow the anemia may be extreme

As the disease progresses there is continuous loss of weight with cachexia

If untreated few patients survive more than two or three years Exitus is usually due to cachexia mechanical interference with respiration or secondary infections

There are several variations from the usual clinical course of Hodgkin s disease (1) In the *acute form* death occurs within a few weeks or at most months In this form the enlargement of the lymph nodes is often remarkably widespread but not very great (2) In the *localized form* the cervical nodes are most often affected The solitary masses grow slowly for two or three years, and the disease assumes a chronic course Sooner or later, however there is an extension of the process to neighboring groups and the disease becomes more generalized (3) In the *generalized form* the disease is widespread sometimes involving practically all groups of lymph nodes and many internal organs In rare instances there is almost uniform dissemination of small lesions resembling the distribution of miliary tubercles (4) The *mediastinal type* represents one variety of the localized form in which the mediastinal nodes are especially involved The patient presents a tragic picture with all the symptoms and signs of mediastinal tumor cough dyspnea dysphagia orthopnea pain and other evidences of pressure supervene It is in this form that pulmonary lesions are most frequent The lesions usually extend from the root of the lung towards the periphery affecting one or several lobes The pleural surfaces may become involved and effusions appear When there is no enlargement of the superficial lymph nodes *it is almost impossible to make the diagnosis* The radiograph is usually of value in determining the extent of the process Hypertrophic pulmonary osteo arthropathy sometimes complicates the mediastinal form of Hodgkin s disease (5) the *larval* or *abdominal form* presents features of great importance In this type the disease is confined more or less exclusively to the thoracic or abdominal lymph nodes the superficial nodes escaping completely The symptoms are varied and indefinite Abdominal pain jaundice, diarrhea, or effusions into the pleural and abdominal cavities may occur The spleen and liver are often enlarged Fever is frequently present Some of the most pronounced examples of remittent fever are seen in this type The diagnosis is extremely difficult Cases have been mistaken in the early stages for appendicitis typhoid fever tuberculosis or liver abscess and in the later stages for malignant growths (6) In the rare *splenomegalic form* the disease is confined principally to the spleen Whether Hodgkin s disease can be entirely localized in this organ is dubious (7) Every large series of cases contains a few that show involvement of the *periosteum* and *bone marrow* It may be one of the first evidences of the disease When the bone marrow is replaced by a large amount of granulomatous tissue the anemia develops with astonishing rapidity In one case with involvement of the vertebrae there was compression of the spinal cord and paraplegia The cord itself and even the brain have been invaded (8) In the *gastro-intestinal form* large solitary or multiple tumors appear in the wall of the stomach or intestines They may occur in the absence of enlargement of the superficial lymph nodes and may result in fatal hematemesis in intestinal obstruction or in perforation

Diagnosis —The enlarged lymph nodes of Hodgkin's disease are confused most frequently with tuberculosis lymphosarcoma and follicular lymphoblastoma less often with lymphocytic leukemia Boeck s sarcoid syphilis inflammatory enlargements infectious mononucleosis and secondary carcinoma of the lymph nodes

Tuberculosis of the cervical lymph nodes is difficult to differentiate from Hodgkin s disease In tuberculosis it should be remembered that the glands are frequently tender firm and adhere one to the other and that they are likely to lie deeper in the neck than the tumors in Hodgkin s disease If the tuberculous glands have softened or are adherent to the skin or if an acute sinus has formed the diagnosis is simplified The presence of tuberculosis elsewhere in the body is an aid in arriving at a correct conclusion The tuberculin reaction is sometimes of assistance An x ray *plate often* reveals areas of calcification in tuberculous

nodes these do not occur in Hodgkin's disease

The most conclusive method of differentiating tuberculosis as well as other diseases of the lymph nodes from Hodgkin s disease is furnished by the histologic examination of an excised node It must be kept in mind however that tuberculosis may occasionally coexist with Hodgkin s disease This may lead to confusion Examination of material obtained by puncture of a lymph node is much less satisfactory and can rarely be depended upon for accurate diagnosis A positive Gordon test gives confirmatory evidence for it is obtained in about 70 per cent of cases of Hodgkin s disease

Lymphosarcoma and *follicular lymphoblastoma* simulate Hodgkin s disease even more closely than does tuberculosis Lymphosarcoma is perhaps more commonly a cause of mediastinal tumor It is less often accompanied by fever When lymphosarcoma and follicular lymphadenoma affect the cervical and submental lymph nodes the tonsils are frequently involved and greatly enlarged a condition that very rarely occurs in Hodgkin s disease In the commoner forms of lymphosarcoma the spleen is rarely if ever enlarged but in follicular lymphoblastoma involvement of the spleen is frequent and the organ may reach a great size The exact diagnosis must almost always be made from the histologic examination of an excised node

Lymphocytic leukemia should not be confounded with Hodgkin s disease the blood picture of the former disease will immediately determine the diagnosis Confusion can only arise when one is dealing with those rare cases of leukemia in which for temporary periods the leukocytes approach the normal in number and proportion The histologic changes in the lymph nodes are distinctive *Boeck s sarcoid* may occur without an eruption and without changes in the bones and under these circumstances when the lymphadenopathy is marked differentiation from Hodgkin s disease is almost impossible without the histologic examination of a lymph node *Infectious mononucleosis* can be distinguished by its acute course by the blood picture and the appearance of heterophile antibodies

There is rarely any difficulty in distinguishing the *gummatous lymph nodes* of syphilis from Hodgkin s disease The Wassermann reaction is of assistance in the diagnosis The enlarged cervical and submaxillary lymph nodes which are the seat of *metastasis from carcinoma* arising in the nasopharynx are extremely difficult to differentiate from Hodgkin s disease especially when metastatic cells are not seen When the spleen is prominently involved, there may be confusion with *Gaucher s disease*

Cases in which there is little or no enlargement of the superficial lymph nodes present the most difficult problem in diagnosis The thoracic group may be mistaken for many forms of mediastinal tumor The abdominal group has been confused with tuberculosis typhoid and where there is relapsing fever with Brucellosis The condition sometimes simulates abscess of the liver other obscure abdominal infections or carcinoma of the gastro-intestinal tract When however, there is relapsing fever enlargement of the spleen or liver progressive loss of weight and anemia with leukopenia or leukocytosis Hodgkin s disease should be considered

Prognosis —The disease tends to run a fairly steady and unfavorable course with only temporary remissions Untreated cases in collected series seldom survive longer than three years Of forty nine patients personally observed thirty four died within two years of onset It is impossible to say how efficacious treatment is but two of our patients under treatment lived for seven years one was living after fifteen years The disease progresses slowly and steadily even though the size of the nodes is controlled somewhat by the use of radium or x ray The loss of weight cachexia and anemia even in the patients treated by x ray or radium become more severe and toward the last fever is frequently present and constant Patients may die with negligible enlargement of lymph nodes Amyloid disease though rare does occur as a complication The immediate prognosis is most serious in those patients who have involvement of the mediastinal and abdominal nodes

Treatment —Surgery used to be more popular than it is at present Even though not curative it is permissible to remove large masses of the cervical nodes when the patient so wishes Any foci of infection

about teeth or tonsils should certainly be removed If surgery is employed it should without exception, be followed by radio therapy

Radium and *x-ray* are at present the most valuable therapeutic measures Although it is doubtful whether actual cures have been obtained by these procedures the course of the disease has been completely changed through their use Irradiation is most effective when the enlarged glands are localized particularly in the neck A few patients in this group are reported to have lived for fifteen to twenty years Repeated treatment by x ray or radium reduces the size of the tumor masses and thereby controls or eliminates much discomfort as well as the pain and agony that comes from pressure upon nerves, the trachea and bronchi X ray and radium are least effective in the abdominal form of the disease Bacterial vaccines preparations made from Hodgkin s disease glands and antiserum must for the present be considered experimental Arsenic has been employed for many years—it sometimes relieves the distressing pruritus and may be employed in intervals between x ray or radium treatments Preparations of iron or liver extracts have little beneficial effect upon the anemia, transfusions often give temporary help, they are sometimes followed by a remission if the fever is high

DISEASES OF THE CARDIOVASCULAR SYSTEM

INTRODUCTION

In the light of modern physiologic concepts the heart and the entire vascular bed must be considered as a unit comprising together the circulatory system for the blood A classification of the diseases of this system which aims to be comprehensive and at the same time of practical use cannot follow rigidly the lines of structural changes or of functional derangements Nor can it adhere strictly to etiologic types for varying causative factors may produce lesions and physiologic disturbances exhibiting similar clinical patterns A ready instance is aortic regurgitation associated with congestive heart failure this combination may be the result of rheumatic fever syphilis arteriosclerosis or bacterial infection Perhaps at first glance the arrangement here followed may appear to be neither logical nor consistent But it is designed to furnish information about all of the more important diseases of the heart and blood vessels and to accomplish this purpose with a minimum of overlapping in discussion The grouping has been made according to a simple plan

In the first group are the *diseases which affect the cardiovascular system as a whole* Under this caption there has been included a discussion of the pathologic physiology of generalized circulatory failure and of cardiac pain in which particular consideration is given to the basic disturbances in function responsible for various symptoms and signs In the next group are the *diseases of the heart* divided in part according to structure and in part according to etiology The clinical features of chronic valvular heart disease are common to all types regardless of cause and are described therefore under one heading The *functional disorders of the heart* may properly be regarded as a separate group because they are not dependent for their cause upon any specific etiologic agent nor upon particular anatomic lesions Indeed some of them are occasionally observed in the absence of demonstrable cardiac pathology *Diseases of the arteries* include the manifestations of arteriosclerosis and of syphilitic aortitis and aneurysm Concerning affections of the peripheral vessels much has been learned in recent years by the use of special methods for their study Peripheral circulatory failure is taken up in a section on circulatory collapse and shock

It is hoped that this manner of presenting such a relatively large mass of material will prove helpful in promoting orderliness and clarity of thought For clear thinking leads to understanding and so to effective therapeutic procedure

ROBERT L LEVY

CLASSIFICATION OF DISEASES OF THE HEART

The difficulties in nomenclature particularly when correlating etiologic anatomic and physiologic cardiac diagnoses have made it necessary to have a standard form of classification in order that some degree of precision in nomenclature could be attained The New York Heart Association has taken the initiative and now for several years has published such a classification in the Criteria for Classification and Diagnosis of Heart Disease According to their system a complete diagnosis of heart disease must consist of three parts etiologic anatomic and physiologic

When a diagnosis of heart disease is uncertain a diagnosis of possible heart disease is made When a history is given of some condition for instance rheumatic fever hypertension or other which frequently causes heart disease and no anatomic evidence of heart disease is noted a diagnosis of potential heart disease is made

ETIOLOGIC TYPES OF HEART DISEASES

Rheumatic Heart Disease—Rheumatic fever is responsible for progressive and usually permanent structural changes in the

heart, producing a clinical picture called 'rheumatic heart disease" Reference should be made to the article on rheumatic fever (p 435) for a discussion of the incidence morbid anatomy, and symptomatology of the *active phase* of this disease In the appropriate *sections on myocarditis, chronic* cardiac valvular disease and pericarditis *structural changes* and resultant symptomatology are described Rheumatic heart *disease is essentially* a disease of the young The initial infection is most likely to occur between the ages of nine and eleven though *about 30 per cent of cases begin in the post* adolescent period It would seem that although accurate data are at present lacking the duration of life should depend to a large extent on the continued presence of active infection and the amount of damage produced On the other hand analyses of case records have shown that the number of attacks of carditis or the number of valves involved bear no relationship to the life expectancy The *average* time interval from the initial infection to the appearance of symptoms of cardiac insufficiency is about ten years and the average duration of life is about fifteen years Occasional patients however are known to have had rheumatic heart disease for as long a period as fifty years

Congenital Heart Disease—Even in childhood congenital heart disease represents only a small proportion of the heart diseases The course and prognosis depend entirely on the structural defect When little or no interference is produced with hemodynamics the condition is not incompatible with a normal life span It must be remembered however, that slight congenital defects may form the site for a superimposed subacute bacterial endocarditis See *congenital* heart disease (p 1057) and subacute bacterial endocarditis (p 1073)

Syphilitic Heart Disease—*With the exception* of a gumma of the heart which is rare syphilitic heart disease is secondary to involvement of the aorta or aortic valve and the ostia of the *coronary arteries* Reference should be made to the article on syphilis under infectious diseases (p 334) and to the article on syphilitic aortitis (p 1166) and aneurysm in the section on diseases of the arteries

Hypertensive Heart Disease—Hypertension produces secondary changes in a number of organs including *the heart* The effects of hypertension on the heart are discussed in the article on essential hypertension (p 1030) When patients begin to have *symptoms of heart failure* in this disease the prognosis is grave Fatal termination may be due to the heart itself in about two thirds of the cases This disease is frequently associated with arteriosclerotic heart disease

Arteriosclerotic Heart Disease—When *arteriosclerosis involves the coronary* arteries sufficiently to produce symptoms the condition is generally called 'arteriosclerotic heart disease (See Arteriosclerosis p 1160) Unless the course of the disease is shortened by coronary artery thrombosis or some other complication the patient may live for many years while he suffers a gradual diminution in cardiac reserve and eventually dies in congestive heart failure This disease is frequently characterized clinically by the presence of the anginal syndrome (see p 1155)

Bacterial Heart Disease—Many different organisms may produce damage to the heart *Staphylococcus Pneumococcus Gonococcus* and *Streptococcus haemolyticus* usually produce cardiac damage subsequent to a bacterial invasion of the blood stream and therefore the endocardium is chiefly affected The tubercle bacillus on the other hand produces a pericarditis (see p 1039) The *Streptococcus viridans* gives rise to a typical clinical picture which is usually designated as subacute bacterial endocarditis (see p 1073)

ARTHUR C DEGRAFF

THE PATHOLOGIC PHYSIOLOGY OF GENERALIZED CIRCULATORY FAILURE AND OF CARDIAC PAIN

An adequate blood supply is *essential for* the proper function of every organ and tissue of the body When the circulation as a whole fails as it does in heart disease or shock none of the organs of the body *functions* normally The fact that the disturbance in circulation affects every organ and *tissue is* easily *overlooked because* in many tissues a *partial loss of function* does not produce

striking clinical symptoms Interference with the function of the muscles produces a much less dramatic effect than does the same degree of disturbance in the function of the brain

Failure of the circulation as a whole occurs whenever the heart is unable to pump out sufficient blood to meet the metabolic requirements of the body This may result simply from the inability of the heart to pump out the blood which is returned to it by the great veins (heart failure) or it may result from an inadequate venous return to the heart (peripheral circulatory failure)

In the first instance—*heart failure*—symptoms and signs are produced by the following two mechanisms (1) diminished blood flow to the various tissues of the body (forward heart failure) (2) accumulation of an excess amount of blood in the various organs because the venous drainage becomes inadequate when the heart is unable to pump out the blood returned to it (backward heart failure) Although backward and forward failure must of necessity occur together since the circulation is a closed system the distinction is useful because certain symptoms result primarily from congestion while others are produced by poor tissue nutrition The observation that the basal cardiac output is normal in many of these patients does not invalidate the fact that the reduction in the cardiac output is the chief factor in the production of the symptoms of both backward and forward failure The basal cardiac output *per se* is of little significance Evidence of heart failure will be present as long as the heart is not able to respond with a normal increase in cardiac output to the demands of the patient s daily routine of living It is not possible to conclude moreover that a given disturbance in the function of an organ is not due to poor nutrition simply because the resting blood flow to the organ is normal The widespread disturbance in intermediary metabolism produced by the inability of the cardiac output to increase normally in response to the metabolic needs of the patient may cause symptoms in the presence of a normal basal blood flow

In the second type of generalized failure of the circulation—*peripheral circulatory failure*—symptoms are produced primarily by the inadequate blood supply to the tissues Though heart failure and peripheral circulatory failure have many symptoms in common they will be discussed separately

Symptoms of Heart Failure —*Dyspnea* —The patient s term for dyspnea is breathlessness or shortness of breath Dyspnea is said to be present when the patient becomes conscious of his breathing It is to be differentiated from rapid breathing (tachypnea) in which the patient may have no feeling of respiratory distress and from the deep breathing of acidosis (hyperpnea) Because dyspnea is a subjective complaint it cannot be correlated closely with objective signs of circulatory failure An anxious apprehensive and introspective patient will complain of shortness of breath when there are few objective signs of circulatory failure On the other hand a phlegmatic individual may have advanced congestive failure before he becomes conscious of shortness of breath Hence by study of the circulation one cannot determine the extent to which a given person will experience dyspnea

Normal persons have dyspnea on *unusual exertion* In a given normal subject breathlessness will appear whenever the tidal air exceeds a given portion of the vital capacity At this point the accessory muscles of respiration are brought into action and the subject becomes aware that breathing is an effort Thus dyspnea in normal persons is primarily dependent on a large increase in pulmonary ventilation In patients with diminished vital capacity less exertion will produce breathlessness because an increase in pulmonary ventilation more quickly causes the tidal air to approach the vital capacity Failure of the heart produces a decreased vital capacity by causing the lungs to become engorged inelastic and edematous As the vital capacity becomes progressively diminished smaller and smaller increases in pulmonary ventilation will cause dyspnea

The *severity* of dyspnea will depend not only on the extent of the pulmonary engorgement and the resulting encroachment on the vital capacity but also on the volume of air respired per minute A patient with a moderate degree of pulmonary engorgement may have no dyspnea at rest but when the volume of air required is increased by ex

ercise, dyspnea *may occur* *Thus the factors* which control the rate and depth of respiration play an important part in the pathogenesis of dyspnea In cardiac patients who complain of dyspnea at rest, the vital capacity is usually reduced and the ventilation is increased It was believed heretofore that this increase in ventilation rate was the result of stimulation of the respiratory center *by anoxemia or by an increase in the hydro*gen ion concentration in the region of the respiratory center because of slow cerebral blood flow

Studies of the *oxygen content the carbon* dioxide content, and the hydrogen ion concentration of the arterial blood and the blood from the internal jugular vein showed however that in cases with moderate dyspnea there was no arterial anoxemia and no measurable decrease in cerebral blood flow These observations stimulated the study of the reflex control of respiration and it was conclusively demonstrated that most of the *changes in ventilation which occurred in* normal subjects during the day were of reflex rather than chemical origin Reflexes originating from moving muscles from emotional stimuli from the lungs the great vessels and the auricles have all been shown to influence the respiratory rate In cardiac failure the increased ventilation with the resulting tendency towards alkalosis is produced by the reflex stimulation of respira*tion from the congested lungs and great* vessels

Pathogenesis of Pulmonary Congestion and Edema—There are two main factors in the pathogenesis of pulmonary congestion and edema in heart failure (a) increase in pulmonary venous pressure and (b) failure of the kidneys to excrete salt and water normally The increase in the amount of blood in the lungs with its at*tendant rise* in venous pressure occurs whenever the right ventricle pumps more blood into the pulmonary vessels than the left ventricle is able to remove (left heart failure) Such difficulty in transferring blood from the lungs may result either from interference with the filling of the left ventricle as in mitral *stenosis or from* the inability of the left ventricle to empty itself adequately with each contraction as in the heart failure produced by hypertension coronary artery disease, aortic insufficiency, and aortic stenosis It is important to remember that excess blood may accumulate in the lungs even *when the output of the left ven*tricle is normal or increased With fever exercise anemia beriberi and thyrotoxicosis signs of pulmonary engorgement may appear when the output of the left ventricle is still above the normal basal level The explanation is that in such cases the output of the left ventricle though 'normal is lagging behind that of the right ventricle

In massive infarcts of the left ventricle in a patient without previous evidence of congestive failure the increase in pulmonary venous pressure appears to be the only factor operative in producing the pulmonary engorgement and edema The loss of fluid into the lungs causes a moderate degree of hemoconcentration The right ventricle pumps blood into the pulmonary vessels which the infarcted left ventricle is unable to remove

When heart failure develops more slowly as usually happens and when the left ventricle is more nearly capable of keeping up with the right ventricle a second and important factor becomes operative in the development of the pulmonary congestion—namely the tendency for a person with a failing heart to retain salt and water *The* excess normal saline leaves the blood stream and is deposited in the tissues in areas where *the tissue pressure is low or where the* venous and capillary pressures are increased This problem will be discussed in more detail in the section on *edema* In these cases even a slight increase in pulmonary venous pressure because of heart failure is sufficient to cause a considerable portion of the retained water to *accumulate in the* lungs

Dyspnea on *exertion* is the presenting symptom in most cases of congestive failure The patient discovers that he becomes short of breath after an effort which formerly caused no discomfort The first objective sign of this failure is usually a decrease in vital capacity *followed by an increase* in the pulmonary circulation time Moist rales at the bases are frequently present It cannot be emphasized too strongly that in the absence of the anxiety syndrome dyspnea in heart disease always means pulmonary congestion and edema regardless of the physical

findings in the lungs In certain patients the edema is primarily pericapillary and not intra alveolar In these cases intense dyspnea and pulmonary edema may be present even though auscultation of the lungs reveals no rales

Summary—Dyspnea in heart disease is produced by the changes in the lungs which result from interference with the venous drainage of the lungs and from the tendency of the cardiac patient to retain excess salt and water Reflex stimulation from the congested lungs plays an important role in the mechanism of dyspnea The pulmonary changes producing the dyspnea are the result of a combination of backward heart failure (increased venous pressure in the pulmonary veins because of mitral stenosis or failure of the left ventricle) and of failure of the kidneys to excrete salt and water normally The backward failure in the lungs causes a large amount of the saline retained by the kidneys to be deposited in the lungs It is obvious that anything which further decreases the vital capacity or which by reflex action increases the ventilation rate will increase the dyspnea Hydrothorax pulmonary infarcts and pneumonia all increase the dyspnea of cardiac failure through both of the above mechanisms Fright anxiety and pain precipitate attacks of dyspnea in cardiac patients with a lowered vital capacity primarily by a reflex increase in the ventilation

Orthopnea—Orthopnea is a more advanced stage of dyspnea in which the patient refuses to lie flat in bed because when he assumes the horizontal position his difficulty in breathing increases In heart disease dyspnea at rest is a relative state With the trunk raised above a given angle the patient may have no dyspnea When the trunk is below that angle dyspnea will occur Orthopnea like dyspnea is a subjective sensation and so as in dyspnea there is no close correlation between the degree of orthopnea and the objective signs of circulatory failure The reflex sensitivity of the central nervous system of the individual patient determines at what level of pulmonary congestion and edema orthopnea first appears In advanced heart failure with disturbance in consciousness the patient may have less orthopnea despite increasing pulmonary edema Because orthopnea is a subjective sensation an unconscious patient cannot be orthopneic

It was believed formerly that the assumption of the upright position decreased the dyspnea because it relieved the venous congestion supposed to be present in the brain Clinical investigation showed that this hypothesis was untenable because in many patients with orthopnea the venous pressure is normal and because marked elevation of the venous pressure in the brain in cases of superior mediastinal obstruction does not cause orthopnea There is no constant change in arterial oxygen saturation when the orthopneic patient is lowered to a position where he complains of dyspnea Estimation of the cerebral blood flow by determination of the oxygen content of arterial blood and of blood from the internal jugular vein reveals no constant change in cerebral blood flow with change in position Thus there is no evidence that the circulation to the medullary centers is improved when the patient is upright

Orthopnea depends primarily on the active stimulation of the pulmonary reflexes resulting from congestion of the lungs As the trunk is lowered the venous pressure in the lower part of the body is decreased This causes a redistribution of blood with a momentary rise in the output of the right ventricle and an increase in pulmonary engorgement With it comes a tendency towards reduction of vital capacity (In addition the vital capacity may be slightly decreased in the recumbent position because of the upward movement of an enlarged liver) This sequence of events produces a reflex rise in pulmonary ventilation and the patient becomes dyspneic Even in normal subjects the vital capacity is somewhat greater in the upright position than in the recumbent position Hamilton and Morgan observed that the vital capacity of normal subjects in the recumbent position was increased when blood was pooled by the application of tourniquets to the four extremities After the limbs were congested by tourniquets change in posture caused little change in vital capacity These data suggest that even in normal persons the blood volume in the lungs is appreciably increased when the subject lies down

While factors other than those enumerated eventually may be shown to be important in producing a slight lowering of the vital capacity, clinical observations leave little doubt that reflex stimulation from the engorged and edematous lungs is the chief factor in the orthopnea of cardiac failure It is a common observation that the administration of morphine will allow a cardiac patient to rest comfortably in a position he had previously been unable to endure because of dyspnea Reducing the sensitivity of the central nervous system in these patients relieves the dyspnea without producing any measurable change in the circulation

Paroxysmal Dyspnea and Cardiac Asthma.—Attacks of shortness of breath which come on suddenly—often while the patient is asleep—occur frequently in patients with cardiac failure from hypertension coronary artery disease aortic insufficiency and aortic stenosis, all diseases which cause strain or injury to the left ventricle Although these attacks of dyspnea frequently occur in patients who are already incapacitated by chronic congestive failure they may occur at night in patients who during the day seem to have a fairly good cardiac reserve and who are able to carry on their daily work The stroke and minute output of the left ventricle, the velocity of the venous blood flow, and the oxygen difference between the arterial and venous blood obtained from the femoral vessels are all essentially normal In many cases the liver is not palpable and there is no pitting edema In some patients, however the cardiac output is diminished Even though the peripheral circulation appears normal at rest the lungs show signs of congestion The mean velocity of pulmonary blood flow is usually decreased On x ray examination the hilar shadows are enlarged with a fan like radiation towards the periphery Moist rales are usually though not always, present The vital capacity is diminished and the volume of the residual air is increased

During the attack the patient sits up or stands up The skin becomes ashen the small veins are collapsed and there is profuse sweating The respiratory mid position of the thorax becomes elevated and there is a tendency for the chest to become fixed in the forced inspiratory position Both inspiratory and expiratory distress are usually present Asthmatic wheezes and moist rales are frequently audible In some cases only moist rales are heard In certain patients in spite of intense dyspnea there are no rales Tachycardia is invariably present Embryocardia and gallop rhythm are common The pulmonary second sound is accentuated The peripheral circulation shows variable changes The volume output of the heart either remains the same or decreases The arterial pressure is usually elevated, the venous pressure either does not change or shows a moderate increase The oxygen saturation of the arterial blood may show little or no decrease If the bronchial constriction is marked or if severe pulmonary edema develops the oxygen saturation may be markedly decreased The volume of blood flowing through the lungs either shows no change or decreases the mean velocity is decreased Diminished velocity in the presence of a relatively normal volume of blood flowing through the lungs indicates that the cross section area of the pulmonary vascular bed is increased and that the lungs contain more blood during the attack

The above data indicate that the paroxysm of dyspnea is caused by the sudden trapping of a few hundred cubic centimeters of blood in lungs which are already moderately congested Because normal function has been impaired by disease the left ventricle is unable to increase its output sharply enough to clear the lungs This engorgement then is produced by a temporary imbalance between the outputs of the right and left ventricles wherein the output of the right ventricle exceeds that of the left In a short time the balance between the two ventricular outputs is restored but the left ventricle is unable to do more than keep up with the right ventricle It does not have enough reserve strength to remove the excess blood from the lungs This excess blood reduces the efficiency of the lungs by decreasing the vital capacity and by decreasing the pulmonary elasticity These changes in the lungs cause a reflex increase in pulmonary ventilation

If the bronchi respond to the pulmonary congestion by spasm or if the lumina of the bronchi are narrowed by edema of the bron

chial mucosa asthmatic wheezes and groans will be present Bronchial wheezes are more apt to develop if the patient has a history of repeated attacks of bronchitis or if he has chronic lung disease such as emphysema or bronchiectasis In some patients the edema that develops is pericapillary rather than intra alveolar in which case there are no rales In any case the fundamental mechanism of the attack—namely, sudden pulmonary engorgement with a left ventricle incapable of removing the blood—is the same

Paroxysmal attacks of dyspnea usually occur at night In patients who have orthopnea the attack is frequently brought on by sliding into the horizontal position while asleep In patients who are ambulatory the assumption of the horizontal position at rest tends to bring a redistribution of the blood and fluid in the body When the patient lies down blood is shifted from the abdomen and the upper and lower extremities to the lungs and to the great veins of the thorax This redistribution of blood is one of the factors which cause the vital capacity of normal subjects to be less in the horizontal than in the upright position Although there may be no pitting edema in many of these patients who have paroxysmal nocturnal dyspnea the quantity of extracellular fluid is increased During the day this fluid accumulates mainly in the lower part of the body because of the high venous and capillary pressures caused by the upright position When the patient lies down the venous pressure in the lower part of the body is decreased and excess fluid enters the blood stream causing an increase in blood volume If the pulmonary venous pressure is slightly elevated much of the fluid is deposited in the lungs causing edema and further reduction in vital capacity The stage is now set and any stimulus which causes the patient to increase the output of the right ventricle for a short time will precipitate the paroxysms of dyspnea Coughing noise nightmares and a distended bladder often act as the trigger mechanisms The hyperpnea phase of Cheyne Stokes breathing also frequently precipitates an attack

Periodic Breathing—(Cheyne-Stokes Respiration) —In many patients with cardiac failure the regular sequence of respiratory movements is replaced by alternating periods of underbreathing and overbreathing As the condition becomes more marked apnea and hyperpnea occur The periods of apnea may last from 15 to 60 seconds The apneic period is terminated by respirations of a gradually increasing depth until marked hyperpnea occurs The depth of the respirations then gradually decreases until the next period of apnea begins During the period of apnea the patient is frequently drowsy sleepy or stuporous As the hyperpnea begins he frequently arouses moves about restlessly and not infrequently moans or cries out He frequently complains of dyspnea and if he has fallen back on the pillow he will sit upright The hyperpnea of Cheyne Stokes breathing is often the trigger mechanism which precipitates an attack of cardiac asthma

Periodic breathing in heart failure is the result of incoordination of the nervous and chemical factors which normally control respiration The exact nature of the incoordination has not been determined This type of respiration may occur in normal sleeping babies It may also be seen in patients after cerebral accidents or trauma to the central nervous system or in patients with meningitis uremia or other forms of coma In all of these conditions the sensitivity of the respiratory center is depressed In sleep the depression is physiologic in cardiac failure it is the result of the inability of the heart to maintain the normal cardiac output and to nourish the brain properly That cerebral metabolism is disturbed in these patients is shown by their restlessness the narrowing of the field of consciousness and the difficulty in fixing attention

The lowering of the blood flow to the brain because of decreased cardiac output is not the only factor responsible for depression of the respiratory center Changes in cerebral blood flow because of local vascular disease play an important part In addition changes in the cerebral metabolism because of decreased blood supply to the liver kidneys and all other tissues are probably important The respiratory center becomes insensitive to the normal concentration of carbon dioxide and apnea results When respiration ceases the carbon dioxide concentration of the arterial blood steadily in

creases until finally the sluggish respiratory center is stimulated and hyperpnea occurs The carbon dioxide concentration continues to fluctuate and the patient suffers alternately from apnea and hyperpnea

Periodic breathing occurs in normal subjects at high altitudes Both a decrease in oxygen tension and a decrease in carbon dioxide tension of the arterial blood appear to be operative The fall in carbon dioxide tension is secondary to the stimulation of respiration resulting from the anoxemia Whether the anoxemia affects the respiratory center directly or whether it works through peripheral receptors such as the carotid sinus is not clear The administration of carbon dioxide invariably stops the periodic respiration The administration of oxygen frequently makes the periodic breathing less marked and occasionally stops it

In cardiac failure there is usually a tendency for the carbon dioxide content of the arterial blood to be lowered because of the reflex stimulation of respiration from the engorged lungs Both this tendency towards alkalosis and the depression of the respiratory center appear to be important in producing the periodic breathing The interaction between these two factors probably accounts for the effect of sleep and morphine on Cheyne Stokes breathing In cardiac failure periodic breathing frequently begins as the patient is going to sleep Presumably the physiologic depression of the respiratory center combined with the over breathing produced by the reflexes from the congested lungs initiates the periodic breathing As sleep deepens the ventilation decreases the carbon dioxide content of the blood tends to increase and the periodic breathing may cease The effect of morphine is variable In large doses it depresses the respiratory center and causes a marked prolongation of the periods of apnea and hyperpnea In smaller doses it may cause the respirations to be more regular This is probably due to the fact that smaller doses decrease the ventilation rate and reduce the tendency towards alkalosis but are not powerful enough to cause any marked depression of the respiratory center

When periodic breathing is marked the oxygen content of the arterial blood will be decreased during the apneic phase and the carbon dioxide content of the arterial blood will be increased These changes in the blood gases and corresponding changes in hydrogen ion concentration are the result rather than the cause of the periodic breathing Once the periods of apnea and hyperpnea have begun, the changes in hydrogen ion concentration are probably important in explaining the variations in depth of respirations during the hyperpneic period

Periodic breathing in cardiac failure usually results from a combination of forward and backward failure of the left ventricle The reflex overbreathing and pulmonary congestion (backward and forward failure) and the depression of the respiratory center (forward failure) are all factors of importance

Edema—Failure of the heart characteristically results in the retention of water and salt The patient may retain from ten to twenty pounds of water before there is any objective sign of the increased extracellular fluid (sub clinical edema) As the process continues the patient notices that his shoes are tight and that his ankles are swollen in the evening On arising in the morning the swelling has disappeared In the more advanced stages pitting edema is present continually and eventually the scrotum and abdominal wall become waterlogged If the patient is confined to his bed edema of the back and sacral regions may be more extensive than that of the lower extremities Hydrothorax occurs usually first on the right and later bilaterally Ascites may develop

Edema of the lower extremities produces a feeling of heaviness but does not cause actual pain The skin may become so tightly swollen that the body cannot nourish it Therefore low grade cellulitis is not uncommon At times the pressure of the extracellular fluid becomes so great that the skin ruptures and fluid drains freely from the part Hydrothorax produces dyspnea by lowering the vital capacity Less frequently ascites is a factor in the production of dyspnea It is possible that a portion of the anorexia and nausea occurring in congestive failure may be produced by the excess fluid in the tissues of the abdominal viscera The generalized retention of water has already

been discussed as an important factor in the production of dyspnea

The *mechanism* of cardiac edema has never been satisfactorily explained For merly the edema was thought to be a mani festation of backward heart failure (failure of the right ventricle) It is well known that elevation of the venous pressure pro duces edema and it was assumed that the edema in cardiac failure was secondary to the rise in venous pressure Recent studies have demonstrated that in patients with chronic congestive failure edema is present before there is a measurable rise in the rest ing venous pressure The possibility that the venous pressure may be abnormal dur ing activity and thus account for the fail ure of the kidney to excrete salt and water normally has not been excluded

The available data suggest that the re tention of the sodium ion by the kidney is the fundamental cause of cardiac edema The retention of water is secondary to the retention of the sodium ion It is not clear whether this disturbance in renal function results from chronic passive congestion or from a disturbance in renal blood flow be cause of the inability of the heart to main tain an adequate circulation while the pa tient is active As the salt and water reten tion becomes more marked the plasma vol ume gradually increases the quantity of circulating protein rises and finally there is an increase in the resting systemic ven ous pressure The retained salt and water are distributed throughout the body in areas where the capillary pressure is high or where the tissue pressure is low During the day when the patient is upright the high ven ous and capillary pressures produced by gravity cause most of the excess fluid to accumulate in the portion of the body be low the level of the heart When the pa tient lies down the venous and capillary pressures become more nearly equal through out the body *This results* in a redistribu tion of the excess fluid over the body in general If the pulmonary venous pressure is increased due to left ventricular failure much of the excess fluid is deposited in the lungs The remainder is lodged in areas where the tissue pressure is low

In the above discussion a distinction is made between the generalized rise in ven ous pressure which occurs in cardiac failure and the local rise in venous pressure which is produced by placing a part below the level of the heart The rise in pressure throughout the venous system is produced by the large blood volume which distends the venous bed At least in some patients the elevated venous pressure is the *result* rather than the cause of the edema The local increases in venous and capillary pres- sures produced by postural effects are of primary importance in determining the dis tribution of the excess saline retained by the kidney

The low protein content of cardiac edema fluid shows that neither increased capillary permeability nor lymphatic blockage plays a significant part in the mechanism of car- diac edema Even in patients with marked lack of arterial oxygen saturation capillary permeability seems to be normal Lowering of the serum protein concentration always predisposes to the formation of edema This is a secondary factor in certain patients with congestive failure

Cough—Cough and expectoration are fre- quent complaints in patients with cardiac failure The cough is produced by a reflex from the congested lungs and bronchi Less commonly cough results from pressure of an aneurysm on the trachea bronchi or recurrent laryngeal nerve Rarely marked enlargement of the left auricle may pro duce cough by pressure on the bronchi The cough produced by congestive failure may be severe enough to interfere with sleep and it is frequently the trigger mechanism which precipitates an acute attack of nocturnal dyspnea

Hemoptysis—Bleeding from the lung or bronchial mucosa occurs frequently in heart failure In mitral stenosis bleeding from the dilated pulmonary vessels is common and may occasionally be fatal Bleeding from congested vessels in the bronchial mucosa is *seen in severe heart failure* from any cause Bloody sputum is a frequent symptom of pulmonary infarction In severe pulmonary edema caused by left ventricular failure bloody froth may pour from the bronchial tree

Weight Loss—Patients with chronic con gestive failure suffer from a gradual loss of tissue which is frequently unnoticed because

of the accumulation of edema If failure persists for a long period of time, the cachexia may become as marked as that produced by advanced malignancy The loss of weight is a manifestation primarily of forward heart failure The heart does not pump enough blood to nourish the tissues properly The observations of Gross on the nutritional state of children before and after ligation of a patent ductus are particularly significant These studies show that physical development was retarded by poor peripheral blood flow even in the absence of the usual signs of congestive failure When the peripheral blood flow was increased by obliteration of the patent ductus arteriosus, growth was accelerated

Anorexia Nausea, and Vomiting—Gastro intestinal symptoms are common in congestive failure and they may originate in a number of ways The reversible medullary reflex interrelationship existing between the heart and stomach makes it possible for either stomach or heart to be the precipitating agent Irritation of the gastric mucosa may produce reflex heart block or auricular standstill Reflexes arising in the heart from myocardial infarction or from digitalis fixed in the heart may cause contractions of the stomach with reverse peristalsis nausea and vomiting Congestion of the abdominal viscera themselves may cause nausea and vomiting Central stimulation of the reflex pathways producing vomiting may occur when the metabolism of the brain is disturbed Hiccough is present at times in patients with myocardial infarction and is usually a symptom of serious prognostic significance

Abdominal Pain—Pain in the right upper quadrant is a common symptom of congestive failure The pain may be present at rest or it may occur only on exertion In certain patients the right upper quadrant pain and tenderness occur while the venous pressure is still normal and there is no pitting edema Palpation usually reveals an enlarged tender liver Acute enlargement of the liver generally causes severe pain because of stretching of the capsule Once the capsule has been stretched there may be marked enlargement of the liver with little discomfort Engorgement of the liver as the result of increased blood volume and of increased venous pressure is undoubtedly important in causing such pain and enlargement of the liver The lack of close correlation between the height of the venous pressure and the degree of liver enlargement indicates that in addition to this engorgement one or more factors not yet understood are also operative

Cerebral Symptoms—Symptoms of cerebral dysfunction are very common in heart disease although they do not usually appear until the patient has reached the stage when dyspnea is present at rest Pulmonary congestion from poor venous drainage of the lungs and from retention of salt and water usually is present before the cardiac output decreases to a degree sufficient to produce a significant change in the metabolism of the brain As the heart continues to fail however the cardiac output even at rest becomes inadequate to nourish the brain properly and irritability restlessness and difficulty in fixing attention develop The eventual sequence is that of stupor coma and death These symptoms of inadequate cerebral metabolism are often part of the clinical picture of congestive failure during the last few days or weeks of life A change in personality a mild delirium or mental depression is frequently the presenting symptom in the circulatory failure produced by myocardial infarction It is probable that the changes in cerebral metabolism caused by heart failure have a mechanism more complicated than simple reduction of the blood supply to the brain It seems evident that there must be widespread disorders of intermediary metabolism produced by the decreased blood supply to the liver endocrine glands gastro intestinal tract and all other organs of the body Such lack of proper function of other organs may well have a secondary effect on cerebral metabolism The cerebral symptoms are accentuated if the oxygen saturation of the arterial blood is decreased because of severe pulmonary changes either secondary to or independent of the congestive failure

Palpitation—Persons—both sick and well—complain frequently of the fact that they are conscious of the beating of their hearts On the one hand this may be due simply to increased awareness of normal physiologic variations in cardiac output

(anxiety state) On the other hand it may be the result either of changes in stroke volume or rate of the heart or of cardiac enlargement Anything which increases the stroke output of the heart will cause the patient to complain of palpitation unless his attention is centered elsewhere For example the beat after an extrasystole is noticed because a longer period of diastolic filling causes the stroke volume of this beat to increase Exercise excitement thyrotoxicosis and anemia cause palpitation by increase in stroke volume and minute output of the heart Increases in heart rate without a rise in the minute volume output of the heart are less apt to cause palpitation Any change from the usual rhythm may cause awareness of the heart beat When the heart is enlarged palpitation is more likely to be experienced because the heart lies closer to the chest wall Both normal subjects and patients with heart disease commonly complain of palpitation when lying quietly on the left side This position causes the apex impulse to shift nearer the chest wall

Anxiety State in Persons with Heart Disease—The layman knows that proper cardiac function is necessary to sustain life and that heart disease is a common cause of death The diagnosis of heart disease offers such a threat to the security of the individual that it is safe for the physician to assume that anxiety is present whenever the patient knows or suspects that he has heart disease The degree and manner in which this anxiety is expressed will depend on the personality structure of the individual person Failure of the physician to differentiate between the symptoms of anxiety and those of heart failure frequently causes invalidism for years before the circulation actually becomes inadequate

Persons who have real or imaginary heart disease without any circulatory failure are apt to interpret many normal physiologic phenomena as evidence of heart failure The slight feeling of giddiness which is produced by changing suddenly from the recumbent to the upright position and the palpitation which is produced by excitement fear or exercise are frequently interpreted by the patient as signs of circulatory failure Hyperventilation is easily produced by anxiety and may lead to the mistaken diagnosis of paroxysmal dyspnea due to early congestive failure The following sequence of events is common A patient with compensated heart disease is suddenly aroused from sleep by a noise or a nightmare This produces an increase in pulmonary ventilation At the same time the patient notices palpitation because of the increase in cardiac output from the sudden awakening The palpitation is interpreted as a symptom of the circulatory failure and the resulting anxiety causes a further increase in pulmonary ventilation The rise in pulmonary ventilation without an increase in muscular activity produces alkalosis by lowering the carbon dioxide content of the arterial blood The alkalosis alters the cerebral metabolism and the patient feels giddy and uncertain The hands and feet become cold and the extremities tingle Rarely tetany develops These cerebral symptoms are interpreted as symptoms of heart failure and sudden death is feared The patient becomes conscious also of the increase in respiratory rate and this again is interpreted as heart failure

In taking the history one should always ask whether the attacks of dyspnea suspected of being caused by heart disease are accompanied by faintness giddiness sense of unreality loss of consciousness coldness of the hands and feet and tingling sensations around the mouth or down the extremities Whenever the symptoms appear more severe than is compatible with the objective signs of heart disease it is advisable to determine whether the sensations produced by voluntary hyperventilation are similar to those described by the patient as shortness of breath

Symptoms of Peripheral Circulatory Failure—The symptoms of peripheral circulatory failure are caused chiefly by the marked decrease in cardiac output which results from the ineffective filling of the heart because of a decrease in venous return Inadequate filling of the circulatory system is responsible for such a decrease in venous return and it may be due to either one of two circulatory disturbances (1) diminished blood volume (hemorrhage trauma or burns) (2) increase in size of the circulatory bed so that the normal blood volume is inadequate to fill the dilated bed (postural fainting sodium nitrite collapse) The

clinical syndrome produced by a transient failure of the venous return is called collapse or primary shock, that produced by a more prolonged failure of the venous return *is called shock or secondary shock* In peripheral circulatory failure there is pallor of the skin, coldness of the extremities cold perspiration, weak and thready pulse narrowing of the field of consciousness restlessness, low arterial pressure narrow pulse pressure and constricted veins All of these signs are secondary to the fall in cardiac output They are also seen in varying degrees in patients with heart failure In heart disease however the decrease in cardiac output is caused by cardiac weakness rather than by a decreased venous return

Syncope —Loss of consciousness from a *transient decrease in cerebral blood flow* is called syncope The decrease in cerebral blood flow may result from cardiac standstill or from a diminished venous return to the heart The *cardiac standstill* (Adams Stokes syndrome) may be caused by heart block because of disease of the bundle of His or by overactivity of certain vagal reflexes whose afferent limb may originate in any organ of the body Afferent impulses from the carotid sinus the heart itself any portion of the gastro intestinal tract the pleura the peritoneum the gallbladder the uterus the vagina, or the prostate may produce sino auricular standstill or auriculoventricular block by way of the vagus nerves

Diminished venous return to the heart may result from pooling of blood in the lower part of the body as for example in motionless standing or it may result from peripheral vasodilatation due to reflex stimulation from the carotid sinus or various other afferent areas such as the pleura peritoneum or mesentery When widespread disease of the sympathetic nervous system is present, syncope may occur in the upright position because of failure of the normal reflex vasoconstrictor response to standing (postural hypotension) Less commonly syncope occurs because of the decrease in cardiac output from marked tachycardia

Reflex hyperventilation is a frequent cause of syncope The alkalosis caused by the loss of carbon dioxide from the arterial blood either interferes with cerebral metabolism directly or produces its effect by a slowing of the cerebral blood flow The combination of emotional hyperventilation and the decreased venous return to the heart because of the upright position is responsible for many attacks of benign fainting Neurogenic stimuli which cause a reflex fall in blood pressure are also probably important in explaining the ordinary fainting attack

Certain *afferent stimuli* apparently cause unconsciousness by direct action on the central nervous system Stimulation of the *carotid sinus* in certain individuals causes unconsciousness without any slowing of the heart or fall in arterial pressure (central type of carotid sinus response) As far as can be determined by studies of the oxygen content of the blood from the carotid artery and the internal jugular vein, this type of syncope *is not accompanied by a change in* cerebral blood flow

Any severe attack of *pulmonary congestion* from heart disease may be accompanied by unconsciousness Syncope is seen most frequently with aortic stenosis but it has been described with pulmonary congestion resulting from coronary artery disease mitral stenosis and aortic insufficiency It appears that the suddenness and severity of the attack of failure is more important than the type of heart disease The mechanism of these attacks of syncope has not been established They may have a varied etiology Reflex cardiac standstill transient arrhythmia cerebral anoxemia from a sudden inability of the heart to maintain an adequate cardiac output hyperventilation caused by the severe pulmonary congestion may each play an important role in certain cases

Shock Syndrome in Heart Disease—A marked decrease in cardiac output causes a clinical syndrome resembling that described as peripheral circulatory failure or shock Narrowing of the field of consciousness restlessness stupor pallor cold sweat, constricted veins in the extremities low arterial pressure narrow pulse pressure weak and thready pulse are frequently seen in patients with heart disease It is important to realize that though these signs are identical with those found in shock they are the result of heart failure rather than peripheral circulatory failure The picture may develop in a normal heart which is

unable to pump blood successfully because of marked tachycardia In paroxysmal auricular tachycardia auricular flutter or rapid auricular fibrillation the cardiac output may be markedly decreased because the period of diastole has been shortened until there is not sufficient time for proper ventricular filling Interference with proper ventricular filling likewise causes the shock syndrome to develop in pericardial tamponade and to a lesser degree in constrictive pericarditis

In the last few hours or days of life most patients with congestive failure develop the symptoms and signs of a marked decrease in cardiac output These patients with chronic congestive failure usually have a large blood volume and high venous pressure so that it is obvious that the decrease in cardiac output results not from a decrease in venous return but from the inability of the heart to pump blood in the presence of an adequate venous return Patients with a massive myocardial infarct who have never had congestive failure develop the clinical syndrome of shock without distention of the neck veins They tend to show hemoconcentration rather than the increase in blood volume seen in chronic congestive failure Roentgenograms of the lungs however show marked pulmonary congestion and edema The pathologic findings in the heart help to explain the clinical picture The area of infarction usually involves the left ventricle primarily The right ventricle pumps blood into the lungs but the infarcted left ventricle is not able to pump out the blood it receives Sufficient fluid is lost into the lungs to cause some degree of hemoconcentration The lungs become intensely engorged as the output of the left ventricle decreases The decrease in output of the left ventricle causes the clinical syndrome of shock

In summary heart disease may produce the *clinical* picture that is described as characteristic of peripheral circulatory failure or of shock It is clear however that this failure is not peripheral in origin It is caused by the inability of the heart to pump blood not by an inadequate venous return The term "cardiac shock is used only to describe the clinical appearance of the patient It has no physiologic connotation

Cardiac Pain —When the metabolism of the heart muscle exceeds the available blood supply tissue metabolites accumulate and cause pain This does not occur in a normal subject because the extra metabolites produced by an increase in the work of the heart cause coronary vasodilatation with a resultant increase in coronary blood flow In the normal subject dyspnea or fatigue has limited activity before the functional reserve of the coronary circulation is exhausted An inadequate coronary circulation may develop in any one of three ways (1) narrowing or obstruction of the coronary vessels from arteriosclerosis or obstruction of the ostia of the coronary arteries by syphilitic aortitis (2) cardiac hypertrophy without a corresponding increase in the number of capillaries so that there are fewer blood vessels per unit area of tissue (3) interference with the coronary circulation because of the altered hemodynamics present in aortic insufficiency aortic stenosis and in certain cases of advanced mitral stenosis

When coronary insufficiency first begins to develop there are no symptoms at rest because the resting coronary blood flow is normal and metabolites are removed in the normal way from the heart muscle Pain occurs when the work of the heart is increased by exercise excitement eating anemia or thyrotoxicosis In patients with coronary artery disease the increase in the work of the heart causes dilatation in many portions of the coronary vessels just as it does in normal subjects This vasodilatation however is ineffective if there are fixed obstructions to the coronary tree or if there are too few blood vessels to nourish properly the hypertrophied muscle fibers or if the dynamics of the circulation are so altered that coronary vasodilatation does not cause the normal increase in coronary blood flow The coronary blood flow is then inadequate for the metabolic needs of the muscle and pain develops When the work of the heart is reduced by rest the coronary circulation is again sufficient for the metabolic needs of the heart and the pain disappears As the insufficiency of the coronary circulation becomes more marked a smaller increase in cardiac work will be capable of producing pain And finally pain may be present at rest

Epinephrine produces coronary vasodilatation in normal subjects but at the same time it increases the work of the heart In patients with coronary artery disease the administration of epinephrine causes pain because the heart reacts with an increase in cardiac output, although the sclerotic narrowed areas in the coronary vessels are not capable of the normal physiologic vasodilatation in response to epinephrine which would compensate for the increase in cardiac work This explains the apparent paradox that a drug which produces coronary vasodilatation also produces cardiac pain

Occlusion of a coronary artery does not in itself produce pain If sufficient collateral circulation has been established before the vessel is occluded so that the heart muscle is properly nourished there will be no pain Indeed several coronary branches are often occluded before the insufficiency of the coronary circulation becomes marked enough to produce pain on exertion Myocardial infarction occurs when the coronary circulation is not able to nourish the muscle at rest This produces prolonged pain which is not relieved by rest and it is accompanied by the signs of muscle necrosis namely fever leukocytosis and an increase in sedimentation rate Not infrequently in patients with angina pectoris acute insufficiency of the coronary circulation may develop without actual myocardial infarction Under these circumstances the pain is prolonged but there are no signs of muscle necrosis These attacks of acute coronary insufficiency are produced in three ways (1) occlusion of an additional branch of a coronary vessel so that the coronary circulation —though still adequate enough to keep the muscle alive—is incapable of preventing the accumulation of metabolites which produce pain (2) prolonged increase in the work of the heart such as occurs after the administration of epinephrine (3) interference with the hemodynamics of the circulation as a whole as in pulmonary infarction The pain produced by insufficiency of the coronary circulation is typically substernal rather than precordial In a classical case it radiates down the ulnar aspect of one or both arms or up to the neck This radiation is apt to be modified if there is inflammation in other parts of the body If there is an abscessed tooth radiation to the jaw is frequent If there is inflammation around the kidney pain may radiate to the costovertebral angle

Patients with acute pericarditis or acute rheumatic myocarditis frequently complain of dull precordial pain A constant dull precordial ache with tenderness on palpation beneath one or both breasts is a common symptom also in anxious persons who have no heart disease

ESSENTIAL HYPERTENSION

Definition —*Essential hypertension* is a term employed to indicate the existence of abnormally high systolic and diastolic arterial blood pressure in individuals who have neither inflammatory kidney disease urinary tract obstruction or other disorders which are known to result in elevation of the blood pressure It is clear according to this definition that the term can be used correctly in diagnosis only after known causes of hypertension have been excluded It should be emphasized that in essential hypertension we may be dealing really with a number of different disorders even though the above restrictions in the use of the term are observed However if this is the case these disorders have in common (1) *elevation* of the blood pressure and (2) the absence of either primary parenchymal renal disease or other conditions which are known to produce hypertension Until more is known concerning etiology and pathogenesis it serves a useful purpose to continue to employ the term essential hypertension

History —Hypertension was formerly regarded as always being an expression of either Bright's disease (nephritis) or arteriosclerosis In 1874 Mahomed described the "prealbuminuric stage of Bright's disease" a term indicating that hypertension may precede frank nephritis but not disassociating the two Von Basch 1894 recognized that hypertension may exist in the absence of nephritis and demonstrable arteriosclerosis and attributed it when present under these circumstances to latent arteriosclerosis" Allbutt 1896 differentiated hypertension ("hyperpiesia") from Bright's disease and senile arteriosclerosis Huchard 1899 also recognized hypertension in the absence of Bright's disease and, to emphasize its importance in the etiology of arteriosclerosis called it presclerosis" Hypertensive cardiovascular disease" was the designation used by Theodore Janeway in 1913 and it became widely accepted at the time Frank in 1911 introduced the term essential hypertension" Volhard and Fahr (1914) and Keith Wagener and Kernohan (1928) have especially directed attention to cases of essential hypertension which are characterized by kidney involvement and a rapidly progressive fatal course—"malignant nephrosclerosis or "malignant hypertension" in contrast to the commoner "benign" disorder The importance of cerebral vascular spasm in the production of symptoms was emphasized by Pal (1905) and discussed in detail by Oppenheimer and Fishberg (1928)

Etiology and Pathogenesis —The high incidence of essential hypertension is indicated by Janeway's figures on a large group of private patients The systolic blood pressure was over 165 mm in 11 per cent This was a result of essential hypertension in the vast majority of instances Hypertension was present in somewhat less than 2 per cent of more than 600 000 candidates for life insurance (Frost Knight) Fahr estimates that hypertension or its sequelae were responsible for the death of 140 000 persons in the United States in 1924 The existence of a definite hereditary tendency has apparently been established Although elevation of the blood pressure may appear at any time it rarely occurs in children and is not commonly encountered in young adults It develops usually after the fourth decade of life over 80 per cent of Janeway's cases occurring after the fortieth and before the seventieth year The incidence figures for males and females indicate no striking difference although the frequent development of hypertension at the time of the menopause is noteworthy It occurs more frequently in individuals of the sthenic body type than in the asthenic The frequent association of hypertension with obesity is an observation of considerable practical importance It is thought to occur more frequently in tense overworked city dwellers than in the more phlegmatic leisurely rural population

The cause of essential hypertension is unknown Certain observations bearing upon the underlying nature of hypertension may be summarized

Experimental —Hypertension may be produced experimentally by (1) bilateral denervation of the carotid sinus and section of the aortic depressor nerve (Koch and Miles Heymans), (2) the production of a sudden increase in intracranial pressure and acute cerebral anemia by the injection of kaolin (Dixon and Heller) (3) subtotal nephrectomy (Cash Chanutin and Ferris), and (4) irradiation of the kidneys (Hartman Bolliger and Doub) Finally the work of Goldblatt Lynch Hanzal and Summerville reveals that renal ischemia in dogs induced by the application of clamps to the renal arteries results in a condition quite similar to that called essential hypertension in man Moderate impairment of the blood flow brings about an elevation of blood pressure with little or no gross disturbance of renal structure or function (*cf* benign hypertension) Severe constriction of the vessels leads to changes similar to those encountered in malignant hypertension in man The available evidence indicates that experimental hypertension resulting from renal ischemia is brought about by peripheral vasoconstriction and that this vasoconstriction is due probably to the presence in the blood of a pressor substance This pressor substance is thought by many investigators to be derived from the interaction of renin an enzyme like substance from the kidney and an activator in blood plasma The pressor substance has been called angiotonin (Page) and hypertensin (Munoz) It is further hypothecated that an antipressor substance exists in certain extracts of kidney intestinal mucosa and muscle tissue which is capable of inactivating the pressor substance This concept forms the basis for current attempts to treat hypertension by feeding or injecting renal extracts

Clinical —Hypertension may develop in man in association with acute and chronic glomerulonephritis bilateral or unilateral pyelonephritis prostatic obstruction or other types of obstruction to the flow of

urine, polycystic disease of the kidney tumors of the kidney renal amyloid disease periarteritis nodosa of renal arteries and renal artery occlusion, partial or complete due to embolism or arteriosclerotic narrowing Other conditions in which renal involvement is absent or not so conspicuous are endocrine disorders (Cushing syndrome ovarian and thyroid disease), polycythemia increased intracranial pressure, coarctation of the aorta

The above experimental and clinical observations have profoundly affected current concepts of essential hypertension and it is not surprising that the term renal hypertension is becoming popular again Is so called essential hypertension in truth renal hypertension? The practical importance of the question in those rare cases in which hypertension is not essential but actually due to unilateral renal disease has been demonstrated by the brilliant results which may follow appropriate therapeutic measures

Hypertension regardless of cause eventually produces changes in the heart and blood vessels The cardiac hypertrophy and arteriosclerosis which follow long standing essential hypertension differ in kind little if at all, from the cardiac and arterial lesions associated with chronic glomerulonephritis The earliest recognizable change produced in the heart is *hypertrophy of the left ventricle* This is due apparently to an increase in the thickness of the individual muscle fiber In association with this increase in the muscle mass (compensatory hypertrophy), there may be some deficiency in the supply of oxygen to the thickened muscle fibers (Harrison) Thus an inadequate supply of oxygen to the heart muscle may constitute a myocardial handicap in addition to the increased mechanical load of high blood pressure and contribute to the development of left ventricular dilatation

Fig 116—Essential hypertension Note hyaline thickening of the intima resulting in extreme narrowing of the lumen of a small renal artery (× 275 H & E Department of Pathology Vanderbilt University Hospital)

When the latter is sufficiently pronounced changes in the left auricle (hypertrophy dilatation) are conspicuous The right side of the heart is least affected in hypertension Nevertheless marked hypertrophy and dilatation of the chambers are often present in individuals with hypertension of long standing especially when failure of the left ventricle has occurred Heart failure attributable to either hypertrophy and dilatation from mechanical overloading or to coronary sclerosis and myocardial degeneration is the cause of death in approximately 60 per cent of patients with essential hypertension

As has been stated arteriosclerosis is

always present in long standing hypertension. Its occurrence in the coronary arteries has been referred to and is a common cause of coronary thrombosis and death. Cerebral arteriosclerosis secondary to hypertension frequently results in thrombosis or hemorrhage. Although changes may occur throughout practically the entire arterial system they develop first in the smaller vessels, the arterioles (arteriolosclerosis). Here the lesions are characterized by the presence of hyaline degeneration with or without fat, hyperplasia of the internal elastic membrane and proliferation of connective tissue in the intima and atrophy of the muscularis (Fishberg). In larger vessels hypertrophy of the muscular layers is usually conspicuous. The vessels of the viscera are involved in essential hypertension much more frequently than the vessels of the extremities. This is in striking contrast to senile arteriosclerosis which so often develops in the absence of hypertension.

In 72 cases of essential hypertension studied by Fishberg arteriolosclerosis was present in the kidneys in 100 per cent, spleen 66, pancreas 49, liver 30 and brain 19 per cent. However Fishberg and others have observed rare instances in which no renal arteriolar lesions whatsoever were demonstrated. Usually at autopsy well marked arteriolosclerosis with varying degrees of parenchymal atrophy are demonstrable. The cortex is thin, the arteries thickened and gaping. Arteriolosclerosis with secondary hyalinization of glomeruli, tubular atrophy and replacement fibrosis characterizes the kidney in essential hypertension of long duration. Death from uremia is relatively rare, occurring in less than 10 per cent of cases.

In the malignant type of essential hypertension the kidney presents a different picture from that described above. Its surface appears flea bitten as the result of numerous subcapsular hemorrhages. In addition to the arteriolosclerosis, glomerular hyalinization, tubular atrophy and fibrosis which are present in benign essential hypertension, a necrotizing endarteritis is present in the afferent and interlobular arterioles. The contiguous glomeruli may be necrotic and this is associated with marked degenerative changes in the corresponding tubules. The latter often contain blood and debris. The necrotizing endarteritis is not confined to the kidneys. As in benign hypertension the arteriolar lesions may be widely distributed. Changes in the optic nerve head and retina are of great diagnostic importance. Fishberg

Fig 117.—Malignant hypertension. Necrotizing sclerosis. Hyalinization and necrosis of the walls of an afferent arteriole (a) to glomerulus (d). The lumen of the arteriole is almost obliterated at (b) and completely obliterated at (c). (× 200 H & E Department of Pathology, Vanderbilt University Hospital.)

considers that they are consequences of hypertension and prefers the term "hypertensive neuro retinopathy" He considers that three factors may be involved con striction of the retinal arterioles lesions in the retinal arterioles and increased intra cranial pressure These produce circulatory disturbances in the retina of varying types depending upon which factor is dominant Edema of the nerve head and distended veins indicate increased intracranial pressure Thin columns of blood in the retinal arte rioles suggest constriction Hemorrhages and so called exudates (lipoid accumulations) are related to arteriolar lesions The major ity of patients with malignant hypertension die of uremia, commonly in association with congestive heart failure and not infre quently cerebral vascular accidents

Hugh J Morgan

BENIGN ESSENTIAL HYPERTENSION

Symptoms —In private practice the con dition is commonly discovered during the course of routine physical examinations, or examinations for life insurance on individ uals entirely free from symptoms Under such circumstances especially with neurotic patients it is important for the physician to avoid laying the foundation for an anxiety neurosis by attaching great significance to the observation It is sometimes a tempta tion to explain many symptoms on the basis of hypertension when the latter is present actually in an asymptomatic stage and such practice often results in failure to detect the real cause of the patient s complaints

Headache, vertigo restlessness insomnia asthenia, and loss of accustomed zest for living' are frequent early symptoms of hy pertension and may be encompassed by the unobservant patient in the sole complaint of a decline in general health In individuals past the fortieth year of life such complaints are common especially in the neurotic They should never be dismissed by the physician without careful consideration

Cardiac symptoms may constitute the in itial complaint Heart consciousness espe cially in the recumbent position palpitation inability to sleep without two or three pil lows instead of the accustomed one may exist for months or even years before impres sive evidence of diminished cardiac reserve or frank congestive heart failure ensues The latter is usually ushered in by dyspnea cough or cardiac asthma " symptoms due to failure of the left side of the heart As decompensation progresses the development of hepatic engorgement with tenderness edema of the dependent parts and transu dations into serous cavities indicate that fail ure of the right ventricle has ensued Symp toms of coronary artery disease may occur (angina pectoris, coronary thrombosis) with little or no relation to the manifestations of congestive heart failure, or they may be associated with this condition The majority of patients with essential hypertension even tually experience cardiac symptoms and die of heart failure

Symptoms indicative of cerebral arteriosclerosis occur frequently Approximately 20 per cent of deaths in essential hypertension are due to cerebral thrombosis or hemorrhage The sudden occurrence and rapid disappear ance of focal cerebral symptoms such as syn cope aphasia paresthesia monoplegia or hemiplegia or the development of more gen eralized cerebral manifestations as intense headache vomiting amaurosis drowsiness convulsions or coma without azotemia consti tute strong arguments for cerebral vascular spasm (Pal s Gefassenkrisen) the hyper tensive encephalopathy concept of Oppen heimer and Fishberg Hypertensive enceph alopathy is not a manifestation of renal insufficiency or uremia with which it may be easily confused especially when the gen eralized cerebral manifestations are present It is apparently caused by arterial hyperten sion regardless of whether the latter is due to acute or chronic glomerulonephritis essential hypertension eclampsia or other causes

Renal symptoms are not conspicuous Nocturia in association with diminished cardiac reserve is common It may when accompanied by polyuria indicate the pres ence of nephrosclerosis with impaired renal function in cases of long standing and it is almost always present in the malignant phase of essential hypertension

Physical Signs —The recognition of hypertension rests upon the results of the manometric determination of the blood pres

sure Certain physical signs usually accompany high blood pressure and may be listed as follows (1) the pulse may be hard and difficult to compress and thickening of the walls and elongation of the peripheral vessels may be present The brachial temporal and radial arteries may be conspicuously tortuous and pulsating (2) Ophthalmoscopic examination reveals varying degrees of arterial tortuosity Narrowing of the lumina of the vessels may be present The veins may appear nicked at points where they are crossed by arteries In more advanced cases with excessively high pressure and especially in malignant hypertension papilledema hemorrhage and retinal and choroidal lesions (exudate') occur (3) Increased retromanubrial dulness a diastolic shock over the aortic area and a ringing tympanitic aortic second sound a forceful localized thrust at the apex of the heart enlargement of the heart downward and to the left—these in varying degrees are commonly present

The urine may be entirely normal Traces of albumin hyaline and finely granular casts and occasional red blood cells may be present Renal function as determined by urine concentration tests phenolsulfonphthalein excretion blood nitrogen determination and the urea clearance test is usually normal

The electrocardiogram as a rule exhibits left axis deviation together with inversion of the T wave in lead I

The blood pressure readings vary greatly not only in different patients but often in the same patient When the systolic pressure is consistently more than 140 mm of mercury it is definitely abnormal The term hypertension is reserved by many to indicate systolic pressures of 160 mm or more and in essential hypertension there is a commensurate rise to 90 mm or more in the diastolic pressure The blood pressure may be observed to rise rapidly from month to month more slowly from year to year or to remain stationary It is not unusual to observe variations in pressure of from 30 to 40 mm during an office visit

Prognosis —The height of the systolic and diastolic blood pressure is an extremely important factor in prognosis Frost s tables indicate that mortality increases in direct proportion to the elevation above the normal of the systolic pressure However marked variations occur Allbutt observed a patient for eighteen years after the discovery that the blood pressure was 250 mm ! The height of the diastolic pressure is of especial prognostic significance since a diastolic pressure in excess of 150 mm usually indicates that the hypertension has entered the malignant phase and this is followed soon in most instances by uremia congestive heart failure or less frequently cerebral vascular accident In normal individuals the blood pressure levels usually rise with increasing weight In essential hypertension obesity can be shown frequently to be responsible for an appreciable increment of the pressure More important from the standpoint of prognosis perhaps is the extra work performed by the heart in the obese an excess above that entailed by hypertension alone Paullin and others have noted that women with hypertension survive much longer than men This is possibly a reflection of the usually benign character of the hypertension which may develop in association with the menopause Age is an important factor the younger the patient the more unfavorable the outlook Hemorrhages associated with white spots in the retina (hypertensive neuro retinopathy) are ominous signs Death commonly follows within a year Hypertension leads to death from heart disease in approximately 60 per cent of cases from cerebral hemorrhage or thrombosis in 20 per cent and uremia in 10 per cent

Diagnosis —The very definition of essential hypertension renders it necessary that inflammatory kidney disease and urinary tract obstruction be excluded before the term can be properly applied in diagnosis This has been discussed under etiology and pathogenesis Interest in hypertension has been greatly stimulated by recent experimental work and this is reflected in a more critical use of the term essential hypertension in diagnosis Thus cases which formerly would have been classified essential hypertension are now being recognized as exhibiting hypertension directly related to endocrine disorders (pituitary basophilism tumors or hyperplasia of the adrenal cortex menopause) obstruction to the flow of urine (congenital anomalies ureteral and urethral obstructions and so on) urinary tract in

fections (pyelitis pyelonephritis) renal artery disease (narrowing of lumen by arteriosclerosis, infarcts) tumors of the kidney coarctation of the aorta, and others Heretofore interest centered chiefly in the separation of certain cases of hypertension from acute and chronic glomerulonephritis These were labeled essential hypertension When the clinician excluded glomerulonephritis the diagnosis of essential hypertension almost became automatic and etiologic interest promptly dwindled Of course nephritis still remains the commonest problem in differential diagnosis Nevertheless recent work in experimental hypertension has redirected attention to the kidney and has stimulated more critical study of patients with hypertension especially with reference to the possible existence of primary remedial urinary tract disease A considerable number of cases have been reported in which striking improvement or disappearance of hypertension has followed the removal of the diseased kidney in unilateral hydronephrosis pyelonephritis and tumor or the relief of urinary obstruction due to prostate or stricture or the treatment of renal pelvis infection

It should be borne in mind that very infrequently, hypertension which develops at the time of the menopause may be transient Hypertension occurring before the age of forty years suggests nephritis After forty essential hypertension is a common disorder and glomerulonephritis is relatively uncommon Extremely high arterial pressures are more apt to be associated with essential hypertension especially malignant essential hypertension than with glomerulonephritis A past history of acute glomerulonephritis is strong circumstantial evidence that subsequent hypertension is due to chronic glomerulonephritis The malignant phase of essential hypertension may present a picture similar in all respects to chronic glomerulonephritis

Treatment —Many patients with benign essential hypertension require no treatment When treatment is indicated it is directed toward protecting the patient as far as this is possible, from the consequences of the disorder rather than toward lowering the blood pressure The latter may be accomplished in the obese by weight reduction in the apprehensive, nervous overworked individual by reassurance and measures conducive to rest and relaxation However the reduction in pressure which follows correction of these secondary factors is usually temporary The patient should develop 'a way of life' compatible with the handicap which exists Careful consideration should be given by the physician to the personal problem involved Sedatives (phenobarbital 0 03 Gm three times a day, bromide 1 Gm twice daily) are useful especially to reduce nervous tension and allay apprehension Estrogenic preparations may be useful in climacteric hypertension' Drugs which are prescribed specifically for blood pressure reduction are of little value This statement applies to the continuous administration of potassium thiocyanate the nitrates extracts of mistletoe garlic or watermelon seed veratrum viride acetylcholine and nicotinic acid Except for the temporary effects obtainable from hypnotics narcotics anesthetics and vasodilators during critical elevation or crises of hypertension which are due to psychic disturbances or pain little can be accomplished with drugs Critically evaluated clinical and experimental evidence indicates that the results of treatment by renal extracts are irregular and possibly nonspecific The nitrites are sometimes employed for headache A combination of acetylsalicylic acid 0 3 Gm phenacetine 0.3 Gm and caffeine citrate 0 15 Gm is more effective Physiotherapy (relaxing hydrotherapy and massage) is very useful Diet plays an unimportant role though excessive sweets overeating and condiments are to be avoided Physical activity is ordered in such a way as to avoid periods of sudden physical strain thus conserving cardiac reserve

The *surgical treatment* of essential hypertension by renal denervation splanchnic denervation or partial adrenalectomy is in the experimental stage The outlook is not very encouraging

The *management* of hypertensive heart disease is discussed elsewhere When urgent cardiac symptoms are present as a result of acute left ventricular failure and pulmonary edema prompt venesection morphine and oxygen may save life *If the diastolic* blood pressure is over 100 digitalis in small daily doses (Christian) appears to be

rational treatment and when employed with appropriate regulation of physical activity it doubtless postpones the advent of congestive heart failure The treatment of cerebral thrombosis and hemorrhage and of nephrosclerosis and renal insufficiency is discussed elsewhere

In the treatment of hypertensive encephalopathy whether associated with essential hypertension acute or chronic glomerulonephritis or eclampsia the following measures are important (1) a reduction of the intracranial pressure if lumbar puncture reveals it to be increased by cautious slow drainage of cerebrospinal fluid and the use intravenously of hypertonic sugar solutions (2) venesection (in adults who are not anemic 500 cc is the amount of blood usually removed) and (3) morphine magnesium sulfate and the barbiturates as antispasmodics and sedatives

HUGH J MORGAN

MALIGNANT ESSENTIAL HYPERTENSION

In hospital practice one encounters not infrequently individuals with essential hypertension in whom the entire clinical course from the appearance of symptoms until death is telescoped into a period of months or a year or two In others after years of relatively asymptomatic or benign hypertension a marked intensification of symptoms and acceleration of progression occurs Negroes appear to be particularly susceptible Necrotizing endarteritis of the renal arterioles with extensive glomerular and tubular changes constitutes the characteristic renal lesions The pathologic changes can be reproduced experimentally by severe constriction of the renal arteries (Goldblatt) Fishberg describes the clinical picture as one characterized by manifestations of increased intracranial pressure (headache vomiting papilledema) and renal insufficiency (albuminuria cylindruria hematuria nitrogen and phenolsulfonphthalein retention) Stupor and frequently convulsions occur Commonly the evidence of renal insufficiency afforded by the laboratory is quantitatively not as great as might be expected were the uremic state due to chronic nephritis The systolic blood pressure is usually excessively high 220 to 250 mm and more and the diastolic pressure is correspondingly elevated Retinal hemorrhages and white spots together with papilledema characterize the ophthalmoscopic findings Manifest congestive heart failure commonly complicates the clinical picture and cerebral vascular accidents are not infrequent The condition is invariably fatal

HYPOTENSION

Under normal conditions the blood pressure in the aorta is about 10 mm higher than in the brachial arteries in the digital arteries it is about 10 mm lower than in the brachial This represents a drop of approximately 20 mm from the aorta to the periphery Beyond the arterioles the pressure falls markedly for the normal capillary blood pressure is usually stated to be between 25 and 10 mm of mercury The regu

latory mechanism of the arterioles, then chiefly determines the pressure of the blood in the capillaries maintaining it at a more or less constant level regardless of the arterial pressure Thus the efficiency of the capillary circulation need not suffer in the least from moderate alterations of the arterial blood pressure This doubtless is the explanation of the fact that individuals with relatively low blood pressures may experience *no untoward effects*

There is no agreement as to the etiology or clinical significance of the constantly low blood pressure levels which are present in some patients The average blood pressure of normal Orientals is distinctly lower than that of Europeans and Americans It is impossible to arrive at a figure for the minimal normal level of the blood pressure in health Certainly one observes patients commonly enough whose circulatory efficiency is in no sense impaired by systolic pressure of 110 mm or lower ('essential hypotension') Indeed in the mass low blood pressure favors longevity distinctly Nevertheless psychoneurotic states including neurocirculatory asthenia have been ascribed to hypotension constitutional factors splanchnoptosis and capillary stasis have been implicated in etiologic considerations of the latter In the psychoneuroses hypotension is more often an effect than it is a cause Low blood pressure is frequently found in association with wasting diseases (malignancy chronic infection) anemia malnutrition hypothyroidism myocardial insufficiency amyloid disease and others

It is important to recognize the significance of hypotension in certain clearly defined reflex and organic disorders It is an important clinical manifestation of Addison s disease in which the blood pressure remains usually at a persistently low level Common *fainting attacks* are associated with a progressive decrease in pulse pressure and a decreased venous return to the heart In individuals with *hypersensitive carotid sinuses* pressure on the sinus at the bifurcation of the common carotid artery may be associated with the development of bradycardia hypotension and syncope and rarely convulsive twitchings This may be due to an abnormally sensitive carotid sinus without demonstrable lesions or to hypersensitiveness of the carotid sinus reflex due to arteriosclerosis or to tumors at or near the bifurcation of the carotid artery The disturbance may be either unilateral or bilateral Spontaneous attacks occur without apparent cause in periods of emotional excitement or with sudden changes in the position of the head Weiss cites the case of a street car motorman who wore a stiff collar which induced attacks when the head was suddenly turned Digitalis renders the carotid sinus reflex hyperactive and may thus be a factor in precipitating attacks especially when arteriosclerosis is present Diagnosis rests upon the reproduction of the spontaneous attacks by pressure on one or both carotid sinuses Atropine and ephedrine have been found useful in treatment When involvement is unilateral surgical treatment consisting of carotid denervation has proved successful This should not be attempted unless the reflex can be abolished temporarily by novocainization of the sinus region

Postural or *orthostatic hypotension* is brought about by a sudden change from the horizontal to the upright position or by prolonged standing and is due to failure of the blood pressure regulatory mechanisms to adjust themselves to changes of posture For example a systolic pressure of 140 mm of mercury, when the patient is supine may fall to 115 mm when a sitting position is assumed and to 70 mm or lower when the patient stands The diastolic pressure exhibits corresponding reductions Normally with these changes in posture the systolic blood pressure drops only slightly and the diastolic pressure tends to rise When orthostatic hypotension is present both systolic and diastolic pressures fall and weakness faintness syncope and even convulsive seizures may occur Hypersensitiveness of the carotid sinus reflex may be demonstrable Ephedrine sulfate (0 025 to 0 05 Gm) or Benzedrine sulfate (0 005 to 0 01 Gm) administered several times a day and abdominal supports have been employed successfully

Hyperinsulinism internal hemorrhages vascular occlusions and shock from any cause are commonly associated with a rapid fall in the blood pressure

DISEASES OF THE HEART

DISEASES OF THE PERICARDIUM

ACUTE FIBRINOUS PERICARDITIS

Definition—Acute fibrinous pericarditis is an inflammation of the pericardium associated with the formation of a fibrinous exudate on the serous membrane The lesion may not pass beyond this stage but in some cases it does and a serous serosanguineous or purulent exudate may form (*pericarditis with effusion*)

Etiology—Pericarditis is probably never a primary disease The six most frequent pathologic conditions with which it is associated are (1) rheumatic fever (2) pneumococcal infections especially empyema (3) pulmonary tuberculosis (4) chronic nephritis with uremia (5) coronary thrombosis with myocardial infarction (6) perforating wounds of the thorax Not uncommonly acute pericarditis may be caused by an infection of unknown etiology as in polyserositis (*Concato s disease*) The micro-organisms most frequently found in the pericardial exudate are the pneumococcus the tubercle bacillus and the pyogenic organisms especially the streptococcus The gonococcus the colon bacillus and the influenza bacillus have occasionally been cultivated from the pericardial exudate In scarlet fever meningococcus meningitis pertussis parotitis and measles acute pericarditis is a rare complication Actinomycosis and malignant tumors may cause pericarditis Recently pericarditis has been observed in tularemia and undulant fever

Morbid Anatomy—Acute pericarditis is associated with an outpouring of fibrin This may be exuded on the pericardial surfaces without effusion of fluid (*dry pericarditis*) or serum may be admixed with the fibrin (*serofibrinous pericarditis*)

Symptoms—Since pericarditis is secondary to disease elsewhere in the body the symptomatology is influenced by the character of the primary or underlying disorder Acute fibrinous pericarditis *per se* is usually painless Where pain occurs one of two complications is likely to be present first a large pericardial effusion which may cause dull aching pain in the precordium second pleuropericarditis especially if the diaphragmatic pleura is affected The pain may be localized in the chest or referred to the neck or abdomen

The pericarditis of nephritis and other terminal conditions is painless probably because complicating pleuropericarditis is infrequent

Physical Examination—Palpation occasionally reveals a friction fremitus caused by the rubbing together of the roughened pericardial surface *Auscultation* yields the most important and not infrequently the sole evidence of fibrinous pericarditis The friction rub is a to and fro sound close to the ear which corresponds to systole and diastole and varies greatly in intensity in different cases and often in the same case The timing of the sound differs from the timing of a to and fro valvular murmur in that it does not begin immediately after the heart sounds and generally overlaps them The rub may be only a slight scratchy noise perceptible with some difficulty and easily overlooked or an intense grating sound In rare instances it may be audible without a stethoscope a few inches from the chest wall It may be heard at one examination and be absent at the next not infrequently it persists only a few hours but it may recur with increased intensity It disappears if a fluid exudate *completely separates* the layers of the pericardium However a pericardial friction rub frequently is audible in the presence of large effusions The rub is most frequently heard over the right ventricle in the fourth and fifth spaces close to the sternum it is however often encountered at the base of the heart or at the apex In rare instances it may be heard posteriorly in the left thorax At times the intensity of the friction is augmented by pressure with the stethoscope Unlike endocardial murmurs peri

cardial friction is not transmitted in definite directions Change of position of the patient may alter the rub s intensity considerably

Diagnosis—The friction rub is pathognomonic of the disease but since it is often present for only a few hours repeated examination of the heart is necessary Difficulty in diagnosis arises if there is intense pain without friction rub at the onset A scratchy or crepitant quality of the heart sounds, particularly the first sound in the tricuspid and pulmonary areas is encountered in a small percentage of normal hearts and may be differentiated from a friction rub by its constancy by its more definite timing with the heart sounds by the fact that it does not change under pressure with the stethoscope and by the absence of fever or other symptoms

A *pleuropericardial friction rub* must be differentiated from a pure pericardial rub The former has in addition to the to and fro rhythm definite intensifications associated with the respiratory cycle which may be temporarily abolished by cessation of breathing The bubbling crunching sounds heard in mediastinal emphysema may be differentiated from a pericardial friction rub by their peculiar acoustics Also the patient with spontaneous interstitial emphysema while he may have severe pain usually presents no clinical signs of infection or of cardiac disease

Electrocardiographic changes in acute pericarditis occur in approximately 65 per cent of all cases and in some instances can be differentiated from electrocardiograms of coronary heart disease by serial tracings The RS T segments may be elevated in all the standard leads in the combined leads I and II or only in lead I The reciprocal depression of the RS T segment in lead III usually seen in anterior infarction due to coronary occlusion does not occur in pericarditis

A second helpful point in differentiation between coronary occlusion and pericarditis is the fact that in the early stages of pericarditis the RS T segment is *concave* upward or straight while in myocardial infarction it is *convex* upward

In acute pericarditis the T waves are upright in the early stages of the disease and may be of increased amplitude Later they may remain upright or become inverted in all of the leads an electrocardiographic finding not often encountered in any other variety of heart disease Occasionally inversion of the T wave in lead I develops while the upright T wave in lead III persists thus simulating the electrocardiographic pattern following infarction of the anterior apical region of the heart

In the apical precordial lead S T segment elevations may occur and the T wave may become inverted However a prominent Q_4 does not appear and the R wave is usually normal in amplitude

Prognosis—The prognosis in acute fibrinous pericarditis is good, provided the underlying disease is not fatal Adhesions of the layers of the pericardium by organized fibrinous exudate are a common sequel and the patient should be followed carefully for the possible development of pericardial effusion or chronic constrictive pericarditis

Treatment—Rest in bed is the essential element of treatment Application to the precordium of an ice bag often affords relief When the pain is severe codeine or morphine is required As the disease is usually secondary to infection elsewhere in the body treatment of the primary disease is obviously most important Sulfonamide derivatives should be administered if pyopericardium develops (see below Pericarditis with Effusion)

JOHNSON MCGUIRE

PERICARDITIS WITH EFFUSION

Definition—Pericarditis with effusion is associated with inflammation of the pericardium during the course of which a fluid exudate collects in the pericardial cavity

Etiology—Pericardial effusion may follow pericarditis due to any of the causative factors described under Acute Fibrinous Pericarditis Pyogenic infections tuberculosis and rheumatic fever are the commonest etiologic agents responsible for pericardial effusion

Morbid Anatomy—The visceral and parietal layers of the pericardium may be covered with varying quantities of fibrin so abundant as to form a coarse shaggy coat

which at times greatly interferes with aspiration of fluid from the sac The fluid exudate may be of several kinds—serous serosanguineous hemorrhagic seropurulent or purulent—but whatever its nature flakes of fibrin are generally found floating in it The quantity of fluid contained in the pericardial cavity varies greatly, in some cases only 100 to 200 cc may be found while in others 1.5 or 2 liters may distend the sac In contrast to transudates the inflammatory exudates have a relatively high specific gravity (1 017 +) and usually a total protein content of more than 30 Gm per liter The fluid is clear serous or cloudy, according to the number of cells and amount of fibrin contained In purulent exudates a thick creamy pus may be found which at times has a putrid odor In the fluids generally associated with tuberculosis neoplasm purpura rheumatic fever or streptococcal infections red corpuscles are more or less abundant while in the purulent exudates pus cells are so numerous as to dominate the field many of the cells are necrotic and stain imperfectly

Pathologic Physiology—Pericardial effusion of sufficient magnitude to produce clinical manifestations does so primarily by causing cardiac tamponade as follows (1) Blood enters the heart with difficulty since the pressure of the fluid between the distended *pericardium and the heart impedes* the entrance of blood from the great veins into the heart This causes a rise of peripheral venous pressure from the normal 5 to 10 cm of water to levels of from 15 to 40 cm of water (2) The cardiac output per minute and per beat is decreased from the normal of ± 3 87 liters per minute to about 2 liters per minute and the stroke volume from the normal of 64 cc to less than 40 cc (3) The lowered cardiac output produces a decrease in arterial blood pressure to approximately 110 90 mm of mercury with a small pulse pressure of about 20 mm of mercury (4) The pulse rate is increased probably due to a compensatory reflex to aid the total blood flow per minute since the output per beat is decreased (5) The velocity of blood flow is diminished as measured from arm to the tongue (6) The movements of the heart are decreased as seen fluoroscopically or in the roentgenkymograph (7) During inspiration the pulse becomes weak or imperceptible This valuable sign of cardiac tamponade while not pathognomonic of this condition is called the pulsus paradoxus and is thought by Katz and Gauchat to be due to the decrease of the normal differential pressure during inspiration between the intrathoracic intrapericardial and extrapericardial veins

The effects of acute cardiac tamponade are described below under Pericardial Diseases as a cause of acute cardiac tamponade

Symptoms—The onset of pericarditis with effusion is seldom abrupt and often very insidious Because the disease is frequently secondary to serious trouble elsewhere in the body it may not perceptibly alter the general condition of the patient The fever is usually of the same type as that of the primary disease although it may be somewhat aggravated

The disease often causes little or no local discomfort If *pain* develops it may be localized or referred as in acute fibrinous pericarditis The intensity of the pain varies there may be merely a dull heavy feeling of discomfort or the most severe stabbing cutting or constricting pain

Dyspnea is usually though not invariably present and orthopnea is common with large effusions Generally the *alae nasi* dilate on *inspiration*

A marked distention of the pericardial cavity may *irritate nearby nerves* Irritation of the recurrent laryngeal nerve may lead to laryngeal paralysis and aphonia irritation of the vagus or pressure on the esophagus to difficulty in swallowing pressure on the phrenic nerves to hiccup An aggravating cough which is usually without expectoration may result from pressure on the trachea and bronchi

Physical Examination—*Inspection* may show a fulness or bulging of the precordium especially in children The apex impulse is often not visible particularly if the effusion is large Fulness of the interspaces may be noted and at times edema of the chest wall particularly in pyopericardium Expansion of the left side of the chest is lessened by large effusions Bulging in the epigastrium may be due to depression of the left lobe of the liver The superficial veins of the neck

thorax and upper *extremities are usually* distended

Palpation—Friction fremitus generally disappears as fluid accumulates but it may be continuously found at the base of the heart with the patient erect even in cases with considerable effusion As the quantity of fluid increases the apex impulse usually becomes less and less distinct until finally, it is no longer palpable, unless the heart is fixed to the anterior chest wall by localized adhesions A vanishing apex impulse is one of the important signs of collection of fluid *in the pericardium particularly when accom* panied by an increase in the relative cardiac dulness

Percussion—The *most valuable single sign of pericardial effusion* is dulness at the base of the heart in the first and second interspaces shifting with change in posture of the patient It is most satisfactorily dem onstrated by Hoover s method of direct per cussion with the middle finger

Widening *of the area of relative dulness* in the first and second interspaces to the right and left of the sternum may be the first evidence of effusion and may precede widening of the right and left borders of cardiac dulness The area of dulness in the first and second interspaces should be mapped out with the patient first recum bent then erect A narrowing of the area of dulness in the erect posture indicates ef fusion *in the pericardial sac*

Likewise the areas of relative cardiac dul ness to the right and left of the inferior cardiac borders also shift with change of position in the presence of effusion but the change here is just the reverse of the change at the base of the heart Thus when the patient sits up the relative dulness ex tends further to the right in the fourth inter space and further to the left in the fourth and *fifth interspaces*

In case of large effusions there may be impairment of the percussion note at the angle of the *left scapula*

Auscultation—A friction rub present at the onset may disappear as accumulating fluid separates the visceral from the parietal pericardium However *if adhesions are pres* ent the friction rub may persist despite the presence of a large effusion With large ef fusions the heart sounds are usually distant *and feeble* At the angle of the left scapula bronchial breathing and pectoriloquy may be present due to compression of the lung by the distended *pericardium* *This physical* finding is called Ewart s sign and is thought by Levine to occur only in rheumatic peri carditis and to be due not to pulmonary compression but to rheumatic pneumonia However this has not been our experience

Radiography—Roesler s studies have con tributed much to the roentgenographic find ings in pericarditis When 300 cc of fluid accumulate in the pericardium definite *x ray changes—the earliest evidence of ef* fusion—appear Even with effusion of mod erate size a bulging of the lowest margin of the cardiac silhouette can be demonstrated In the lateral view there is a convexity pos teriorly where normally the straight contour of the vena cava is seen As additional fluid accumulates the pulsations of the heart as seen fluoroscopically become decreased in amplitude and may cease entirely However *with severe myocardial disease the cardiac* pulsations may likewise become impercep tible Finally with a large effusion the heart assumes a pear shape or water bottle ap pearance The normal curves of the heart can no longer be seen and the transverse diameter may exceed the longitudinal *It is* not always possible by any roentgenographic method to differentiate between dilatation and effusion Roentgen kymography serves *as an excellent check* upon fluoroscopic ex amination when there is doubt concerning the magnitude and character of the cardiac pulsations

Differential Diagnosis—Differentiation must be made between pericardial effusion and cardiac hypertrophy and dilatation In *chronic hypertrophy and dilatation of the heart* the shadow is not so typically pear shaped and does not extend so high along the sternal margins nor so low in the fifth and sixth interspaces on the right Moreover the cardiac measurements in the sitting and in the recumbent position do not undergo the changes so characteristic *of pericardial* ef fusion Fluoroscopic examination usually re veals a well marked forceful pulsation Dila tation of the heart presents great *diagnostic* difficulties Osler has summarized the *most* important differences in the following words (1) The character of the apical impulse in

dilatation particularly in thin-chested people is commonly visible and wavy (2) The shock of the cardiac sound is more distinctly palpable in dilatation (3) The area of dulness in dilatation rarely has a triangular form nor does it except in cases of mitral stenosis reach so high along the left sternal margin or so low in the fifth and sixth interspaces without visible or palpable impulse Dulness shifting with change of position speaks strongly for effusion (4) In dilatation the heart sounds are clearer often sharp or fetal in character gallop rhythm is common whereas in effusion the sounds are distant and muffled (5) Rarely in dilatation is the distention sufficient to compress the lung and produce the tympanitic note in the axillary region or flatness behind (6) The x ray picture may be very definite and unlike any form of dilatation or hypertrophy of the heart

In children of less than one year the shadow of an *enlarged thymus gland* merging with that of the heart may closely resemble the shadow characteristic of pericarditis with a moderate amount of effusion An enlarged thymus however does not change shape with change of position

Diagnosis —The diagnosis of pericardial effusion is often difficult especially if the effusion is not fully developed when the first examination is made If however the patient is examined from day to day as the fluid collects the physical signs usually do permit recognition of the condition in the course of time In doubtful cases fluoroscopic examination may aid greatly in diagnosis

Early in the course of an effusion when the exudate collects rapidly the increased intrapericardial pressure may narrow the coronary vessels sufficiently to produce changes in the electrocardiograms resembling those seen in cases of coronary occlusion (see *Electrocardiographic* changes under Acute Fibrinous Pericarditis) As the symptoms at times also closely resemble those of a coronary thrombosis differential diagnosis may be extremely difficult Sooner or later however signs of pericardial effusion become definite With a large effusion there is often low voltage of all complexes

Diagnostic puncture is the means by which the existence of a pericardial effusion may be definitely demonstrated However it must be remembered that attempts at pericardial aspiration may lead to fatal accidents if the ventricular walls are lacerated or if the coronary vessels torn Indications for pericardial aspiration are two (1) Therapeutic aspiration for the relief of cardiac tamponade when clinical and laboratory data including markedly elevated or steadily rising venous pressure and markedly low or progressively falling arterial pressure indicate the necessity of relieving increased intrapericardial pressure (2) Diagnostic aspiration to determine if purulent pericarditis is present a condition requiring surgical drainage The majority of clinicians believe that the best site for aspiration in pericardial effusion is the fifth left interspace at the outer border of percussion dulness which is of course outside the apical impulse The needle preferably should be attached to a syringe by a three-way stop cock and inserted inward upward and backward If fluid is not encountered promptly or if the cardiac contractions are felt with the needle it is wise to discontinue the procedure at once as either little fluid is present or it is situated elsewhere

In the occasional case where x ray examination shows the fluid to be principally located to the right of the sternum aspiration should be carried out in the fourth right interspace taking care to avoid the internal mammary artery

Occasionally aspiration is successful posteriorly at the angle of the left scapula (if Ewart s sign is present) even though the anterior approach has been unsatisfactory In France there is considerable enthusiasm for the epigastric approach With this technic the needle is inserted just below the lower border of the ensiform cartilage The bevel of the needle should be kept close to the undersurface of the sternum while it is being pushed upward to enter the pericardial cavity above the diaphragm

Prognosis —The duration of the disease depends to a considerable extent upon the nature of the exudate and upon the underlying exciting cause In pericarditis of pyogenic etiology the mortality is high Whitehill and Harvey have reported a mortality of 85 per cent in tuberculous pericarditis whereas in rheumatic cases the prognosis

depends upon the condition of the myocardium

Treatment—Pericardial paracentesis and the aspiration of the pericardial fluid are indicated when the quantity of exudate is sufficient to produce symptoms of cardiac tamponade In rheumatic pericarditis spontaneous absorption often occurs and a conservative attitude is indicated unless the symptoms of tamponade are pronounced In *tuberculous pericarditis frequent aspirations* may be required If thick pus is present rib resection and surgical drainage are necessary Use of sulfonamide derivatives should be employed in pyopericardium in conjunction with surgical drainage if the etiologic agent is susceptible to these drugs In the average case an initial dose of 4 Gm (60 grains) of the sulfonamide chosen followed by 1 Gm (15 grains) every four hours will secure the desired level of the drug in the blood and pericardial fluid

JOHNSON MCGUIRE

ADHESIVE PERICARDITIS

(Adherent Pericardium Chronic Constrictive Pericarditis Pick s Disease Pericardial Scar Concretio Cordis Accretio Cordis)

Definition—Adherent pericardium is a condition resulting from fibrous adhesions between epicardium and pericardium or between the parietal pericardium and various intrathoracic structures Obliteration of the pericardial cavity may be partial or it may be completely obliterated by dense scar tissue (*concretio cordis*) There may also be adhesions extending from the pericardium to the mediastinum the pleurae the diaphragm and the chest wall (*accretio cordis*)

Etiology—Adherent pericardium is usually the result of a previous acute pericarditis and a history of antecedent pericarditis can often be obtained Tuberculosis and pneumococcal infections are frequently responsible Most commonly adhesive pericardial fibrosis is caused by an infection of unknown etiology Rheumatic fever frequently causes pericarditis however rheumatic pericarditis never causes the thick callous pericardial scar of chronic constrictive pericarditis A case of chronic constrictive pericarditis following and probably caused by tularemia has recently been successfully treated surgically at the Cincinnati General Hospital

Pathology and Pathologic Physiology—White has classified adherent pericardium under several groups *First* loose strands of fibrous tissue may join the epicardium to the pericardium Such adhesions have no effect on the function or size of the heart *Second* the visceral and parietal pericardium may be completely adherent but the heart is not bound to the intrathoracic structures by adhesions In such cases the pericardium is not greatly thickened the heart is not seriously handicapped and no cardiac enlargement results *Third* there may be great thickening of the pericardium with the heart encased and constricted by a dense envelope of fibrous tissue Calcium or bone may be found embedded in this scar tissue This condition has been termed *chronic constrictive pericarditis (concretio cordis)* Chronic constrictive pericarditis causes chronic cardiac compression the inflow of blood in diastole is impeded venous pressure is increased and enlargement of the liver and ascites follow The cardiac output is markedly diminished and the circulation time prolonged often to the same degree as in congestive heart failure Because of the inelastic scar tissue surrounding the heart hypertrophy cannot occur even when external adhesions develop and require extra work during systole *Fourth* adhesive pericarditis uniting the visceral and parietal pericardium may be associated with external adhesions binding the heart to the pleurae the diaphragm the costal cartilages or the sternum (*mediastinopericarditis* or *accretio cordis*) In this type of adherent pericardium an extreme degree of cardiac hypertrophy has been described and has been attributed to an increase in work during systole as the heart tugs against the fixed adhesions In recent years there has been considerable controversy regarding the influence of adherent pericardium as a factor in causing cardiac enlargement From a review of sixty five cases of adherent pericardium proved by autopsy at the Cincinnati General Hospital it is our opinion that a moderate degree of cardiac enlargement may follow the addi

tional work necessitated by the pull of the heart against the adhesions during systole However in our series and apparently in Cabot s as well the hearts of extraordinary size (sometimes weighing more than 1000 Gm) not only had internal as well as external pericardial adhesions but also some complicating handicap such as hypertension or valvular disease

The enlargement of the liver in certain cases of adherent pericardium was first described by Pick in 1896 This enlargement of the liver he designated pseudocirrhosis of the liver' The condition is caused by long standing chronic passive congestion of the liver brought about from obstruction of venous return by encasing pericarditis Firmness of the liver according to modern concepts results from a relative increase in connective tissue following necrosis of parenchymatous cells

Symptoms and Signs—Clinically adherent pericardium may be divided into three groups

1 *Asymptomatic Group*—In the majority of cases adhesions between the visceral and parietal pericardium or adhesions between the parietal pericardium and intrathoracic structures cause no symptoms or signs Thus the disorder may first be discovered at autopsy death occurring from some unrelated cause

2 *Chronic Constrictive Pericarditis* (*Concretio Cordis*) —SYMPTOMS —Enlargement of the abdomen and prominence of the veins of the neck and often edema of the feet and legs are the commonest symptoms Dyspnea weakness malnutrition are inconstantly present

PHYSICAL SIGNS —Inspection reveals conspicuous engorgement of the veins of the neck (the venous pressure may be 20–45 cm of water *i e* two to five times the normal) The distention of the veins is often present in the sitting as well as in the recumbent position Cyanosis of the lips and nail beds may be present Inspiratory swelling of the veins of the neck is a common and important sign Orthopnea is inconstant There is moderate or even extreme enlargement of the abdomen usually with a fluid wave Pitting edema of the legs and ankles is often found The liver is regularly enlarged and firm but usually it is not tender and does not pulsate Splenomegaly rarely occurs The pulse is small the systolic blood pressure and pulse pressure are characteristically low or within the lower limits of normal A paradoxical pulse (a fall in systolic blood pressure during inspiration) may be observed Pleural effusion is commonly present The fluid like that found in the abdomen usually has the characteristics of a transudate

The heart is usually small and quiet In most cases the rhythm is regular but irregularity arising from auricular fibrillation or extrasystoles is sometimes encountered The sounds may be distant but otherwise are of normal intensity Systolic apical murmurs may be present

The ELECTROCARDIOGRAM is helpful in the recognition of chronic constrictive pericarditis Usually there is low voltage of QRS complexes and the T waves are frequently of low amplitude or negative If the heart be immobilized by adhesions the electric axis may not alter with change of position of the body but fixation of the electric axis is by no means pathognomonic The detection by x ray of calcareous deposits encircling the heart is helpful in confirming the diagnosis of adherent pericardium The cardiac silhouette is usually of normal size though marked thickening of the pericardium may suggest hypertrophy or dilatation Decrease in the amplitude of the pulsations of the heart particularly of the right border is the usual *fluoroscopic* finding

DIFFERENTIAL DIAGNOSIS —Chronic constrictive pericarditis must be differentiated from the following disorders

ARTERIOSCLEROTIC HEART DISEASE WITH CONGESTIVE HEART FAILURE —High venous pressure ascites and a feebly pulsating heart are not uncommon in congestive heart disease due to coronary artery sclerosis as well as stenosis of coronary ostia due to syphilis The history the electrocardiogram the persistence of an elevated venous pressure despite bed rest and digitalization in constrictive pericarditis help to differentiate the two conditions Also careful x ray and fluoroscopic studies may demonstrate evidence of calcium deposits within the pericardium itself

MITRAL AND TRICUSPID VALVULAR DISEASE —Enlargement of the liver edema and

dilatation of the cervical veins are commonly present with tricuspid stenosis and failure of the right heart secondary to mitral stenosis The history, configuration of the heart and the presence of a presystolic or diastolic murmur are helpful differential findings

BERIBERI HEART —The generalized edema and signs of right sided heart failure in this condition are theoretically confusing The history of dietary deficiency peripheral neuritis tenderness and atrophy of the muscles therapeutic response to vitamin B_1 in beri beri and the enlarged liver fluoroscopic and electrocardiographic findings in chronic constrictive pericarditis help to differentiate these diseases

PORTAL CIRRHOSIS OF THE LIVER—The age of the patient with cirrhosis of the liver the history of alcoholism the absence of venous engorgement of the cervical veins the presence of splenomegaly and the absence of signs referable to the heart make the differentiation from adherent pericardium comparatively simple In fact the normal level of venous pressure in the veins of the arm in hepatic cirrhosis eliminates Pick s disease from consideration

POLYSEROSITIS —In polyserositis the serous effusions are primarily inflammatory In adherent pericardium effusion into the pleural and pericardial cavities results from elevated venous pressure and chronic passive congestion

3 *External Pericardial Adhesions* (*Mediastinopericarditis Accretio Cordis*) —SYMPTOMS —Unless the symptoms of myocardial insufficiency are present there are no characteristic symptoms of external pericardial adhesions

SIGNS —The most important physical sign of external adhesions is systolic retraction of the interspaces near the cardiac apex This phenomenon may however be seen during the systole of a greatly enlarged heart without adhesions Systolic retraction may be seen posteriorly on the left side between the eleventh and twelfth ribs (Broadbent s sign) Pulsus paradoxus may be present If rheumatic fever is the etiologic factor a variety of valvular murmurs may be encountered

Only when valvular disease or hypertension coexists does one find the enormous cardiac enlargement referred to in the older textbooks *X-ray* and *fluoroscopy* may be of aid If during inspiration the heart rises especially if one side rises more than the other there is additional evidence for the diagnosis Bands of adhesions extending from the parietal pericardium to various intrathoracic structures are sometimes visualized by fluoroscopy or x ray

TREATMENT —Chronic constrictive pericarditis may be cured by pericardial resection in properly selected cases as suggested by Delorme Brilliant results from this operation have been secured within the past few years by surgeons specially skilled in thoracic surgery Medical treatment consists of the usual measures for combating myocardial insufficiency although digitalis is of no value and may be harmful The use of mercurial diuretics (1 to 3 cc of Salyrgan or Mercupurin intravenously) preoperatively and postoperatively may be life saving in the extremely edematous patient In adherent pericardium with external adhesions Brauer has advocated the resection of several ribs and costal cartilages overlying the pericardium in order that the heart may pull against yielding rather than rigid structures This procedure is palliative rather than curative

JOHNSON MCGUIRE

PERICARDIAL DISEASES AS A CAUSE OF ACUTE CARDIAC COMPRESSION

BECK has described a triad which characterizes acute cardiac compression ' (1) A rising venous pressure (2) a falling arterial pressure (3) a small quiet heart The principal causes for acute cardiac compression are penetrating wounds of the chest causing laceration of the heart or coronary vessels and extravasation of blood into the pericardial cavity Other causes are rupture of a myocardial infarct of an aortic aneurysm a dissecting aneurysm or rupture of a contusion of the myocardium Rapidly developing effusions or the formation of gas within the pericardial cavity also cause acute cardiac compression

The condition is characterized in its early stage by weakness of the pulse and often pulsus paradoxus The skin is pale cold and clammy and the heart sounds are weak The veins may not be conspicuously dis

tended but measurement of venous pressure shows definite elevation above the normal Treatment depends upon the cause of the compression In cases of cardiac laceration immediate operation and suture of the site of hemorrhage is frequently life saving and is superior to expectant treatment as shown by the results of cases treated by both

cordial pain tachycardia dyspnea and occasionally cyanosis Electrocardiographic changes in the T waves and RS T segments may occur in either tamponade or myo cardial contusion resembling the changes de scribed under Acute Fibrinous Pericarditis

JOHNSON MCGUIRE

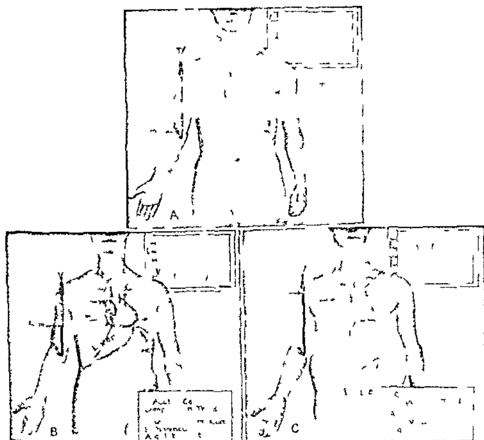

Fig 118—Cardiac compression triads For comparison normal (*A*) acute (*B*) and chronic (*C*) The acute compression is produced by fluid in the pericardial cavity Note collapse of the venous gateway and distention of the veins outside the pericardium The ventricles are shrunken and the heart *per se* is smaller than normal The parietal pericard um has not had time to dilate nor has there been sufficient time for the liver to en large and for ascites to form In the illustration for chronic compression of the heart the compression is pro duced by scar tissue The heart is a small shrunken organ in contradistinct on to cardiac dilatation The veins dilate in response to the high venous pressure The liver and spleen enlarge and ascites develops (Beck, C S J A M A *104* 714 1935)

methods at the Cincinnati General Hospital Contusion of the heart following penetrating or non penetrating injuries to the chest occasionally produces pericardial effusion and compression Even in the absence of effusion cardiac contusion resembles and must be differentiated from cardiac tam ponade The diagnostic features of cardiac contusion *include* thoracic trauma pre

OTHER CONDITIONS AFFECTING THE PERICARDIUM

Pneumopericardium — Pneumopericar dium resulting from the presence of gases in the pericardium is a rare condition This condition may follow penetrating wounds an infection caused by gas forming organ isms rupture of a hollow viscus or rupture of the lung into the pericardium

When pneumopericardium is present, relative cardiac dulness is replaced by tympany, and if a fluid exudate collects peculiar splashing and churning sounds are audible On x ray examination the air within the pericardium is apparent If the fluid is purulent or pneumocardiac tamponade develops, drainage is indicated

Hydropericardium — Hydropericardium is that condition in which a transudate collects in the pericardial cavity In many chronic disorders especially cardiac and renal disease a slight excess of fluid (25–200 cc) may be found at autopsy

Hydropericardium *per se* causes no symptoms except in rare instances when an excessive amount of fluid develops In such cases the usual signs found with pericardial effusion appear and paracentesis may be necessary

Calcified Pericardium —When any inflammatory exudate about the heart becomes organized, lime salts may be deposited Such calcification of the pericardium most commonly follows tuberculous and pneumococcus pericarditis The extent of the calcification is variable, in some instances it involves the entire pericardium The signs of chronic constrictive pericarditis may be found More often the condition is found at autopsy or by x ray examination and is of no clinical significance *per se*

Tumors of the Pericardium —Primary neoplastic disease of the pericardium is extremely rare Secondary invasion by carcinoma malignant lymphoblastoma melanoma or fibrosarcoma may occur

Congenital Pericardial Defects —Rarely the parietal pericardium is absent This results in unusual mobility of the heart, and pain and sudden death have been reported with this condition owing to sudden kinking of the great vessels as a complication of excessive cardiac mobility

DISEASES OF THE MYOCARDIUM

DISEASES of the myocardium may be divided into the acute and the chronic forms The term *myocarditis* has been applied to both forms but it seems unsuited to the chronic types in which the pathologic process is more commonly degenerative than inflammatory With rare exceptions all of the diseases of the myocardium are secondary to local or general diseases The primary disease may be infectious, toxic or of unknown cause such as hypertension or arteriosclerosis These result directly or indirectly in alterations in the heart muscle which may or may not produce anatomic change that is demonstrable after death but which during life gave rise to symptoms due to impairment of the heart s efficiency as a pump Dilatation and hypertrophy of the heart are fundamental changes nearly always present in myocardial disease

Dilatation —When the normal ventricle is made to eject blood against a greater resistance than that to which it is accustomed or when the contractile power of the ventricle is impaired while the resistance remains normal strain of the heart sets in Under such conditions the ventricle tends to reduce its systolic discharge, the blood which consequently remains in it when added to that which enters during diastole increases the diastolic volume and raises the initial tension to which the muscle is subjected It is a cardiac law that increased lengthening and stretching increase the irritability and contraction so that the systolic output in relation to diastolic inflow is restored to normal This capacity for adaptation is large in a healthy person but is limited or even lost in the presence of disease or impairment of myocardial integrity or efficiency so that pathologic dilatation develops readily and leads to congestive heart failure In cardiac failure the heart is no longer able to

discharge as much blood as it receives and venous pressure rises throwing added strain on the myocardium Dilatation may result then from two causes passive distention when the elastic resistance of the myocardium is overcome by increased initial intraventricular pressure, and diminution of tonus which allows the ventricle to accommodate an increased volume of fluid without raising the initial tension necessary to increase the strength of its beat

Hypertrophy is a compensatory phenomenon by which the diameter of the muscle fibrils is increased The nature of the responsible stimulus is unknown but both experimental and clinical evidence indicates that it is a physiologic reaction to continued overwork Starling s law states ' that the mechanical energy set free in passing from the resting to the contracted state depends on the area of chemically active surfaces *i.e* on the length of the muscle fibers Although the thicker and longer muscle fibers of the enlarged heart are mechanically advantageous they work under chemical and physiochemical disadvantages which lead them to fail under strain more readily than fibers of normal size Their hypertrophy is not accompanied by a proportional increase in their blood supply that is in oxygen and nutrition and this contributes to their easier exhaustibility The dilated and hypertrophied heart is therefore one that has a limited reserve

It follows from these considerations that enlargement of the heart may result from a variety of factors and may be expected to predominate in that chamber which is subject to the greatest mechanical strain Thus necropsy generally reveals preponderant enlargement of the right side of the heart in patients whose hearts failed as the result of interference with blood flow through the pulmonary circuit Such a condition is likely to be found in chronic emphysema long standing asthma pulmonary fibrosis stenosis of the pulmonic valve and other conditions It is often called *Cor Pulmonale* In the higher degrees of mitral stenosis enlargement of the left auricle is likely to be predominant but this is very often associated with much enlargement of the right ventricle or the whole right heart Conversely in systemic hypertension aortic valve lesions coarctation of the aorta and so on left sided enlargement generally shows significant dominance It must be remembered that the heart arteries and veins form a complete circuit so that alterations in flow originating in one portion are certain to be reflected by secondary alterations in the others Hence in most cases of heart failure all of the chambers of the heart are generally involved to a greater or lesser extent in the process of dilatation and hypertrophy

Congestive heart failure is described elsewhere but in view of the foregoing paragraph it should be mentioned that such failure may also be dominantly one-sided may result from failure of both sides or may begin as one sided and rapidly become generalized *Failure of the right heart* is manifest clinically by increased pressure stasis and congestion in the systemic veins The veins are visibly distended there is enlargement of the liver renal congestion causes albuminuria and oliguria splanchnic congestion produces digestive disorders edema pleural effusion and ascites develop *Left heart failure* leads to venous stasis and congestion in the pulmonary circuit This produces dyspnea orthopnea and cough along with cyanosis and owing to the relative lesser strength of the right heart secondary dilatation and failure are prone to follow shortly resulting in the commonest clinical picture that of generalized cardiac failure

Acute Myocarditis —*Definition* —Acute myocarditis is an acute inflammation of the walls of the heart

Incidence —The disease occurs at all ages and in both sexes It is commonest in childhood and early adult life and is comparatively rare in individuals more than forty The frequency with which acute myocarditis occurs cannot be stated because it often runs its course without producing any symptoms which make diagnosis possible The clinical diagnosis is sometimes made erroneously no myocardial lesions being found at autopsy

Etiology —Acute myocarditis is probably always secondary It may be caused by any of the acute infections but occurs most frequently in acute rheumatic fever diphtheria influenza typhoid fever scarlet fever smallpox erysipelas septicemia pyemia

When pneumopericardium is present relative cardiac dulness is replaced by tympany, and if a fluid exudate collects peculiar splashing and churning sounds are audible On x ray examination the air within the pericardium is apparent If the fluid is purulent or pneumocardiac tamponade develops, *drainage is indicated*

Hydropericardium — Hydropericardium is that condition in which a transudate collects in the pericardial cavity In many chronic disorders, especially cardiac and renal disease a slight excess of fluid (25–200 cc) may be found at autopsy

Hydropericardium *per se* causes no symptoms except in rare instances when an excessive amount of fluid develops In such cases the usual signs found with pericardial effusion appear and paracentesis may be necessary

Calcified Pericardium —When any inflammatory exudate about the heart becomes organized lime salts may be deposited Such calcification of the pericardium most commonly follows tuberculous and pneumococcus pericarditis The extent of the calcification is variable in some instances it involves the entire pericardium The signs of *chronic constrictive pericarditis* may be found More often the condition is found at autopsy or by x ray examination and is of no clinical significance *per se*

Tumors of the Pericardium —Primary neoplastic disease of the pericardium is extremely rare Secondary invasion by carcinoma malignant lymphoblastoma melanoma or *fibrosarcoma may occur*

Congenital Pericardial Defects —Rarely the parietal pericardium is absent This results in unusual mobility of the heart and pain and sudden death have been reported with this condition owing to sudden kinking of the great vessels as a complication of excessive cardiac mobility

DISEASES OF THE MYOCARDIUM

DISEASES of the myocardium may be divided into the acute and the chronic forms The term *myocarditis* has been applied to both forms but it seems unsuited to the chronic types in which the pathologic process is more commonly degenerative than inflammatory With rare exceptions all of the diseases of the myocardium are secondary to local or general diseases The primary disease may be infectious toxic or of unknown cause such as *hypertension* or arteriosclerosis These result directly or indirectly in alterations in the heart muscle which may or may not produce anatomic change that is demonstrable after death but which during life gave rise to symptoms due to impairment of the heart s efficiency as a pump Dilatation and hypertrophy of the heart are fundamental changes nearly always present in myocardial disease

Dilatation —When the normal *ventricle* is made to eject blood against a greater resistance than that to which it is accustomed or when the contractile power of the ventricle is impaired while the resistance remains normal strain of the heart sets in Under such conditions the ventricle tends to reduce its systolic discharge the blood which *consequently remains in it* when added to that which enters during diastole increases the diastolic volume and raises the initial tension to which the muscle is *subjected* It is a cardiac law that increased lengthening and stretching increase the irritability and contraction so that the systolic output *in* relation to diastolic inflow is restored to normal This capacity for adaptation is large in a healthy person but is limited or even lost in the presence of disease or impairment of myocardial integrity or efficiency so that pathologic dilatation develops readily and leads to congestive heart failure In cardiac failure the heart *is no longer* able to

easily compressible and reflects the irregularity of the heart The blood pressure is usually diminished and the systemic veins are collapsed The apex impulse is diffuse displaced to the left and may be feeble when palpated The heart is usually dilated and when this is marked the area of cardiac dulness is enlarged and systolic murmurs may be present at the base or apex or over the whole heart The sounds are often slapping and the first sound is likely to be of poor quality These symptoms are due chiefly to a circulatory failure of vasomotor origin

When CONGESTIVE HEART FAILURE sets in the usual symptoms of passive venous congestion and deficient circulation develop cyanosis dyspnea orthopnea and cough and the veins of the neck are full There may be nausea and vomiting with a sense of fulness and pain in the epigastrium and right hypochondrium Dependent edema begins to appear and the urine becomes scanty and contains albumin and casts With these symptoms there are moist rales and impaired voice and breath sounds with diminished resonance at the base of the lungs or evidences of pleural effusion especially on the right side The liver may be considerably enlarged by congestion its lower border may extend down to the umbilicus and it may pulsate with systole There is marked tenderness in the hepatic region Ascites may develop These are all symptoms common to cardiac failure and are in no way peculiar to acute myocarditis but when they occur during or shortly after an acute infection in a patient whose heart was previously normal the diagnosis of acute myocarditis can be made with reasonable assurance

The clinical picture is often that of a combination of the phenomena of peripheral vascular failure with those of congestive heart failure

FEVER is common but is often masked by that due to the primary infection It is usually moderate (seldom above 103° F) and may be continuous or intermittent Moderate leukocytosis may occur with or without a relative increase in the polynuclear cell count but a normal count or even leukopenia is quite as *frequent* The red cell sedimentation rate is usually increased The increase is likely to persist as long as the inflammatory process remains It is commonly a more sensitive and trustworthy guide to healing than either leukocytosis or differential white cell counts There is usually moderate secondary anemia

RHEUMATIC MYOCARDITIS occurs to some extent in probably not less than 90 per cent of all patients with acute rheumatism The myocardial changes however in the majority of cases are slight and often transitory or heal without leaving clinical evidence of their existence Such slight involvement usually passes unrecognized unless special search is made In the more pronounced cases, the usual signs and symptoms are those just described Impulse conduction is frequently delayed This is recognizable only when graphic records are made because the heart block is seldom sufficient to cause dropped beats Premature contractions and nodal rhythm are very common but more serious arrhythmias such as auricular fibrillation are rare in the acute stage of rheumatic myocarditis Tachycardia is the rule although bradycardia may be encountered as a rare and usually grave symptom Rheumatic endocarditis and pericarditis very frequently accompany myocarditis and render its recognition difficult in many cases

DIPHTHERIA is complicated by myocarditis fairly often especially when the use of antitoxin has not been adequate or early This form of myocarditis may be slight and cause few symptoms but when diphtheria is severe or its treatment has been neglected the myocarditis is likely to be very severe and often rapidly fatal Even in patients with few or no recognizable cardiac symptoms the heart may be so extensively damaged that moderate exertion may cause collapse or sudden death The heart is dilated the pulse is feeble and readily compressible and the patient is easily exhausted A systolic murmur due to a relative mitral insufficiency is common Tachycardia is the rule in the first few days and sinoauricular block or premature contractions are frequent Bradycardia is more likely to occur in this form of myocarditis than in any other and is of gravest significance for it indi*cates extensive damage to the conduction* system with consequent severe heart block

and malaria It may result from direct invasion of the heart by the infecting organisms or from the action of their toxins which reach the heart through the blood stream Phosphorus arsenic chloroform and other poisons may also be causes as may severe degrees of thyrotoxicosis *Fiedler's myocarditis* is an acute or subacute form of unknown etiology occasionally seen in adults This is also called *idiopathic myocarditis* Acute myocardial infarction produces a localized area of acute degenerative myocarditis

Morbid Anatomy—The lesion may be a diffuse parenchymatous degeneration Grossly this appears as cloudy swelling of the muscle and microscopically as a granular change in the sarcoplasm of the muscle cells which may more or less obscure the striations This lesion is usually due to the action of bacterial or other toxins It may undergo complete resolution More commonly the lesions are focal in the interstitial tissues or around the blood vessels Between the muscle fibers there may be infiltration of round cells leukocytes and an albuminous exudate The muscle fibers undergo albuminous degeneration and lose their markings or show evidence of hyaline or fatty degeneration Infiltrations of round cells frequently occur beneath the pericardium and the mural endocardium so that these membranes are involved with the myocardium and the condition becomes pathologically carditis rather than pure myocarditis The destroyed muscle cells may be absorbed gradually and replaced by fibrous scar tissue These lesions are usually microscopic but occasionally they may produce scars visible to the naked eye

In some cases the chief or only lesion is an acute interstitial productive myocarditis This manifests itself as a primary increase in the cells of the fixed connective tissue and adventitia of the vessels with invasion of lymphocytes plasma cells and eosinophilic leukocytes Healing results in the formation of multiple minute scars which are very difficult to discover

A rare form of myocarditis occurs in sepsis and pyemia when bacterial emboli lodge in the finer arteries of the heart This may produce one or many abscesses A single large abscess may involve the entire thickness of the ventricular wall and may cause sudden death by rupture or may heal and leave a thin wall of fibrous tissue which bulges and forms a cardiac aneurysm

Rheumatic myocarditis is accompanied by characteristic lesions known as *Aschoff's nodules* These are submiliary collections of large spindle shaped or branching cells with large sometimes multiple nuclei They probably arise from the connective tissue and are accompanied by collections of lymphocytes and eosinophilic leukocytes They occur in the interstitial tissues usually around the blood vessels and just beneath the endocardium The interventricular septum is frequently involved and invasion or destruction of portions of the conducting system often produces varying grades of heart block The nodules are seldom visible on gross examination but are readily seen under the microscope They occur only in rheumatic fever but cannot always be demonstrated even in proved cases Parenchymatous and interstitial myocarditis may accompany the nodules

Diphtheritic myocarditis is due to the action of the toxin upon the heart muscle In most instances the heart muscle is flabby and edematous and especially where heart block is present there is an interstitial infiltration of polynuclear cells and lymphocytes in the region of the bundle of His If the damage is not too extensive the destroyed muscle cells are absorbed and replaced by scar tissue which is widely distributed and usually not grossly apparent

Symptoms—The onset of acute myocarditis rarely can be determined with accuracy because the condition usually develops during or immediately after an acute infection There are no characteristic symptoms but the condition is to be suspected if circulatory disturbances appear during or following acute infection Even under such circumstances diagnosis can seldom be made with certainty The symptoms of myocarditis may not develop for several weeks after subsidence of the acute infection

ACUTE MYOCARDITIS often causes anxiety and a sense of oppression or pain in the chest especially in the precordial region The *heart action* is usually disturbed the rate is rapid and any of the forms of irregularity may appear Bradycardia is an occasional manifestation The pulse is soft small

may be dangerous in peripheral vasomotor failure by diminishing further the already constricted vascular bed as well as the output of the heart Epinephrine is sometimes of value when administered slowly and continuously in the form of intravenous drip 1 cc of the 1 1000 solution being added to each liter of a 5 per cent solution of dextrose in normal saline solution From 1 to 3 liters may be injected slowly within twenty four hours Glucose given by rectum or clysis is valuable as a supportive measure at times The use of an ice-bag over the heart may be of some value and at least insures periods of complete quiet to keep it in position

During *convalescence* rest should be continued until the heart rate remains normal and the more serious disturbances of rhythm have disappeared Massage passive and later mild active movements should be begun before the patient is permitted to sit up Sitting up should be allowed for only a few minutes at first and the time very gradually increased The patient should not be permitted to get out of bed until he can sit up in bed without fatigue for several hours A nutritious easily digestible diet adequate in vitamins should be given Iron may be useful to combat anemia When the patient can be up and about a very gradual course of physical training may be instituted but in the more serious cases marked exertion cannot be allowed for several months

Chronic Myocardial Disease—Several types of chronic disease of the myocardium are generally described the differentiation being made on the basis of the pathogenesis or of the pathologic changes in the heart muscle This division may be reasonably satisfactory to the pathologist but from the clinical point of view it does not seem to serve any useful purpose because the majority of cardiac symptoms and signs are common to all types irrespective of pathology or pathogenesis The separate clinical discussion of each of these types has tended to confuse the minds of both students and physicians since however distinct they be pathologically they constitute symptomatically but a single syndrome The inclusion of the several types under the single title of *chronic myocardial disease* on the other hand serves to emphasize their clinical unity This plan of presentation simplifies the entire subject of chronic disease of the heart muscle and obviates much unnecessary repetition

Incidence.—Chronic myocardial disease occurs more frequently in men than in women (about 3 to 2) One third of all cases occur between the ages of fifty-one to sixty while three fourths of all are found in the three decades between forty-one and seventy years These figures are for conditions without structural lesions of the valves When those with organic valve lesions are included the age of greatest incidence is lowered by the large rheumatic group in which myocarditis accompanies the more evident endocarditis

Morbid Anatomy and Pathogenesis—CHRONIC MYOCARDITIS—The term 'chronic myocarditis has been used loosely to designate most or all of the conditions included by the term chronic myocardial disease' The term myocarditis should however be restricted to those conditions in which there is a productive inflammatory process in the heart muscle in contradistinction to those in which the lesion is essentially degenerative Chronic myocarditis may develop as a late stage of the acute process or may occur without previous evidence of the acute form The most common *acute infections* which cause it are acute rheumatic fever typhoid fever influenza the septicemias and occasionally diphtheria Chronic myocarditis of some degree is almost always associated with the various forms of chronic or subacute endocarditis and is often the most important cause of the cardiac symptoms in such cases

Gross examination of the heart reveals hypertrophy and dilatation and in some instances evidence of an increase in the quantity of fibrous tissue Microscopically there is round cell infiltration in the interstitial tissues and parenchymatous degeneration of the muscle fibers in areas where the process is active In older lesions there is connective-tissue proliferation and degeneration of the muscle cells which are ultimately replaced by fibrous scar tissue The latter process may end in healing but in many cases the processes are progressive or the inflammation undergoes remissions and exacerbations Chronic myocarditis may finally develop in a heart which is already the seat of old healed lesions remaining from an earlier at

This symptom may develop suddenly during convalescence from diphtheria, and is to be anticipated when tachycardia persists beyond the fourth or fifth day It is rapidly fatal in the majority of cases Studies by Burkhardt Eggleston and Smith indicate that the presence of changes in the electrocardiogram particularly increasing delay in the conduction time is of greater value in the early diagnosis of this condition than are any of the clinical findings

Diagnosis of acute myocarditis is always difficult and sometimes impossible In many cases it is little more than an inference based on the conditions under which the symptoms have developed The diagnosis at best is usually one of probability only and must often be reached mainly by a process of exclusion Acute myocarditis is not infrequently seen after death in patients who have had no symptoms from which a diagnosis could be made during life

Feeble, rapid pulse low blood pressure weakness exhaustion digestive disturbances restlessness and anxiety are produced in acute infections by *circulatory failure of vasomotor origin* as well as by acute myocarditis Differential diagnosis of their cause is often impossible Dilatation of the left ventricle may cause relative insufficiency of the mitral valve The signs of this type of insufficiency are the same as those evoked by mitral endocarditis Inasmuch as endocarditis is a common accompaniment of acute myocarditis especially in rheumatic fever differentiation between the two forms of mitral incompetence is often difficult

Course and Prognosis —Acute myocarditis may be very mild and permit early and complete recovery or so extremely severe that it is fatal within a few days Death is most likely to ensue in the septic and diphtheritic types The intensity of the clinical manifestations may not be a true index of the ultimate prognosis Patients with few and slight symptoms may succumb rapidly while others with marked clinical symptoms may recover gradually and suffer little permanent functional impairment of the heart Partial recovery is common the heart remaining permanently damaged to a considerable extent or the myocarditis may become chronic The physician should always therefore be guarded in giving a prognosis either as to probable duration or ultimate outcome

Treatment should begin with efforts to prevent the development of acute myocarditis in every patient with one of the probable causative infections The patient should be kept at complete rest in bed until all evidences of active infection have disappeared Where the infection has been severe or of long duration this should continue well into convalescence In acute rheumatic fever the patient should not be allowed to sit up in bed until the temperature has remained normal for at least two weeks and the red cell sedimentation rate has fallen to normal When cardiac symptoms have been present this period should be lengthened The early and adequate administration of antitoxin is the most effective means of preventing the development of diphtheritic myocarditis This should be combined with the measures just outlined

The treatment of acute myocarditis itself consists primarily in securing *maximum rest for the heart* along the lines set forth in the foregoing paragraph During the active stage the patient must be confined to bed The use of the bed pan and urinal must be insisted upon and the subject should not even feed himself and must not sit up in bed All forms of mental excitement must be avoided and abundant sleep secured by the use of bromides and simple sedatives *Drug therapy* is not called for unless there be evidence of cardiac failure Cardiac stimulants may then become necessary Strychnine and alcohol have their advocates but there is no satisfactory evidence that they are of any real value The administration of oxygen may enhance the patient s comfort and perhaps the chance of recovery Digitalis which is a most valuable agent in the treatment of chronic cardiac disease is usually useless in acute myocarditis and may be dangerous It is best to omit it entirely If tried it should be administered in small doses (0 1 Gm [1½ grains] of the leaf three or four times daily) and a close watch maintained for unfavorable effects Caffeine and theobromine are often better stimulants in such conditions and are best given subcutaneously in the form of one of their soluble preparations Intramuscular injection of epinephrine (adrenalin) is rarely of value and

degeneration It often appears in chronic valvular disease with other evidences of chronic myocarditis and may be produced by prolonged infections and by chronic poisoning with phosphorus arsenic and chloroform it occurs very commonly in severe anemia The heart may appear almost normal grossly it may be flabby and yellowish in color In severe anemia small patches or strips of yellow may be visible beneath the endocardium especially in the papillary muscles and the trabeculae (tiger heart) The fat is probably deposited in the heart to replace destroyed muscle tissue and comes from without rather than from within the heart itself

FATTY INFILTRATION or the FATTY HEART is a part of general obesity and is said to be especially common among excessive beer drinkers In this condition the heart is encased in an excessively thick layer of subpericardial fat This often penetrates into the myocardium between the muscle bundles and may even cause degeneration and destruction of some of them The heart is usually somewhat dilated and hypertrophied The only symptoms are those of heart failure in an obese patient

Symptoms of chronic myocardial disease not infrequently appear in exophthalmic goiter and toxic adenoma of the thyroid The frequency and extent of structural change in the myocardium in these disturbances has not been adequately studied The left ventricle and later the whole heart may undergo hypertrophy and dilatation Patchy or diffuse thickening of the endocardium may occur and at times extend into the adjacent muscle There may be some lymphocytic infiltration of the myocardium Structural changes may be wholly lacking This is evidenced clinically by the fact that relief of the thyrotoxicosis is often followed by prompt and lasting disappearance of all evidences of cardiac involvement Myxedema may be accompanied by symptoms of myocardial insufficiency and an enlarged heart There are however no specific pathologic changes to be found other than coronary sclerosis and some parenchymatous degeneration of the muscle Myxomatous degeneration is rare

The prolonged excessive physical exertion required of professional athletes and certain classes of laborers has been thought to cause hypertrophy and chronic myocardial damage Studies by Gordon Levine and Wilmaers on a series of Marathon runners failed however to reveal cardiac enlargement even in men who had engaged in the most vigorous physical effort for many years It seems probable that physical exertion alone does not cause myocardial damage in the absence of infection vascular changes or other disease

BERIBERI HEART (vitamin B deficiency) has been thought by Weiss and his associates and earlier by Wenckebach to be a definite clinical entity accompanied by manifestations of myocardial insufficiency low blood pressure and enlargement of the heart especially of the right side There are no specific pathologic changes though there may be some hydropic degeneration of the muscle fibers along with other nonspecific changes The diagnosis is a clinical one and rests upon the preceding phenomena found in a patient with a history of gross deficiency of vitamin B in his diet or with clinical beriberi as revealed by symptoms The diagnosis is felt by some to be confirmed by favorable response to the administration of thiamine chloride or the vitamin B complex which may have to be given parenterally The electrocardiogram in beriberi heart disease is characterized mainly by low voltage of the QRS and the T waves

Symptoms —Chronic myocardial disease may produce no symptoms whatever and may even be the cause of sudden death in apparently healthy individuals Careful examination will in most cases however reveal abnormalities which are sufficient to establish the probable diagnosis Close questioning also brings to light symptoms indicative of some impairment of cardiac efficiency which the patient often considers unimportant such as moderate shortness of breath following stair climbing walking against a high wind or running a short distance Some degree of hypertrophy and dilatation is almost invariably associated with chronic myocardial disease even when there are no symptoms This should be found in the course of routine examination especially if this includes fluoroscopic study and should arouse suspicion of chronic disease of the heart muscle Occasionally fibrillation of the

tack The changes are least marked in the auricles and usually best developed in the left ventricle

Syphilis.—Despite its frequent involvement of the aorta syphilis is rarely a direct cause of chronic myocarditis by virtue of invasion of the myocardium by the *Treponema* It may produce solitary or multiple gummata but even these lesions are rare *Chronic focal infection* in the teeth, tonsils sinuses gallbladder or elsewhere may occasionally be a cause It is difficult and often impossible however to establish any relationship between chronic myocarditis and such disturbances *Tuberculous myocarditis* is extremely rare except in association with tuberculous pericarditis or general miliary tuberculosis In both conditions the myocarditis is masked by the symptoms of the underlying tuberculous process

Fibrosis of the Myocardium (Interstitial Myocarditis) —This is by far the commonest form of chronic myocardial disease and is usually the result of arteriosclerosis of the coronaries generalized arteriosclerosis syphilitic coronary ostial stenosis or arterial hypertension Each of these conditions may cause destruction of muscle fibers from impairment of the circulation to the heart The muscle fibers become fragmented lose their nuclei and may ultimately be replaced by new fibrous tissues The interstitial fibrous tissue may also proliferate Scars are thus formed in the myocardium When a coronary artery is narrowed at its mouth or in one or more of its main branches the lesion is more or less diffuse in the entire area which it normally supplies when one or more small branches are chiefly affected or completely occluded by thrombi the process is focal The occlusion of a medium sized branch results in myocardial infarction with destruction which may involve the entire thickness of the ventricular wall Healing produces a fibrous scar which is called a 'myocardial cicatrix If large this may stretch gradually and bulge with the production of a cardiac aneurysm Hearts with this type of degeneration are dilated and hypertrophied The fibrosis may not be visible to the naked eye or small whitish areas of fibrous tissue scattered throughout the ventricular musculature may be apparent on close examination Such areas are most commonly found near the apex of the left ventricle and in the papillary muscles but they may appear anywhere The focal lesions are usually readily visible as grayish white patches beneath the endocardium and within the ventricular wall on section

Chronic myocardial disease due to *hypertension* causes fairly characteristic pathologic changes There is marked hypertrophy of one or both ventricles with extensive dilatation Some of the largest hearts are found to be the result of prolonged hypertension Macroscopically the muscle appears essentially normal but microscopically there may be diffuse proliferation of connective tissue within and between the muscle bundles or there may be no evidence of pathologic change other than hypertrophy The auricles are much less affected than the ventricles They are usually dilated however and at times undergo considerable hypertrophy The condition known as *essential hypertension* and the hypertension associated with *chronic nephritis* are the two great causes of this type of myocardial degeneration and are regarded by some as the commonest causes of chronic myocardial disease in general The left side of the heart is predominantly affected but in the later stages right sided dilatation and hypertrophy are usually also found Involvement may be limited chiefly to the right ventricle and auricle in congenital pulmonary stenosis in long standing bronchial asthma or pulmonary emphysema and under other conditions in which there is continued hypertension in the pulmonary circuit

Autopsy sometimes reveals no pathologic changes in the myocardium other than dilatation or hypertrophy yet the patient may have presented during life a typical picture of congestive heart failure The failure in such cases seems best explained on the theory of a gradual exhaustion of the dilated and hypertrophied ventricular muscle as the result of prolonged overwork combined with the physiologic disadvantages under which the hypertrophied muscle fibers have been compelled to labor A relative physiologic inefficiency has led to a final functional insufficiency with exhaustion and death

MISCELLANEOUS CONDITIONS —Fatty degeneration is frequently one of the pathologic changes associated with chronic myocardial

block causes dropping of the beats which can be differentiated from premature beats by the silence of the heart during a period nearly equal to that of two normal cycles In partial or complete block the ventricular rate may suddenly fall so low as to cause temporary cerebral anemia The patient goes into syncope and often has a convulsion (Adams Stokes syndrome) The electrocardiogram may show the presence of some degree of intraventricular block

The *heart sounds* are altered in various ways They are often diminished but may be loud and have a slapping quality If systemic blood pressure is much elevated the second aortic sound is accentuated The pulmonic second sound is accentuated by increased pressure in the pulmonary circulation with or without signs of passive congestion of the lungs The first sound at the apex may be increased when there is ventricular hypertrophy or it may be diminished and of poor muscular quality in dilatation It is sometimes impure and often split Reduplication of either sound may cause a gallop rhythm

Murmurs may or may not be present They are due to an associated valvular lesion caused by preceding endocarditis valvular sclerosis or to extensive dilatation of the heart with resulting functional incompetence of the valves Differentiation between their causes is difficult and may be impossible Dilatation of the left heart often produces functional mitral incompetence evidenced by signs identical with those of incompetence due to mitral endocarditis Rarely extreme dilatation renders the aortic valves incompetent by stretching the aortic ring Incompetence of the tricuspid valve occurs frequently when the right heart is dilated It may produce the typical systolic murmur over the lower end of the sternum but a murmur is often absent or is obscured by the systolic murmur of mitral insufficiency With marked relative tricuspid insufficiency the neck veins are full and show a ventricular type of pulsation With this the liver is enlarged usually tender and often shows an expansile pulsation with cardiac systole

The *physical signs* in the cardiovascular system vary greatly Some enlargement of the heart is almost invariably present because of hypertrophy and dilatation Since it is rarely possible to determine by physical examination which of the two factors predominates it is customary to use the inclusive term enlargement In the presence of failure however, dilatation may be assumed to be in the ascendency The extent of enlargement varies, although it is pronounced in the majority of cases The apical impulse is usually forcible and often heaving when there is great hypertrophy, marked dilatation on the other hand usually renders it diffuse and feeble The lower outer point of the apex impulse is the most trustworthy clinical evidence of enlargement of the heart

The most important symptoms of chronic myocardial disease are those due to congestive heart failure or to the anginal syndrome For clarity as well as emphasis they are accorded separate descriptions

CONGENITAL AFFECTIONS OF THE HEART

Definition—In the course of intra uterine life anomalies in the position and structure of the heart or great vessels sometimes result from faulty development or disease Such defects comprising the congenital affections of the heart usually lead to disturbances in the circulation and give rise to abnormal physical signs

This group of conditions affects a relatively small number of individuals for it comprises only about 2 per cent of all cases of organic heart disease Many of the infants with such defects die during the first few days or weeks after birth The etiology is but imperfectly understood The distinction between congenital and acquired lesions as a rule is not difficult To date the only defect which has been repaired successfully by operation is patent ductus arteriosus

Etiology—Congenital affections of the heart are frequently associated with other

auricles may be unnoticed by the patient, a reduplicated first sound may be found, or pulsus alternans may be discovered during auscultatory determination of the blood pressure Finally, a routine electrocardiographic examination may reveal defects in conduction such as intraventricular block

Usually chronic myocardial disease evokes the common symptoms of heart failure or myocardial insufficiency These are not pathognomonic of the condition which causes the failure The number or severity of the symptoms varies greatly and *there is no* necessary relationship between their number or intensity and the nature or extent of the structural changes in the heart although certain syndromes are more characteristic of one type of myocardial disease than of others Anatomically slight lesions may cause severe symptoms especially if they involve the conduction system, while extensive damage of the ventricular musculature may produce only minor symptoms of impaired cardiac efficiency It is important to keep these facts always in mind if serious errors in diagnosis or prognosis are to be avoided

The *symptoms referable to the cardiovascular system* are few and relatively unimportant in most cases Palpitation fluttering or subjective precordial beating may accompany auricular fibrillation auricular flutter premature beats (extrasystoles) or marked enlargement of the heart There may be a sense of fulness in the precordial region fleeting pains or a dull heart ache and some precordial tenderness is not uncommon *Throbbing of the peripheral arteries* especially in the neck may occur with aortic insufficiency or hyperthyroidism but is uncommon otherwise and is unimportant

The NERVOUS SYSTEM is affected by the inadequate circulation which causes a sense of weakness or exhaustion and drowsiness Sleeplessness may occur and hallucinations or delirium may develop The memory is often impaired and mental effort may cause severe fatigue

CYANOSIS is the rule but it is often slight and may be absent Pallor is frequent and in the late stages the skin and sclerae may be icteric Digestion is usually impaired the appetite is poor or lost and gaseous distention is often a prominent and troublesome symptom Nausea and vomiting are rather common as the result of congestion in the splanchnic area They may be associated with pain and soreness in the epigastrium and right hypochondrium which is usually due to more or less acute congestion and swelling of the liver

KIDNEY FUNCTION is impaired, oliguria is often marked and the urine is concentrated and of high specific gravity It may be dilute with a low and fixed gravity when there is an associated nephrosclerosis It may contain considerable albumin and all types of casts except the waxy The excretion of phenolsulfonphthalein may be as low as 15 to 30 per cent With the impaired renal function nitrogenous waste products may be retained in the blood but this is seldom marked

The *heart rate* is commonly increased even during rest Auricular fibrillation is present in the majority of cases This may be transitory or paroxysmal but is generally permanent The rate of the ventricles is usually rapid (120 or more beats per minute) and there is total irregularity of the beats both in force and in rhythm The rate varies from minute to minute and is peculiarly subject to marked acceleration after exertion Many of the ventricular beats are too feeble to transmit a wave to the wrist so that the radial pulse rate is usually less than that of the heart This difference is called the *pulse deficit* and its degree is usually more or less parallel to the degree of cardiac failure The radial pulse rate must never be considered an index of the heart rate in fibrillation

AURICULAR FLUTTER is comparatively uncommon PREMATURE VENTRICULAR BEATS (extrasystoles) are often present if the heart rate is not very high They are characterized by their prematurity and by the long subsequent diastole The premature systole can be heard over the heart but sometimes cannot be felt in the pulse Premature beats have relatively little significance unless they are very numerous They may then contribute to the embarrassment of the circulation *Complete heart block* is not infrequent especially in cases with extensive coronary sclerosis It is easily recognized by the very slow heart rate (below 40 per minute) the rhythm being regular *Incomplete*

great vessels or abdominal viscera There is sometimes complete *situs inversus* Transposition of the large arterial trunks is likewise not uncommon If unassociated with structural defects dextrocardia may give rise to neither symptoms hypertrophy cyanosis nor heart murmur and may be accidentally discovered in the course of a physical examination

Anomalies of Structure—Structural anomalies may result from incomplete development of certain parts of the heart such as one of the septa from fetal endocarditis or from persistence of fetal conditions such as the foramen ovale or ductus arteriosus (Botalli)

Pulmonic Stenosis—Narrowing of the pulmonic orifice is one of the commonest forms of congenital heart disease It was formerly regarded as being often the result of fetal endocarditis but is now usually believed to be due to a failure of proper development of the infundibulum of the right ventricle

The stenosis varies in degree depending in a measure on whether it is located in the muscle of the ventricle in the infundibular region or in the valvular ring Usually there is an associated defect in the ventricular or auricular septum or a patent ductus arteriosus A frequent combination is stenosis of the infundibulum of the right ventricle and of the pulmonary valve defect in the interventricular septum dextroposition of the aorta and enlargement of the right ventricle (tetralogy of Fallot) The patency of the septum or ductus is to be regarded as a compensatory mechanism for relieving the heightened pressure within the right ventricle

Pulmonic Atresia—Obliteration of the pulmonic orifice is a less frequent but more serious lesion than pulmonic stenosis The pulmonary artery is very small and there may be persistence of the ductus arteriosus together with patency of the foramen ovale or defect in the ventricular septum

Pulmonic insufficiency is relatively rare It is usually due to fetal endocarditis

Tricuspid or mitral defect is uncommon Stenosis or atresia is more frequently seen than insufficiency

Anomalies of the Cardiac Septa—(1) Defect in the Interauricular Septum—Patent foramen ovale is a frequent congenital defect, commonly found in association with pulmonic stenosis or an imperfect ventricular septum The membrane closing the foramen ovale may fail at one point to become attached to the ring about it leaving a valvelike slit Neither this opening nor small fenestrations which may occur in the membrane are of any clinical significance and are not infrequently encountered in necropsies on persons who have died of various unrelated affections

(2) Defect in the Interventricular Septum—A defect in the interventricular septum (Roger s disease) is one of the common congenital lesions and in about half the cases is associated with pulmonic stenosis The opening between the ventricles under such circumstances acts as an escape valve for the overloaded right heart The defect is usually in the upper part of the septum If the septa of both auricles and ventricles are lacking the heart consists of only two chambers as in fish If in the absence of the ventricular septum the auricular septum is present the heart is composed of three cavities—*cor triloculare* Defect of the membranous septum when the only lesion present is not incompatible with a long and fairly active life Such was the case in the instance of Professor Brooks of the Johns Hopkins University who although he knew from early manhood that he had heart trouble accomplished an extraordinary amount of work and lived to be about sixty (Osler)

Patent Ductus Arteriosus—An open ductus Botalli is comparatively rare as a solitary lesion about two thirds of the cases have other congenital cardiac defects as well This fetal vessel however frequently remains patent in the presence of pulmonic stenosis usually in combination with a defect in one or both septa The blood may thus reach the lungs by an accessory channel when the pulmonic orifice is narrowed The persistence of the ductus arteriosus is often necessitated by other structural changes in the heart

Coarctation of the Aorta—When the ductus arteriosus shrinks the aorta sometimes becomes narrowed or completely occluded at the point of juncture The condition is often overlooked for it is compatible

forms of imperfect development notably mental deficiency They are said to occur more often in firstborn children than in later ones The causes of defective growth are not known Occasionally it appears that heredity plays a part in that such anomalies may appear in direct or collateral line for several generations Consanguinity is regarded as an important factor in exerting this hereditary influence Instances have been recorded in which infections in the mother during pregnancy particularly rheumatic fever and syphilis have been followed by the birth of children with imperfect hearts, although the association between cause and effect has not been definitely established

Fetal endocarditis is probably responsible for valvular deformities in a small number of cases It is almost invariably of the right side affecting chiefly the pulmonic valves It is nearly always of the chronic or sclerotic variety and it is often difficult to say whether the lesion has resulted from infection of the heart valves or represents an error in development In many instances the processes are combined infection being superimposed upon a structurally imperfect valve The majority of congenital cardiac lesions can be traced to defective growth

Pathology —In most cases several lesions are present so that a variety of combinations is possible and is indeed encountered To enumerate them would involve making a catalogue of cardiovascular curiosities and would serve no practical end The following clinical classification proposed by Maude Abbott is particularly useful for prognosis

I *The Group without Cyanosis* —There is no abnormal communication between the two circulations the anomaly itself is the seat of strain The lesions are mostly on the left side They include simple dextrocardia anomalies of the pericardium (defect or diverticulum) coarctation of the aorta (adult type), primary congenital hypertrophy sub aortic stenosis, aortic or mitral stenosis or atresia bicuspid aortic valve right or double aortic arch right subclavian artery arising from the descending aorta and left coronary artery arising from the pulmonary artery

II *The Group with Possible Transient or Terminal Cyanosis* (*Cyanose Tardive*) —An arterial venous shunt is present but there is no cyanosis unless circumstances arise which raise the pressure in the right side of the heart Then transient or terminal reversal of flow takes place, with venous blood entering the arterial stream Included in this group are patent ductus arteriosus, defect of the aortic septum defect of the auricular septum patent foramen ovale and defect of the ventricular septum

III *The Group with Cyanosis* —There is a permanent venous arterial shunt and venous blood in considerable quantity enters the systemic arterial circulation In this group are included pulmonic stenosis with or without septal defect, pulmonic atresia transposition of the great arterial trunks cor triloculare, persistent truncus arteriosus, and the tetralogy of Fallot, in which there is pulmonic stenosis defect of the ventricular septum dextroposition of the aorta and right ventricular hypertrophy

The commonest lesions encountered in the order of frequency are interauricular septal defect interventricular septal defect patent ductus arteriosus pulmonic stenosis anomalies of the semilunar cusps coarctation of the aorta (adult type), and transposition of the arterial trunks It is important to remember that in the great majority of cases several lesions are present The most frequent combinations are pulmonic stenosis with defective ventricular septum pulmonic stenosis with defective auricular septum the three defects associated or pulmonic stenosis and defective ventricular septum with patent ductus arteriosus Of 242 cases tabulated by Holt only 23 showed a single lesion

For purposes of description two main types of defect may be distinguished (1) anomalies of position (2) anomalies of structure

Anomalies of Position —Absence of the heart *acardia* is a rare monstrosity In *ectopia cordis* the ventral thoracic wall fails to unite in the midline and the heart may lie outside the chest cavity though enclosed by pericardium and covered by skin and subcutaneous tissue The heart may be situated in the cervical pectoral or abdominal regions Under these circumstances extra uterine life is rarely possible

Of some clinical interest are the instances of *dextrocardia* which may or may not be associated with transposition of the

per cent The leukocytes are increased but little, if at all The temperature tends to be subnormal The children are often under sized and backward in development Mental retardation may be an associated anomaly or an effect of the circulatory condition In infants feeding furnishes a difficult problem Attacks of syncope precordial pain and epileptiform convulsions are sometimes very distressing In some instances despite the presence of cyanosis and cardiac enlarge ment the patient may make no complaint of discomfort

Diagnosis —In the diagnosis of congenital heart disease two distinct problems are presented first a congenital must be dis tinguished from an acquired lesion second a precise anatomic differentiation of the va rious defects may be attempted The recog nition of a congenital lesion is of prognostic importance and is usually relatively easy The complexity of the numerous combina tions of defects and the variability of the physical signs make precise definition of the structural anomalies extremely difficult In the majority of cases only a probable anatomic diagnosis can be made

Cyanosis clubbed fingers a loud murmur (usually systolic) and cardiac hypertrophy are the chief diagnostic features Occurring in a young individual who has never had any of the manifestations of rheumatic in fection with a history of symptoms begin ing in infancy or early childhood they are of particular significance The cases without cyanosis seen in older children occasionally offer some difficulty in distinguishing con genital from acquired disease The intensity of the murmur the absence of left ventricu lar hypertrophy the persistent absence of symptoms and a lesion which gives no signs of progres ion favor the opinion that there is a congenital malformation In an emic children basal systolic murmurs may raise the question of the existence of a con genital lesion Such murmurs are softer than those due to congenital defects and are un accompanied by cardiac enlargement or cyanosis Subsequent examination when the general condition has improved serves to decide the issue

Murmurs are present in practically every case sometimes particularly in infants none is heard They are usually systolic in time and harsh in quality Though often audible over a wide area the point of maximum in tensity is either at the base or over the body of the heart very rarely at the apex. A systolic murmur at the base is most fre quently *due to pulmonic stenosis* less com monly to aortic stenosis When heard loudest over the body of the heart especially along the left sternal border it is some times indicative of a defect in the inter ventricular septum In view of the fact that pulmonic stenosis and patency of one of the cardiac septa are so often associated it is difficult to decide upon which lesion the murmur depends In pulmonic stenosis the second pulmonic sound is usually diminished in intensity A systolic thrill may or may not be present It is not of diagnostic impor tance Cardiac enlargement especially to the right is present in most cases

A *patent ductus arteriosus* is recognized by the presence of a long loud continuous murmur with systolic intensification best heard in the second or third left interspace It may be audible only during systole The second pulmonic sound as a rule is sharply accentuated As pointed out by François Franck the murmur is often heard loudly in the left side of the back over the area at which the aorta comes in contact with the chest wall at the level of the third and fourth dorsal spines The louder the mur mur the smaller is apt to be the caliber of the ductus and vice versa When the patent vessel is wide the systolic blood pressure tends to be elevated and the diastolic low so that the pulse pressure is increased Fluoroscopic examination may show an ab normal bulging of the left upper border of the heart shadow due to dilatation of the pulmonary artery The electrocardiogram usually shows no axis deviation

In *coarctation of the aorta* hypertension develops in the brachial vessels and this is associated with feeble or absent femoral pulsation The blood pressure in the legs is lower than in the arms and often is difficult to obtain Signs of enlargement of the left ventricle are present in about half the cases A systolic murmur at the aortic area is fre quent Sometimes attention is first directed to the condition by dilated strongly pulsat ing dorsal scapular or intercostal arteries which as anastomotic channels convey

with arduous activity The average duration of life is about thirty five years

ANOMALIES OF THE VALVE CUSPS are not uncommon and usually involve the semilunar segments at the arterial openings The segments may be increased or decreased in number Supernumerary segments, if present are apt to be small and are more frequently seen at the pulmonary opening than at the aortic The bicuspid condition is present more often at the aortic orifice Observations of Thomas Lewis suggest that the bicuspid aortic valve is of more than casual interest and importance He believes that valves so formed antenatally are malformations there being no evidence that they result from fetal endocarditis Among males reaching adult life and possessing congenitally bicuspid aortic valves 23 per cent at least die of active endocarditis In an unselected series of thirty one cases of subacute bacterial endocarditis 26 per cent presented bicuspid aortic valves and among those of the thirty one cases in which the aortic valve was the seat of vegetations 40 per cent showed the bicuspid malformation Thus a congenitally bicuspid aortic valve often appears to determine the localization of subsequent bacterial endocarditis owing to a susceptibility to infection induced by the congenital malformation Why this happens is unknown

Anomalies of the AURICULOVENTRICULAR VALVES are rarely seen

Less than 50 cases of CONGENITAL HEART BLOCK, with complete or partial auriculoventricular dissociation confirmed by graphic records have been reported It is probable that in all of these a congenital malformation of the conduction system was responsible for the cardiac irregularity although careful histologic study of the heart was made in only a few instances

Anomalies in the origin of the CORONARY ARTERIES are rare They may cause cardiac hypertrophy and inverted T waves in the electrocardiogram

Symptoms and Signs —The evidences of congenital heart disease are usually apparent soon after birth but may not manifest themselves until later in life The onset of symptoms may be definitely related to a contributory cause In a case observed several years ago cyanosis first appeared at the age of two on the day following tonsillectomy Up to that time there had been no suspicion of a cardiac defect The child died at the age of six Occasionally there are no symptoms until after puberty

Cyanosis is the most striking objective symptom and is responsible for the employment of the term *morbus caeruleus* by the earlier writers The mother often refers to the fact that the child was a 'blue baby at birth In the severer cases cyanosis is almost invariably present but taking into account all varieties of defect it is observed in about half of the total number It is conspicuous particularly in the lips cheeks nose ears fingertips and toes The patient may be of a livid color as though stained with the juice of blueberries In 1861 Knapp called attention to the dilatation tortuosity and deep violet color of the vessels in the fundus of the eye If congestion is marked retinal hemorrhages may occur The factors concerned in the production of cyanosis have not been conclusively established It is presumably due in part according to Lundsgaard and van Slyke to the passage of unaerated blood directly from the right heart to the arterial system in part to deficient oxygenation of the blood in the lungs due to disturbances in the pulmonary circulation If heart failure is present and the circulation is slowed increased oxygen consumption by the tissues per unit of blood flow may enter into the group of causes concerned

Clubbing of the terminal phalanges of the fingers and toes usually accompanies cyanosis The changes affect chiefly the soft tissues very rarely the bones The occurrence of dyspnea is determined by the character and severity of the lesions If there is no cyanosis there may be no shortness of breath The degree of respiratory discomfort varies in large measure with the amount of oxygen unsaturation In the later stages when cardiac failure dominates the picture dyspnea is extreme and is accompanied by other symptoms of myocardial insufficiency Hemoptysis and epistaxis are not infrequent

In the cases showing marked cyanosis polycythemia is present The red blood cells may vary from 7 000 000 to 12 000 000 and there is a corresponding increase in hemoglobin This I have observed as high as 160

Medical treatment is largely symptomatic Infections particularly of the respiratory tract should be prevented as far as possible The amount of physical activity which is permitted must be determined according to the functional capacity in each case Congestive heart failure if present is managed in the usual manner

RHEUMATIC HEART DISEASE

Definition —Heart disease is one of the manifestations of rheumatic fever It is not a complication as related lesions may be present elsewhere Although the heart may be involved simultaneously with such other manifestations of rheumatic fever as polyarthritis chorea and subcutaneous nodules it is frequently the first and only structure to be implicated The various inflammatory changes in the heart which arise in rheumatic fever together with the valvular deformities and other scars that remain constitute rheumatic heart disease

Classification —Rheumatic heart disease may be active or inactive or both The former implies that rheumatic infection is present in one or all of the structures of the heart. Inactive rheumatic heart disease means that infection has ceased but that healed lesions remain usually valvular deformities the result of previous inflammation

Another clinical grouping (Swift) includes four types namely, fulminating recurrent active chronic active and chronic inactive. The first type which usually terminates fatally during the initial attack of rheumatic fever is rare and almost always occurs in children The recurrent active type is characterized by intervening intervals of quiescence or inactivity the chronic active type by signs of inflammation persisting over periods of months or years The chronic inactive type exists for years with no signs or symptoms of rheumatic infection and presents healed structural lesions

Incidence —Rheumatic heart disease is the commonest form of heart disease occurring in childhood It is responsible for fully 90 per cent of defective hearts in children It is the second most prevalent form of heart disease in adults and accounts for about 30 per cent of the crippled hearts in that age period About 90 per cent of rheumatic heart disease occurs before fifty years of age and more than half before thirty

Rheumatic heart disease usually exists alone In a small number of cases it is associated with other forms of heart disease such as that of syphilis or with congenital malformations Not infrequently however rheumatic heart disease is accompanied by hypertension especially in older individuals with mitral stenosis

Sex —Rheumatic heart disease is equally distributed between the sexes although it is sometimes said that girls are more often affected

Race —The part played by racial susceptibility in rheumatic fever and rheumatic heart disease has not been fully established largely because methods for determining race prevalence are not satisfactory

Climate —That rheumatic heart disease has different geographical distributions apparently depending on climatic influences is recognized but no single satisfactory explanation has been offered thus far It is agreed that it is commonest in northern latitudes particularly in the northeastern part of the United States and in the British Isles

Age —Rheumatic heart disease is predominantly one of childhood and early adult

blood to the lower aorta through the internal mammary and superficial epigastric vessels In x ray films the borders of the ribs may show erosion due to the repeated pulsations of the enlarged intercostal arteries against the adjacent bone

An abnormal position of the heart as in *dextrocardia* causes the apex beat to appear in an unusual location and the cardiac out line as mapped out by percussion does not occupy its customary place Confirmatory evidence is afforded by x ray examination

Transposition of the great vessels is un common and is incompatible with survival for more than a few days unless there is an associated septal defect Cyanosis is an al most invariable sign Murmurs and thrills depend upon the presence of other anomalies Roentgenologic examination may show little except cardiac enlargement

Electrocardiographic examination is of particular diagnostic aid in dextrocardia In this condition the cardiac axis is rotated so that in Lead I the usual waves are in verted Lead II corresponds to the usual Lead III and Lead III to the usual Lead II In other forms of congenital defect vari ous types of change have been recorded The excursions are often wide and there may be right or less often left axis deviation In congenital heart block electrocardio graphic records clearly demonstrate the disturbed cardiac mechanism

Course and Prognosis—These vary with the type of lesion Some forms of malforma tion do not permit of survival for more than a few days weeks or months In cases with no shunt between the arterial and venous systems and hence without cyanosis life may be normal with respect to both ac tivity and duration Patients with minor septal defects uncomplicated patent ductus arteriosus dextrocardia or coarctation of the aorta of moderate degree fall into this cate gory The intensity of the murmurs is of no prognostic significance

When cyanosis is present the outlook is more serious for anoxemia places an added burden upon a heart already laboring under a mechanical handicap The degree of con gestive heart failure which develops deter mines the issue unless life is terminated by an intercurrent complication Occasionally a patient with pulmonic stenosis may survive to a mature age provided this lesion is ac companied by an adequate compensatory anomaly, such as a patent interventricular septum or an open ductus arteriosus

Of 225 cases collected by Holt 60 per cent died before the end of the fifth year and nearly half of these during the first two months 16 per cent lived over sixteen years and 8 per cent over thirty years Patients with congenital cardiac disease are particu larly susceptible to infection superimposed upon the lesions, and a number die of bac terial endocarditis Any acute malady may prove fatal When coarctation of the aorta is present the end sometimes comes as the result of spontaneous rupture of this vessel or of cerebral hemorrhage In the group with cyanosis sudden death is not infrequent some die of pulmonary tuberculosis but con gestive heart failure is the commonest terminal event

Treatment—A notable advance in the surgical therapy of congenital cardiac dis ease was made in 1939 when Gross reported the first successful ligation of a patent duc tus arteriosus Since then, a sufficiently large series of cases has been operated upon in various clinics to demonstrate the safety and efficacy of the procedure Indications for operation are malnutrition retardation of growth or evidence of cardiac insuffi ciency The hope has been expressed that ligation might lessen the likelihood of the subsequent development of bacterial en darteritis at the site of the anomaly but data in support of prophylactic closure are not yet available Certainly in many per sons an open ductus is compatible with a long and active life

After infection has occurred and particu larly if this is of relatively short duration ligation may cure the resulting sepsis The most common invading organism is *Strep tococcus viridans* Chemotherapy with one of the drugs of the sulfonamide group or with penicillin sometimes appears to aid in sterilizing the blood stream In the presence of an associated congenital cardiac anomaly of valvular involvement or of peripheral embolization a favorable outcome is doubt ful

A technic for the surgical therapy of other congenital defects has not yet been devel oped

one in 40 per cent of cases In about half of all patients there are no evidences of infection after thirty years of age

Symptomatology —The signs and symptoms of rheumatic fever are discussed in detail in the chapter on Rheumatic Fever (p 435)

The clinical signs and symptoms of *carditis* are caused as a rule by inflammation of the myocardium and valves less commonly of the pericardium Acute rheumatic myocarditis may be recognized by tachycardia fever and leukocytosis rapid sedimentation rate gallop rhythm changes in quality and intensity of the first heart sound blowing systolic murmur at the apex and enlargement of the heart due to dilatation Sometimes irregularities in rhythm including premature contractions or auricular fibrillation make their appearance Auricular fibrillation always indicates a severe degree of myocardial damage and invariably leads to cardiac insufficiency However the latter may occur in the presence of sinus rhythm Complete heart block is rare but a partial degree of block especially first stage block is common

It has been shown that a mid diastolic rumbling sound or murmur at the apex previously considered indicative of mitral stenosis and quite commonly heard in children during severe rheumatic infection may be caused by myocardial dilatation alone. The blowing systolic murmur so frequently heard at the apex may also be the result of cardiac dilatation although dysfunction of an inflamed mitral valve may play a role The most important aids in the recognition of myocarditis are the electrocardiographic changes These are found in the majority of patients As a rule frequent tracings are necessary because the abnormalities are often transient Among the more common deviations are prolongation of the P R interval denoting increased auriculo ventricular conduction (partial block) abnormalities in the QRS complexes and S T and T waves

Active valvulitis especially of the mitral less frequently of the aortic valves invariably accompanies the active myocarditis of rheumatic heart disease It is perhaps the commonest lesion of the heart in rheumatic fever Whether it is present however is largely a matter of conjecture The active inflammatory changes in the valve itself and the verrucae on its margins are probably not sufficient to produce deformity of the orifice but may cause dysfunction of the valve by improper closure of the leaflets thereby producing murmurs These changes together with inflammation of the ring portion of the valves and the concomitant myocarditis may cause dilatation of the valve rings and resultant incompetency This is most common at the mitral and somewhat less frequent at the aortic orifice Enlargement of the heart may be detectable in such instances but an early high pitched diastolic murmur over the base or along the left border of the sternum resembling that of aortic insufficiency may be audible as well as a blowing systolic murmur localized at the apex. Both murmurs may disappear after the inflammatory changes have subsided but may reappear when valvular deformities develop

In from 5 to 25 per cent of all cases acute valvulitis and myocarditis may be part of a *pancarditis* in which the pericardium is likewise involved This occurs in children who are usually severely ill with rheumatic fever about 1 per cent of them suffer a rapidly fatal course In all children with rheumatic pericarditis however the prognosis is bad both immediate and ultimate In older patients pericarditis may in an occasional case occur without involvement of the valves or of the myocardium or with only slight inflammation of one or the other of those structures Years later examination of such patients may reveal no evidence of organic heart disease

Contrary to belief *pain* is not a common symptom in rheumatic pericarditis The *pathognomonic sign* is the to and fro friction rub a superficial scratchy sound heard over the precordium This rub may last for hours or persist for days or weeks even in the presence of relatively large effusions In the latter circumstances it may be audible only over the basal regions With the increase of fluid in the sac the area of cardiac dulness especially to the right but also to the left may be increased the heart sounds may grow fainter and a paradoxical pulse may appear In addition *Ewart s sign* may be elicited It consists of dulness bronchial breathing and bronchophony in the left infrascapular area Occasionally children with

life and usually runs its course within the first four decades The onset is oftenest between the ages of five and ten with the maximum at eight years On the other hand, it may begin at any age even as late as the sixth decade About 70 per cent of individuals afflicted with this disease are known to have acquired it before fifteen years of age The period of economic usefulness of a rheumatic cardiac patient is on the average not more than eleven years after the initial infection

Etiology and Morbid Anatomy—The cause of rheumatic heart disease is rheumatic fever However in from 20 to 30 per cent of patients with rheumatic heart disease no antecedent history of rheumatic fever is obtainable Therefore the criteria for the diagnosis of rheumatic fever as a cause of heart disease have been made rather broad and include (1) a history of polyarthritis chorea muscle or joint pains or subcutaneous nodules and evidences of a structural lesion of the heart, (2) evidence of a structural lesion plus a history of periods of recurrent fever and cardiac insufficiency' A discussion of the etiology of rheumatic fever including its bacteriologic and immunologic aspects is given elsewhere (p 437) This also holds for the pathologic aspects which are covered under Rheumatic Fever (p 435) and Chronic Valvular Diseases (p 1076)

Development and Mode of Onset—Infection in the form of polyarthritis muscle and joint pains chorea and carditis is the characteristic mode of onset in more than 80 per cent of patients who acquire rheumatic fever before the age of ten years After the age of forty somewhat more than 20 per cent exhibit this form of the disease Before the age of ten valvular lesions alone are the first manifestations in about 15 per cent of cases after forty in almost 80 per cent In childhood the onset of rheumatic heart disease is characterized by polyarthritis in about 50 per cent of all cases and by carditis and chorea in about 33 per cent In young adults the onset is marked mainly by polyarthritis and in older individuals by the appearance of valvular lesions alone that is to say without a history or signs of infection

Chorea, the muscle and joint pains occur as initial manifestations almost exclusively before puberty and practically never after twenty-one years of age Both are associated with a milder form of rheumatic fever and the incidence of carditis is low

It is now conceded that rheumatic fever is a chronic infection Recurrent signs of an active inflammation are commonly seen in children and one or more recrudescences occur in about 75 per cent The largest number of recurrences occur between five and fifteen years although no age is exempt Of interest is the observation that the younger patient is likely to present several different manifestations of infection during the recurrences whereas the adult is apt to show the same manifestation repeatedly and usually it is the same as that which characterized the initial attack

The earlier the age at which rheumatic fever and rheumatic heart disease are acquired the more common are the recurrences of active infection It has been shown that recurrent infections begin to decrease at puberty suggesting that some form of resistance develops Other observers believe that regardless of age recurrences of rheumatic fever are less likely to occur five or more years after the initial episode because of the development of immune processes This five year period frequently coincides with the beginning of puberty The studies of Cohn and Lingg ' tend to support the opinion that it is puberty, and not necessarily the first five years after the initial infection that influences the frequency of recurrent activity They further state that There can be little doubt that knowledge of this diminishing susceptibility to rheumatic infection at puberty is of value in judging the effect of therapeutic measures on the subsequent course of the disease and that age therefore is an important factor in estimating the effect of treatment

Type of Infection—When rheumatic fever begins in childhood carditis is the commonest but rarely the only type of infection The mixed type especially the combination of carditis and polyarthritis is commonest among children but decreases in the older age periods During adolescence and early maturity carditis is seen more frequently as a single manifestation At all ages polyarthritis is the most frequent single sign Between fifteen and thirty years it is the only

sidered characteristic of valvular disease It has been reported by others that in groups of patients followed for still longer periods of time 20 to 37 per cent recover completely Since it is known that the later in life a patient suffers a first attack the better the chances for recovery it is probable that these latter groups included many older patients About one half of those who are afflicted between the ages of twenty and forty years do not develop rheumatic heart disease After the age of forty the percentage is higher

Inactive Rheumatic Heart Disease —This form of heart disease is symptomless unless complications supervene such as congestive heart failure auricular fibrillation or flutter embolism or subacute bacterial endocarditis The period during which a patient remains symptom free averages ten to twelve years This may be followed by signs of cardiac insufficiency and subsequently by those of congestive heart failure

The mitral valve is involved in almost every patient with rheumatic heart disease An occasional patient usually a young adult may show involvement of the aortic valve alone invariably with insufficiency More rarely isolated aortic stenosis is recognized in patients about fifty years of age Mitral stenosis usually combined with insufficiency is the commonest lesion of rheumatic heart disease occurring in approximately two thirds of all patients but mitral insufficiency alone is uncommon especially in adults It is found more frequently in children and oftenest in the course of the five years following the first attack of rheumatic fever

Clinically combined mitral and aortic valvular lesions occur in approximately one third of all cases of rheumatic heart disease Mitral or aortic deformity combined with tricuspid lesions occurs in a smaller group about 10 per cent The pulmonic valve is rarely affected On the other hand involvement of the tricuspid and pulmonic valves as determined by necropsy is more common The degree of deformity which occurs in these circumstances is usually mild and is not sufficient to cause appreciable alterations in the function of the valves Hence it is not clinically recognizable

Patients afflicted with rheumatic valvulitis in the first decade of life and especially in those with severe infections or recurrent periods of activity are apt to develop more than one valvular deformity This explains why multiple valvular lesions are so frequently found in adolescents Among individuals infected later especially among those who survive the age of thirty years mitral stenosis is commonly found as an isolated lesion

Diagnosis —The determination of inactive rheumatic heart disease in the absence of symptoms depends largely on detection of the signs produced by the several valve deformities This aspect is more fully considered in the chapter on Chronic Valvular Disease (p 1076)

Complications —Although complications may occur in both the active and inactive forms of rheumatic heart disease they are distinctly more common in the latter group Probably the most frequent is *cardiac insufficiency* as revealed by increased fatigue and dyspnea which constitutes the first signs of diminution in functional capacity of the heart Such symptoms are sooner or later experienced by nearly all rheumatic cardiac patients although the interval between the onset of rheumatic fever and signs of cardiac insufficiency is about ten years Within three or four years after these symptoms appear for the first time about 50 per cent of the patients die in spite of treatment

When symptoms of cardiac insufficiency are so easily induced that patients become distressed on slight exertion or even while at rest *heart failure* may then be said to exist As a general rule patients begin to show signs of heart failure about two years after symptoms of cardiac insufficiency appear About 80 per cent of rheumatic cardiac patients suffer at least one attack of heart failure The signs and symptoms include dyspnea on effort or paroxysmal dyspnea or both orthopnea distended neck veins tenderness of the liver pulmonary congestion and edema hydrothorax and sacral and leg edema When the patient shows signs of heart failure his life expectancy is brief—from three to five years

A common complication of rheumatic heart disease is *embolism* The source of emboli is usually a thrombus in one of the auricles or auricular appendages Emboli may be carried to almost any part supplied

large pericardial effusions show signs of respiratory distress such as marked dyspnea and orthopnea

Fluoroscopy may show an enlarged cardiac silhouette of pyramidal shape if the effusion is moderate and water bottle in outline if marked The cardiac pulsations are diminished or absent A characteristic electrocardiographic pattern is found in many cases consisting of elevation of the S T segments in the standard leads as well as in the chest leads In the former, elevation may be especially marked in lead 2 or in leads 1 and 2 combined These abnormalities are usually found early notably during the stage of fibrinous exudation and are transient disappearing in a few days If marked effusion occurs these changes are usually not seen but there may be lowering of the voltage of the QRS complexes and the T waves sometimes with shallow inversion of the latter

In children *congestive heart failure* may be precipitated by carditis even during the initial attack of rheumatic fever In fact at any time during childhood or adolescence its presence in a patient with rheumatic heart disease should be regarded as evidence of active rheumatic infection The clinical manifestations include dyspnea orthopnea cough distended neck veins moist basal rales enlarged and tender liver and sacral or leg edema or both It indicates a bad prognosis and is the commonest cause of death in all forms of rheumatic heart disease

Subsequent Course—In children it is unusual for all signs of carditis to subside within a few weeks of the onset of the initial phase of rheumatic fever The inflammatory lesions are more often of several or many months duration and in some may persist for years In others the process seems never to become quiescent these are the chronically active rheumatic cardiac patients The chronicity of rheumatic fever although frequently emphasized is not sufficiently recognized

Disappearance of the clinical signs of active carditis does not necessarily mean that the inflammatory process has become inactive Other evidence of its presence may persist for periods ranging from weeks to months and occasionally years Helpful laboratory findings include electrocardiographic abnormalities especially prolonged A V conduction time and elevated sedimentation rates It is important to recognize this phase of active rheumatic heart disease in order to prevent further damage to the heart by ill advised premature physical activities

Rheumatic fever in childhood is a chronic or recurring disease It is unusual for a child to have only one attack of carditis Recurrent active rheumatic heart disease is usually met with during the five or six years following the initial attack It is important to recognize recurrent periods of activity because progressive damage to the heart may occur during these periods and not infrequently heart failure and death if adequate rest and similar measures are not enforced Active infection is responsible for most deaths in children with rheumatic heart disease Clinical recognition of infection is sometimes difficult but use of the laboratory tests mentioned may lead to a correct diagnosis

Development of Inactive Rheumatic Heart Disease—The conception that the heart is always involved to some degree in rheumatic fever is widely entertained but that it is possible for individuals who have had carditis to have normal hearts years later is not fully recognized Undoubtedly such patients may have had enlargement of the heart together with systolic and diastolic murmurs during their initial attacks of rheumatic fever but they probably did not have valvulitis or if they did at most a minimal degree It is even probable that some who have had appreciable degrees of valvulitis may develop scarring without significant valvular deformity it persists however although the characteristic murmurs have disappeared

Valvular deformities of sufficient degree to produce stenosis at the orifice or insufficiency of the valve develop as a rule six months to two years or even longer after the onset of infection of the valves However not all individuals who suffer an attack of rheumatic fever develop permanent heart disease Over an observation period of ten years about 8 per cent of children reveal regression or even complete disappearance of those physical signs which are con

two thirds of them die during this period Nearly one third of the patients in whom the onset is in childhood do not survive beyond childhood and about another one third do not survive adolescence However it appears to be true that children who survive adolescence have a good chance of reaching maturity The main factor here as previously discussed is the influence of puberty

In about 80 per cent of all cases the cause of death in children with rheumatic heart disease is rheumatic fever and carditis with or without congestive heart failure Unknown causes and causes other than heart disease account for an additional 10 per cent

In adults death is due to heart disease in about 75 per cent of cases the largest number dying of congestive heart failure and about 6 per cent of bacterial endocarditis About 10 per cent of deaths are the result of thrombosis or infarction and the remaining are caused by conditions other than heart disease

Prophylaxis—The association of rheumatic fever with hemolytic streptococcal infections led to the prophylactic use of sulfanilamide After seven years of investigation by many different observers it has been established that this drug has a beneficial effect in preventing recurrent attacks of rheumatic fever During this time several hundred children and young adults received sulfanilamide prophylactically and recrudescences occurred in less than 1 per cent

Adequate protection seems to be afforded by small doses such as 1 to 1.5 Gm daily even in older patients At present there is no basis for determining the minimal blood level which will give protection against invasion of the streptococcus Toxic reactions such as transient rashes fever gastro intestinal disturbances and slight leukopenia rarely occur with such doses Patients who tolerate the drug for two weeks are apt to remain symptom free thereafter Those who develop untoward symptoms should discontinue the drug for several weeks They may resume it in smaller doses gradually increasing the dose over a period of weeks to the desired level Complete white blood counts and hemoglobin determinations are the only routine measures that need be performed particularly during the early weeks of its administration Since most of the recurrent attacks of rheumatic fever occur within five years of the initial attack prophylactic sulfanilamide therapy should be continued over a period of at least five years

Because it is agreed that one of the best preventive measures in the care of the patient with rheumatic heart disease is to keep him free from hemolytic streptococcal infections it is often necessary to remove contributing foci such as diseased tonsils and adenoids and infected sinuses Preceding such operative procedures sulfanilamide should be administered to prevent the development of subacute bacterial endocarditis

Treatment—The care of the patient with rheumatic fever and its cardiac manifestations is described in detail in the chapter on Rheumatic Fever (p 435–450) The treatment of the *recurrent active* or *chronic active forms* of rheumatic heart disease is essentially the same as that of the initial attack of carditis One of the complications in active rheumatic heart disease is congestive heart failure Its treatment is not agreed upon by all authorities Some employ digitalis others do not or even regard it as hazardous The latter group administers mercurial diuretics instead Experience with digitalis on the whole has been satisfactory although there are some patients especially those with fulminating infections who do not respond because of widespread myocardial inflammation It should be given by mouth and with caution especially in children One should be on the alert for evidences of therapeutic effect and for signs of early toxicity Frequent electrocardiographic records should be made

Treatment of the *inactive phase* of rheumatic heart disease is directed mainly toward those complications which may arise Cardiac insufficiency can usually be corrected by digitalis Auricular fibrillation may sometimes be abolished by quinidine particularly when this arrhythmia first makes its appearance and there are no contraindications to its use The majority of such patients cannot be maintained at regular sinus rhythm by the daily use of quinidine for longer than six to eight months Auricular fibrillation invariably returns In such

by the systemic or pulmonary circulations when they arise in the left side of the heart however they are apt to lodge in the brain, spleen kidneys or extremities and in the lungs when they arise in the right side Pulmonary infarction is probably the commonest postembolic manifestation of rheumatic heart disease and is particularly common in patients with mitral stenosis attended by auricular fibrillation It occurs oftenest in the lower lobe of the right lung and is frequently associated with pleuritis Involvement of the pleura is the cause of the sudden sharp pain in the side experienced by many patients at the time that infarction of the lung takes place Hemoptysis is a fairly frequent occurrence in patients with mitral stenosis Cerebral emboli with resultant paralyses of various degrees and locations are common occasionally they cause almost immediate death Embolic occlusions of vessels in the extremities usually the lower if complete result in gangrene irrespective of treatment. Many cause only partial occlusion or resolve so that the circulation returns and restoration follows Emboli to the kidneys although they are usually painful may be silent Subsequent infarction gives rise to hematuria

Arrhythmia —The commonest irregularity of rhythm complicating rheumatic heart disease is caused by auricular fibrillation and occurs in about 50 per cent of rheumatic cardiac patients The longer rheumatic heart disease lasts the more likely is auricular fibrillation to occur *It is most commonly* observed in the fourth decade of life

Auricular fibrillation occasionally occurs in childhood and in the adolescent period as an acute complication of the active phase of rheumatic heart disease It contributes also to the fatalities occurring during the *initial five year* period of infection It indicates severe infection of the myocardium and the prognosis is correspondingly bad Patients with rheumatic heart disease and auricular fibrillation who die of congestive heart *failure before* the age of forty years invariably present evidences of active rheumatic infection at necropsy and sometimes clinically

The highest incidence of auricular fibrillation is in patients with mitral stenosis It is less frequent in those with combined mitral and aortic valvular deformities That it is present in the majority of patients with mitral and tricuspid lesions is a fact of some importance

In an appreciable percentage of rheumatic cardiac patients especially those with mitral stenosis, embolism occurs following intra auricular thrombosis Embolism of course may cause infarction of any organ with so called terminal arteries or in any organ when the arteries are too small to permit the passage of emboli

The view that auricular fibrillation is a *late phase in rheumatic heart disease* appears to be supported by statistical analyses These seem to show that about 75 per cent of rheumatic cardiac patients who develop auricular fibrillation die within three years of its onset

Bacterial Endocarditis —About 6 per cent of children with rheumatic heart disease die of acute or subacute bacterial endocarditis Among adult rheumatic cardiac patients the incidence varies between 6 and 10 per cent the majority succumbing to the subacute type of infection As a rule subacute bacterial endocarditis in both children and adults involves valves which do not present severe degrees of stenosis and hence it is commonly seen in uncomplicated mitral or aortic insufficiency or both It practically never happens in association with auricular fibrillation because subacute bacterial endocarditis usually occurs in the second and third decades of life during which periods *auricular fibrillation is almost* never present However in about one half of the cases bacterial invasion takes place while rheumatic infection is still active in the heart. This may not be proved clinically but is readily demonstrated at necropsy

Prognosis —Life expectancy in rheumatic heart disease is apt to be short About 50 per cent live nine years about 25 per cent longer than seventeen years and about 10 per cent longer than thirty years after the onset The *mean* duration from onset to death is about thirteen years and there is no essential difference between the sexes The *mean* age at death is given as thirty three years

The highest mortality rate in children occurs during a period of from three to five years after the initial attack of carditis *about*

two-thirds of them die during this period Nearly one-third of the patients in whom the onset is in childhood do not survive beyond childhood and about another one third do not survive adolescence However it appears to be true that children who survive adolescence have a good chance of reaching maturity The main factor here as previously discussed is the influence of puberty

In about 80 per cent of all cases the cause of death in children with rheumatic heart disease is rheumatic fever and carditis with or without congestive heart failure Unknown causes and causes other than heart disease account for an additional 10 per cent.

In adults death is due to heart disease in about 75 per cent of cases the largest number dying of congestive heart failure and about 6 per cent of bacterial endocarditis About 10 per cent of deaths are the result of thrombosis or infarction and the remaining are caused by conditions other than heart disease

Prophylaxis—The association of rheumatic fever with hemolytic streptococcal infections led to the prophylactic use of sulfanilamide After seven years of investigation by many different observers it has been established that this drug has a beneficial effect in preventing recurrent attacks of rheumatic fever During this time several hundred children and young adults received sulfanilamide prophylactically and recrudescences occurred in less than 1 per cent

Adequate protection seems to be afforded by small doses such as 1 to 1.5 Gm daily even in older patients At present there is no basis for determining the minimal blood level which will give protection against invasion of the streptococcus Toxic reactions such as transient rashes fever gastro intestinal disturbances and slight leukopenia rarely occur with such doses Patients who tolerate the drug for two weeks are apt to remain symptom free thereafter Those who develop untoward symptoms should discontinue the drug for several weeks They may resume it in smaller doses gradually increasing the dose over a period of weeks to the desired level. Complete white blood counts and hemoglobin determinations are the only routine measures that need be performed particularly during the early weeks of its administration Since most of the recurrent attacks of rheumatic fever occur within five years of the initial attack prophylactic sulfanilamide therapy should be continued over a period of at least five years

Because it is agreed that one of the best preventive measures in the care of the patient with rheumatic heart disease is to keep him free from hemolytic streptococcal infections it is often necessary to remove contributing foci such as diseased tonsils and adenoids and infected sinuses Preceding such operative procedures sulfanilamide should be administered to prevent the development of subacute bacterial endocarditis

Treatment—The care of the patient with rheumatic fever and its cardiac manifestations is described in detail in the chapter on Rheumatic Fever (p 435–450) The treatment of the *recurrent active* or *chronic active forms* of rheumatic heart disease is essentially the same as that of the initial attack of carditis One of the complications in active rheumatic heart disease is congestive heart failure Its treatment is not agreed upon by all authorities Some employ digitalis others do not or even regard it as hazardous The latter group administers mercurial diuretics instead Experience with digitalis on the whole has been satisfactory although there are some patients especially those with fulminating infections who do not respond because of widespread myocardial inflammation It should be given by mouth and with caution especially in children One should be on the alert for evidences of therapeutic effect and for signs of early toxicity Frequent electrocardiographic records should be made

Treatment of the *inactive phase* of rheumatic heart disease is directed mainly toward those complications which may arise Cardiac insufficiency can usually be corrected by digitalis Auricular fibrillation may sometimes be abolished by quinidine particularly when this arrhythmia first makes its appearance and there are no contraindications to its use The majority of such patients cannot be maintained at regular sinus rhythm by the daily use of quinidine for longer than six to eight months Auricular fibrillation invariably returns In such

circumstances digitalis is the drug of choice It is also indicated if the arrhythmia is complicated by congestive heart failure When signs of failure become so severe that digitalis alone cannot control them, mercurial diuretics administered intravenously or intramuscularly should be tried If paroxysmal dyspnea with or without pulmonary edema appears the intravenous administration of aminophylline is frequently effective Phlebotomy either by actual venesection or by the application to the extremities of blood pressure cuffs inflated to a pressure a little higher than the patient's diastolic level sometimes gives dramatic relief

The treatment of choice in *embolic occlusion* of the arteries of the extremities is papaverine in large doses (0 1 to 0 2 Gm) given intravenously Paravertebral sympathetic block is also useful to reduce the vasoconstriction of collateral as well as of main branches Some patients respond to these or similar forms of therapy and the affected extremities return to normal Others develop gangrene and amputation becomes necessary Some believe that embolectomy is indicated in all cases but in view of the large number of recoveries with more conservative measures this seems of doubtful utility except in selected cases Pulmonary infarction also responds to papaverine but the pleuritic pain may require codeine Embolism of the spleen or kidneys causes sudden sharp pain which is best treated by codeine alone Mesenteric embolism is apt to result in gangrene of a part of the intestine and is always serious Although the administration of papaverine intravenously is indicated restoration of the ischemic gut is rare and surgical intervention is necessary Emboli to the brain occur not uncommonly and depending on their size and location various degrees of paralysis take place or occasionally, death Complete recovery sometimes occurs

ENDOCARDITIS

Definition—Endocarditis is an inflammation of the tissue lining the cavity of the heart particularly the tissue of the valves The simplest classification of the different types is as follows

1 Nonbacterial (*simple*)
    (*a*) Acute nonrheumatic
    (*b*) Acute rheumatic
2 Bacterial (*myocotic*)
    (*a*) Acute
    (*b*) Subacute

Syphilitic involvement of the endocardium is not considered in this classification since this disease is not primarily of the endocardium

Malignant endocarditis includes those forms of the acute bacterial type which are rapidly fatal In all types the inflammatory foci may ulcerate Since the lesions on the valves except for the simple erosions are spoken of as vegetations the terms *ulcerative* and *vegetative* are not distinctive The vegetations of the nonbacterial variety are called *verrucous* when they represent organized tissue reactions The initial erosion of the valve with its deposition of clot has been called *thrombo endocarditis*

Etiology—1 (*a*) There are cases of acute endocarditis in which no history of acute rheumatic fever can be obtained and in

which at autopsy the lesions usually regarded as typifying rheumatic fever are not found This type of nonrheumatic endocarditis is also nonbacterial because cultures from the valves and microscopic inspection of the valves themselves furnish no evidence of the presence of bacteria This type has been fully described by Libman and Sacks In a series of 44 cases studied by the author such cases occurred five times The etiology in this group is now regarded as associated with disseminated lupus erythematosus since the cutaneous manifestations of the latter disease are frequently though not invariably present. It has been suggested (Gross) that the two groups of cases previously designated as disseminated lupus erythematosus and atypical verrucous endocarditis respectively should be put in a single category of Libman Sacks disease'

The analysis of Gross and associates clarifies the situations in which thrombotic nonbacterial vegetations may occur

(b) The etiology of acute rheumatic endocarditis is discussed in detail in the chapter on Rheumatic Fever (p 435)

2. The etiology of bacterial endocarditis is involved in the double factor of preceding damage to the endocardium with subsequent bacterial implantation on the damaged area When chronicity occurs in this form of endocarditis it is due to the lack of virulence of the causative bacteria

Morbid Anatomy —Erosions are the first lesions to occur and may become infected at once or be organized into verrucous vegetations which may either form scar tissue or themselves be later infected Just how the rims of the valves become eroded is uncertain but the process is apparently non specific because the appearance at autopsy is the same whatever the disease of which the valvular erosion was a complication

The fact that erosion occurs in the absence of demonstrable infection (as in protracted systemic disease) seems to point to a noninfectious origin Whether the agency producing the injury acts upon the surface of the valves or beneath the surface by way of the capillaries is unknown but no connection between the lesion and the underlying blood supply can be shown microscopically The final amount of vegetation and scar tissue depends upon the degree of initial injury and the number and severity of recurring injuries At autopsy it is common to find fresh erosions engrafted on old verrucous vegetations In rheumatic fever such recurrences are apt to be frequent and the consequent dense scarring and contraction destroy valve function Both the erosion and the verrucous vegetation are susceptible to bacterial implantation It is important to regard bacterial infection as a secondary phenomenon which may take place either during the original disease which caused the erosion or later in life. Thus during severe pneumonia the erosions may be immediately infected by the pneumococcus in the blood stream and produce an acute bacterial endocarditis or this immediate invasion may not take place and a streptococcus may later infect the tissue during an attack of tonsillitis

Simple erosions the earliest lesions on the valves consist macroscopically of very small swollen areas on the rim of the valve covered with a small delicate blood clot. Smears taken from these lesions contain fibrin and red blood cells but no bacteria Microscopically the lesion appears as simple loss of substance on the edge of the valve with deposit of eosinophilic material and red blood cells

Verrucous Vegetations —Macroscopically verrucous vegetations are firm white nodular swellings along the rim of the valve which vary in size from 0.5 to 2 mm Microscopically they are composed of homogeneous pink staining fibrinoid material surrounded by a zone of round cell infiltration These vegetations do not contain bacteria In the early lesions of rheumatic endocarditis underlying proliferations resembling Aschoff bodies are frequent In their later stages the nodular appearance is lost in the diffuse thickening and puckering of the valve Fresh erosions may develop on these vegetations

For statistics concerning the anatomic distribution of rheumatic valvular lesions the reader is referred to the exhaustive studies of Thayer which are supported by the evidence of autopsies The simultaneous involvement of the aortic and mitral valves is the most common condition The tricuspid valve was involved in 41 66 per cent of 24 autopsies in the series studied by Thayer

In the early stages of rheumatic endocarditis, fresh areas of infiltration containing characteristic Aschoff lesions may be found also in the wall of the left auricle

In patients who survive the *rheumatic* fever of childhood, and who die in middle age it is not unusual to find typical Aschoff bodies but intercurrent bacterial rather than rheumatic processes may be responsible for the final undermining of cardiac structure This fact, together with the fact that the occurrence of early mild rheumatic fever is easily overlooked or forgotten make the position of so called 'nonbacterial nonrheumatic endocarditis insecure in any classification

Bacterial vegetations differ sharply from the verrucous In gross appearance they measure from 1 to 15 mm in diameter When washed free from their enmeshed blood they are spongelike or coral like in structure and show formations obviously guided by the currents about them They are gray in color but the firmly attached clot gives them a reddish brown appearance They are friable and crush easily between the fingers They are composed entirely of fibrin and bacteria At their bases there is active organization of the tissues of the valve There may be evidence in the neighboring valve tissue of old verrucous vegetations and fresh erosions may be seen elsewhere on the valve On the apparently uninvolved endocardial surface in the neighborhood of the vegetation, one may see microscopically superficial bacterial growth without underlying reaction in the tissues Mural endocarditis and softening and breaking of the chordae tendineae are comparatively frequent in all forms of bacterial endocarditis

Since the vegetation is affected by the character of the disease producing the preexisting or concomitant damage viz rheumatic fever pneumonia syphilis influenza sepsis the distribution of valvular lesions in bacterial endocarditis varies with the type under consideration pneumococcal endocarditis usually comes with lobar pneumonia occurs most frequently in later life and perhaps on account of this latter fact is found usually affecting the aortic valve The gonococcal infections are also most frequently of the aortic valve although the disease occurs at an earlier age In the streptococcal group the distribution of valvular injuries follows more closely the distribution in rheumatic endocarditis

RALPH A KINSELLA

NONBACTERIAL ENDOCARDITIS

Simple erosions are noticed at autopsy in many conditions such as chronic vascular disease and carcinoma in which a long period of debility preceded death This type of endocarditis is not diagnosed during life. Such erosions may also occur simultaneously with verrucous vegetations There is little or no clinical evidence of the existence of this type of endocarditis and frequently when the clinician assumes because of a systolic murmur noted during a terminal or febrile process that such endocarditis exists subsequent autopsy may reveal no valvular lesions In short a diagnosis of simple erosion can be made only at postmortem examination

Frequently, however during the course of a severe infection (acute gonorrheal sepsis pneumonia, or meningitis) when a murmur develops especially a basal diastolic one which is accompanied by embolic phenomena including petechiae in the skin or conjunctivae splenomegaly, and the isolation of a causative organism from the blood stream the diagnosis of acute *endocarditis* is justified In other words the diagnosis of acute endocarditis of whatever type can be made only if some signs of cardiac involvement are added to the preexistent murmur and fever

Acute Nonrheumatic Endocarditis—Of great interest is that type of endocarditis which apparently is not in any of the foregoing classes It is definitely nonrheumatic since microscopic examination of the heart muscle fails to reveal any evidence of rheumatic myocarditis Such cases are not uncommon Mitral lesions are the most frequent This is the type described by Libman and Sacks and later found to be a feature of disseminated lupus erythematosus The symptoms and signs of this disease are considered elsewhere

Acute rheumatic endocarditis is almost constantly associated with acute rheumatic fever and contributes special importance to

this disease Rheumatic endocarditis is discussed in detail in the section on Rheumatic Fever (p 435) See also section on Rheumatic Heart Disease (p 1003)

RALPH A KINSELLA

BACTERIAL ENDOCARDITIS

Acute Bacterial Endocarditis —*Etiology*—Acute bacterial endocarditis develops both as a complication of such infections as pneumonia in which immediate infection of valvular erosions is presumed to occur and as an infection of an old cardiac injury during the course of a bacteremia The source of the bacteremia is usually capable of recognition

Bacteriology—*Staphylococcus aureus Streptococcus haemolyticus* and *Pneumococcus* are the organisms especially prominent in the etiology of acute bacterial endocarditis The malignant character of the disease with its comparatively brief course is no doubt associated with the virulence of these bacteria Infection by the gonococcus and the meningococcus (in subacute cases) has also been described as well as by a number of other organisms

Morbid Anatomy—Besides the lesions typical of the endocarditis there are other changes characteristic of this acute bacterial form which are usually regarded as being embolic in origin They consist of hemorrhages about terminal vessels and subsequent infiltration with polymorphonuclear leukocytes These lesions occur in the skin as petechiae and on the surface of the kidney as rather coarse red spots (1–3 mm in diameter) usually with whitish centers Infarctions in organs such as the spleen lungs and brain are common Meningitis secondary to the brain lesions occurs frequently especially in the pneumococcal type

Symptoms—The type of onset is influenced by the character of the disease which caused the bacteremia Thus if endocarditis is a complication of lobar pneumonia it may be impossible to state exactly when the infection of the heart valve occurred A staphylococcus infection of the valve may have entered the body through a trivial cutaneous abrasion which may have healed before the patient was examined The signs of sepsis are more prominent than those of cardiac failure High fever of the remittent type a leukocyte count of 15 000 in streptococcal and staphylococcal infections or of 30 000 in pneumococcal infections frequent chills errant pains about the body, and violent cardiac action with a coarse murmur are the signs which indicate a bacteremia fed by an infected valve Occasionally besides petechiae hemorrhagic areas appear about the extremities Petechiae and emboli are much more rare in the acute than in the subacute variety of endocarditis Signs of meningitis are common and delirium is invariably established later in the disease Embolic pneumonia develops frequently The average length of the disease is four to eight weeks

The murmurs change gradually as the disease progresses become daily more coarse or new ones appear such as a diastolic murmur at the aortic area and are often accompanied by thrills in the later stages Purulent invasion of the tissues in the neighborhood of joints is a frequent occurrence in the pneumococcal and streptococcal types

Diagnosis—The symptoms of septicemia with special signs indicative of cardiac involvement are important in diagnosis The most conclusive evidence is contained in the blood culture this is invariably positive and may be the only means by which other sources of acute infection are excluded Similar cultures may also be obtained from the urine and spinal fluid

Treatment—The treatment for acute bacterial endocarditis is usually unavailing However recovery may be expected in some cases Reports of cure of gonococcal endocarditis with sulfanilamide have appeared and others such as the staphylococcal type may yield to treatment with sulfonamides Fever therapy either alone or combined with chemotherapy has given favorable results (cure) in several instances of gonococcal endocarditis

Subacute bacterial endocarditis, which was described by Schottmueller and also Libman in 1910 is more important than the acute type on account of its comparative frequency The average hospital of 200 beds usually admits several cases annually and in

localities where rheumatic heart disease is common, a larger number With increased facilities for clinical bacteriology it is being more frequently recognized

Etiology—Two factors are apparently essential in every case—a preexisting injury of the valve and a recent infection which may invade the blood stream In a typical case a patient with rheumatic valvular heart disease suffers from tonsillitis abscesses of the teeth or otitis media Under these conditions bacteria prevalent about the focal disease may enter the blood stream and invade the damaged valve Although both the aortic and mitral valves are commonly affected the former seems to be more often involved alone, particularly when aortic insufficiency is present A slightly damaged mitral valve as seen in the presence of mitral insufficiency, is more susceptible than the severely deformed lesion of mitral stenosis It is now recognized that subacute bacterial endocarditis may become grafted upon a fresh (active) rheumatic infection In older patients atheromatous changes in the aorta and aortic valve may constitute the preceding damage Congenital defects of the heart are also easily infected, notably defective interventricular septa, bicuspid aortic valve and patent ductus arteriosus (Botalli)

Morbid Anatomy—Minute perivascular hemorrhages occur throughout the body These are soon infiltrated by polymorphonuclear leukocytes then by lymphocytes and finally are resolved into minute scars They appear as crops of petechiae about the extremities and on the conjunctival and buccal mucous membranes On the surface of the kidney they produce what Libman has called a 'flea bitten appearance They are numerous in the brain and heart muscle and on endothelial surfaces It has been frequently assumed that these small lesions are bacterial infarctions No definite proof however has been furnished regarding their exact origin Other lesions appear which are larger and occur about the joints and produce redness and pain in circumscribed areas with occasionally an effusion into the joint cavity Of special interest are the partial thromboses of glomeruli which cause in this disease a peculiar form of glomerular nephritis Infarctions of the spleen are constant and cerebral embolism is common and usually terminal The vegetation consists of a mass of bacteria enmeshed in fibrinous material which is studded with neutrophils and lymphocytes It appears to develop as a result of implantation of bacteria on the previously damaged endocardium The idea has been advanced that fibrin protects the imbedded bacteria from the action of drugs This was the basis for using heparin in an effort to prevent the formation of the protective fibrin

Others believe that the vegetation develops as a result of bacterial plugging of fine capillaries in the previously damaged valve and then building up from the interior of the valve breaks through the necrotic material onto the free surface of the valve where fibrin is deposited on its surface Studies of vegetations both in human and in experimental cases seem to support the idea that the bacteria causing the infection of the blood stream are not those imbedded in the mass of pink staining material but rather the bacteria spreading upon the endocardial surface uncovered by fibrin This point of view would give fibrin a more beneficent role as far as the patient is concerned and would support the theory that the formation of fibrin should be encouraged rather than prevented

Bacteriology—The nonhemolytic streptococcus is responsible for 90 to 95 per cent of the cases of this type of endocarditis The gonococcus is an important causative organism among the remaining 5 to 10 per cent Unidentified gram negative bacilli and gram negative diplococci have been reported as the infecting organisms as well as *Staphylococcus albus* In unusual instances there are cultures usually obtained at autopsy of *Streptococcus viridans* in combination with *Streptococus haemolyticus* or with a fine gram negative bacillus but usually the field is occupied by a single strain Whatever the type of micro organism its virulence is always low A low grade serologic immunity is usually incited which may be demonstrated by the agglutination and complement fixation tests

Symptoms—The onset is usually indefinite The attention of the patient is not directed toward the heart as a rule but is diverted by the fever and lassitude to a consideration of other symptoms In some in

stances a severe infection of the throat or upper respiratory passages impresses itself and the patient feels that he has simply failed to recover from such an infection In some cases there is no history of recent infection and the mechanism of implantation cannot be visualized While there is a history of preceding heart disease in nearly all the cases this affection of the heart may not be known to the patient Thus the physician may be led to consider such diagnoses as tuberculosis pyelitis or anemia for several weeks before attention is finally focused upon the heart Very often a routine blood culture leads to a correct diagnosis early in the disease

The absence of a history of acute rheumatic fever is important because it serves to direct attention to the possibility of congenital defect. Syphilitic lesions in the aortic valve or aorta may become infected but much less frequently than rheumatic valvular deformities and congenital anomalies Most of the patients are between twenty and forty years of age with both sexes about equally represented

The fever is of the remittent type daily peaks of 103° F being common In the early days of the disease chills are not uncommon A feature of the fever is that there are phases during which the temperature is at a high level at some time during the twenty four hours and other phases of variable duration sometimes weeks when the temperature may be normal or nearly so This latter phase may arouse hopes that are soon to be frustrated The febrile phases often coincide with other evidences of activity such as splenic infarction or other embolic phenomena

The vegetations on the valves or on the walls constantly supply the passing blood with organisms which commonly induce emboli The murmurs resulting from these vegetations may be extremely faint in the beginning and the cardiac excitement is much more a sign of endocarditis As time goes on the murmurs become coarser or new ones develop and may be accompanied by thrills

The bacteremia is usually easy to detect However about 10 per cent of patients remain bacteria free especially those more than forty years of age as far as blood cultures are concerned It differs from the usual fatal bacteremia in being sustained at a certain quantitative level Some cases continue to yield a small number of colonies per cubic centimeter of blood others a great number but the amount in either case is nearly the same throughout the course of the disease.

The bacteremia itself is probably responsible for the peculiar ashen pallor (cafe au lait) for the gradual wasting for the intense exhaustion leading to a peculiar petulance on the part of the patient and for the anemia The white cell count is often between 12 000 and 18 000 although normal counts are not uncommon and the red cell count is frequently below 3 000 000 In some instances the leukocyte count is surprisingly low (4000–6000) The percentage of stab forms is high

The petechiae are often regarded as embolic in origin but there is no proof of this These little red areas measuring 1 to 2 mm. in diameter are found about the hands and feet and in the conjunctival and buccal mucous membranes They have a tendency to occur in crops as if representing immunologic or allergic phases Larger spots measuring 2 to 5 mm., slightly nodular and definitely tender are discovered by the patient about the small joints notably in the tips of the fingers and toes (Osler s nodes) These little episodes usually clear away in three or four days

Quite distinct from the petechiae in time are the infarctions A pain in the left upper quadrant with a suddenly palpable and tender spleen is evidence of an infarction in that organ Hematuria with bacteria in the urine may be regarded as evidence of such an event in the kidney Hemiplegia is not infrequent and is often of a terminal character Circulatory failure is uncommon during the course of the disease but is the terminal picture in about one third of the cases Focal embolic glomerular lesions are rarely of sufficient extent to disturb kidney function

Clubbed fingers are frequently seen in cases that have lasted several months. The spleen is usually enlarged palable often tender Other clinical features which are to be expected are nosebleed which in this disease is remarkably stubborn and which recurs often abdominal distention which resists the usual measures employed for this

condition and a mild, quiet delirium which often prevails for several days before death

Diagnosis —During any obscure fever with heart murmur the blood should be cultured repeatedly This is the most effective diagnostic procedure When signs of infarction or the familiar petechiae appear the diagnosis is easily made clinically Subacute bacterial endocarditis is to be distinguished chiefly from rheumatic endocarditis in which the blood occasionally contains the *Streptococcus viridans* Subsequent cultures are negative in rheumatic cases and the course of the disease with usual recovery confirms the distinction Furthermore the signs of myocardial affection are not as pronounced in subacute bacterial endocarditis as in acute rheumatic endocarditis However it is well to remember that both diseases may be present in active form

Prophylaxis —In order to avoid the disease anyone known to have valvular lesions should take precautions to prevent infections of the teeth tonsils and middle ear and should have existing foci of infection removed Before and after surgical removal of an infected focus sulfonamide therapy should be given Recognized coccal infections of the upper respiratory tract should be vigorously treated with sulfonamide Such patients should avoid exhausting work or exercise

Treatment —No form of treatment is successful It seems certain that no attempt should be made to *immunize* the patient by vaccines serums or nonspecific shock since such measures seem to shorten life Mercurochrome acriflavine and gentian violet have been used without avail An identical disease produced experimentally in dogs has been cured by intravenous injection of merthiolate and by oral administration of sulfanilamide but neither of these drugs has been successful in human cases There have been reports of favorable effects produced by various members of the sulfonamide group and by combination of one of these with heparin Favorable results have also been reported after the combined use of chemotherapy and artificially induced fever The use of one of the sulfonamides should be instituted and maintained in dosage sufficient to support a level of 5 to 10 mg per 100 cc blood The establishment of the diagnosis of patent ductus arteriosus is of high importance since infection of this congenital defect may be removed in a majority of cases by ligation of the duct Unfortunately other congenital defects may be present which are not as yet amenable to surgical treatment There are occasional reports in the literature of recovery from the disease following the use of sulfonamide with or without some form of fever therapy but the results are not constant nor in many cases are they permanent It is possible that infection of congenital defects can be more easily removed than infection of an old rheumatic injury It seems likely that the cure of the disease will eventually be found in the field of chemotherapy So far none of the evidence is conclusive

CHRONIC VALVULAR CARDIAC DISEASE

Chronic valvular disease of the heart consists of chronic structural change in one or more heart valves Functional valvular defects should not be included under the term valvular disease' they must however be considered in discussing the differential diagnosis of organic defects Myocardial failure also should not be included although many textbooks in the past have included it particularly when the treatment of chronic valvular disease has been discussed Nor will acute and subacute inflammatory processes be considered since the term chronic

valvular disease refers to deformed valves and not to the disease causing the deformity These diseases which are acute and subacute endocarditis syphilis and arteriosclerosis are described elsewhere in this book

Incidence —Chronic valvular disease of the heart is common and is found universally It has been estimated that from 0.5 to 1 per cent of the community is affected This figure is too high for those parts of the world where the rheumatic infection is rare especially in the tropics but is not far from correct for regions where rheumatic fever and chorea are common such as the northeastern part of the United States of America and northern Europe especially Great Britain Accurate statistics are wanting

Lesions occur in both sexes and at any age from birth with its pulmonic stenosis to senility, with its sclerotic valves It is most common between the ages of fifteen and thirty years in those parts of the world where the rheumatic infection is rife and between forty and fifty five where syphilitic aortitis is common and the rheumatic infection rare At the earlier ages the female is more frequently attacked but as an accompaniment of syphilis and arteriosclerosis the disease appears more often in the male later in life

Chronic valvular disease is found in all races and countries but as has been already noted it is commonest in the colder temperate climates

Etiology —There are five types of chronic valvular disease congenital rheumatic syphilitic subacute and chronic infectious endocarditis and arteriosclerotic or calcareous The very rare involvement of the heart valves by neoplasms need not be included under the heading of chronic valvular disease Traumatic disease of the valves may occur and proved ruptures of aortic and mitral valves are on record but they are very rare and almost always superimposed on other diseases of the valves (rheumatism syphilis or arteriosclerosis) Tuberculous involvement is extremely rare

Congenital valvular disease consists almost solely of pulmonic stenosis which is a defect in fetal development the cause of which is not fully known Fetal endocarditis has been considered a reason for some cases of pulmonic stenosis but in other cases maldevelopment is doubtless the cause In a good many cases of so-called 'pulmonic stenosis the stenosis does not involve the valve itself but the upper (infundibular or outlet) portion of the right ventricle producing a subpulmonic or infundibular stenosis a centimeter or two proximal to the valve which in such cases is hypoplastic Congenital pulmonic regurgitation mitral stenosis aortic (or subaortic) stenosis and tricuspid stenosis have been reported but they are all much less common than pulmonic stenosis Lesser congenital abnormalities such as bicuspid and quadricuspid aortic and pulmonic valves need not be further discussed here except to say that bicuspid aortic valves are particularly liable to subacute bacterial endocarditis

Rheumatic valvular disease results from acute infection of the rheumatic type most commonly following rheumatic fever Vague pains in the joints or muscles tonsillitis and scarlet fever may also be followed by chronic disease of the heart valves of the rheumatic type In a certain percentage of cases probably about one quarter it is not possible to obtain a clear history of any of these infections Whether in these cases the infections themselves may be so slight that they are not noticed by the victims whether the infecting organism virus or toxin may gain entrance to the circulation without producing any noticeable local or general reaction or whether other disease may be responsible we do not know

The great majority of persons who have had rheumatic fever (about 85 per cent) develop chronic deforming valvular disease of the heart This generally begins in childhood is found most commonly in the decades from fifteen to thirty five years of age and is much less frequent after fifty years of age because many of its victims do not reach this age Uncomplicated chorea on the other hand is rarely followed by valvular disease

Syphilitic valvular disease results from a spirochetal invasion of the aorta which spreads down to the cusps of the aortic valve and even to the anterior cusp of the mitral valve It occurs much more frequently in males (nine out of ten cases) than in females and generally develops between

the ages of thirty five and fifty, some fifteen to twenty years after the primary syphilitic infection

Miscellaneous Infectious Chronic Valvular Diseases—Other varieties of infectious chronic valvular disease are less common Subacute bacterial endocarditis is not rare but since it is generally fatal ensuing chronic valvular defects are unusual Very rarely does a case of acute endocarditis due to pneumococcus gonococcus, meningococcus streptococcus staphylococcus influenza bacillus or other virulent organism survive so far as is known endocarditis constitutes a terminal infection during severe pneumonia meningitis influenza erysipelas or other septicemia Typhoid endocarditis is almost unknown Tuberculosis of the endocardium is also extremely rare once in a great while the presence of a tubercle on a heart valve is reported There is no evidence that such diseases as smallpox chickenpox measles whooping cough mumps diphtheria dy entery cholera plague typhus leprosy yellow fever or malaria are directly associated with endocarditis

Sclerotic or calcareous valvular lesions may occur in the old and middle aged They may be the result of atheromatous change or of deposition of calcium especially at the bases of the cusps (Monckeberg s sclerosis) like sclerotic or calcareous lesions in arteries or as not infrequently happens they may be superimposed on previous infectious injuries The aortic valve is affected in this way more often than any other valve

Morbid Anatomy—*The Valves*—CONGENITAL VALVULAR DISEASE consists generally in the narrowing of the pulmonic valve ring very rarely in stenosis of the tricuspid aortic or mitral valve Frequently the so called 'pulmonic stenosis' is located in the heart itself and involves the infundibulum of the right ventricle and not the valve This results in a two chambered right ventricle the terminal chamber being very small Pulmonic or infundibular stenosis is uncommonly an isolated lesion usually there are one or more other defects associated with it the most common of which is the combination of interventicular septal defect dextroposition of the aorta and marked enlargement of the right ventricle resulting in a clinical entity called the *tetralogy of Fallot*

Fig 119—Left ventricle opened revealing stenosed mitral valve Note the thickened short chordae tendineae and the coalescence of the valve cusps leaving the major portion of the valve like a circular shelf or diaphragm which can neither open nor shut

CHRONIC RHEUMATIC VALVULAR DISEASE consists of a scarring of the cusps and short

ening of the *chordae tendineae* There is a thickening of the lines of closure of the cusps later a stiffening and adhesion of the cusps to one another often with considerable deformity which may extend to the ring of insertion of the cusps and finally, a fusion of the whole valve into one fibrous mass which leaves but a narrow funnel shaped buttonhole or fish mouthed opening in the valve Hardening even to the point of calcification may occur especially in cases of long-standing aortic stenosis and mitral stenosis The most marked lesion is usually found in the mitral valve but extensive deformity is also common in the aortic valve while the tricuspid valve is not often much damaged and the pulmonic valve is very rarely deformed The relative frequency with which these various valves are attacked to any important degree is about as follows mitral 100 aortic 50 tricuspid 25 pulmonic less than 1

When the valve is so deformed that it can no longer close completely regurgitation or insufficiency is said to be present and when the deformity causes obstruction of the normal onward flow of blood, stenosis is the term used Any one of the four valves may show regurgitation or stenosis or both and not infrequently more than one valve is defective in a single individual The so-called functional regurgitation' or leaking and the relative valvular stenosis—due to dilatation of the ventricles the great vessels or the valve rings—are not included in this discussion since in themselves they are not evidences of chronic valvular disease although they often accompany it Anatomically speaking organic stenosis of a valve is almost impossible without some regurgitation and vice versa but preponderance of either stenosis or regurgitation often warrants the limitation of the clinical diagnosis to the single defect, for example mitral stenosis or aortic regurgitation Such a defect as organic mitral regurgitation can occur in rare cases without any mitral stenosis when shortened chordae tendineae prevent the valve leaflets from closing there also being a negligible degree of fusion of the cusps themselves

A normal heart weighing between 200 and 300 Gm should have valves with approximately the following circumferences

	Cm
Mitral	10
Aortic	7
Tricuspid	12
Pulmonic	8

If the mitral valve measures less than 7.5 cm in circumference the aortic valve less than 5 cm the tricuspid less than 8 cm and the pulmonic less than 6 cm., definite stenosis should probably be demonstrable clinically in a heart of average adult size

The fact that mitral stenosis of rheumatic origin is more common than organic mitral regurgitation has not been recognized until recently The occurrence of both stenosis and regurgitation of the deformed mitral valve is certainly more frequent than the appearance of either alone

Aortic regurgitation is about five times more common as a clinical finding in rheumatic heart disease than is aortic stenosis Often the two are combined and rather infrequently aortic stenosis occurs alone

Tricuspid regurgitation is not so common an organic defect as is mitral regurgitation while tricuspid stenosis of clinical importance is rare both as compared to mitral stenosis and absolutely Slight scarring of the tricuspid valve probably sufficient to produce slight regurgitation or stenosis not demonstrable clinically is fairly frequent but extensive alteration in the valve is decidedly rare

Pulmonic regurgitation is extremely unusual in rheumatic heart disease Stenosis of the valve of rheumatic origin is also very rare

Often the mitral valve is the only valve diseased after a rheumatic infection but in about two fifths of the cases with mitral involvement the aortic valve is also affected Very few of the cases showing aortic valve disease of rheumatic origin have no demonstrable mitral valve disease When the tricuspid valve which is rarely involved alone is affected it is almost always damaged at the same time as the mitral valve and the injury is sometimes accompanied by disease of the aortic valve in addition Pathologic examination shows that in 20 to 25 per cent of the cases of mitral disease there is tricuspid disease which is not demonstrable clinically The pulmonic valve in rheumatic infection is never the only valve affected

Recurrent attacks of rheumatic endocarditis are so common that the valves may bear the scars of several lesions Generally a progressive crippling develops to cause marked deformity of the valves in such cases At times postmortem examination reveals a row of fine nodules at the line of closure near the edge of the valve which is indicative of an *acute rheumatic endocarditis, it may show* a thickened fibrous cusp already contracted with shortened, stiffened chordae tendineae *or it may show the acute process* superimposed on the chronic In some cases, Aschoff bodies (the typical submiliary nodules of rheumatic infection) have been found in the valve substance before any deformity at all has occurred

Chronic syphilitic valvular disease presents the pathologic picture of a progressive infectious process showing not only the scarring but also the acute changes The luetic lesion begins in the aorta just above the valve and in time extends down to the mouths of the coronary arteries and to the valve cusps themselves by way of the commissures Degenerative changes retraction stiffening fusion of the sides of the cusps with aortic walls widening of the commissures and finally even superimposed calcification may occur Aortic regurgitation *is the result and may be still further in*creased by a weakening and dilatation of the aortic ring As a matter of fact quite often in cases of luetic aortic regurgitation the valve itself is little if at all damaged the leak being dynamic or functional in nature due to the stretching of the aorta at the attachment of the valve Stenosis does not occur in the uncomplicated luetic aortic valve lesion With progressive involvement of the aortic valve rupture may occur though this *is less common with lues* than with bacterial endocarditis The loud basal systolic murmur heard over the aortic area in many of the hearts with syphilitic aortic valve disease is not caused by aortic stenosis or by aortic roughening but by dilatation of the aorta Rarely the syphilitic process may by encroaching on the anterior cusp of the mitral valve produce slight deformity of that valve but there probably is no primary syphilis of the mitral valve Neither is there a *primary* luetic lesion of the tricuspid or pulmonary valves although unusual cases of syphilis of the pulmonary artery are on record

Other infectious valvular disturbances involve the valves in a variety of ways In the case of *acute bacterial endocarditis* there is generally extensive ulceration and formation of vegetations the edges of the valves are fringed at times with masses of bacteria and fibrin in various stages up to full organization Any one of the valves may be attacked but the mitral and aortic are the ones involved most frequently Embolism from the vegetations is common The valve cusps may be extensively ulcerated and perforated and even the chordae tendineae may be ruptured These extensive lesions are caused by staphylococcus streptococcus pneumococcus meningococcus and gonococcus Recovery from such disease is rare the lesions heal with great scarring and deformity *of the valves The right side of the heart is* involved in about 25 per cent of the cases of acute bacterial endocarditis and oftener when there is congenital heart disease

Subacute bacterial endocarditis due to the *Streptococcus viridans* and rarely to the *influenza bacillus* or *gonococcus* is of different nature the lesions being more discrete less extensive and fulminating and practically always involving the wall of the *auricle or ventricle in addition to the* valve cusps Subacute bacterial endocarditis is almost always superimposed on abnormalities already caused by rheumatic endocarditis or congenital defect it rarely attacks normal valves The typical lesion is a vegetation larger than in rheumatic but smaller than in acute bacterial endocarditis consisting of bacteria blood platelets and fibrin invaded by leukocytes The process extends apparently by contiguity *Here again embolism is common* and glomerular lesions in the kidneys with hematuria are frequent The scars formed in the uncommon recovered cases are quite similar to those of chronic rheumatic valvular disease but are more extensive they often involve the auricular and ventricular endocardium

Arteriosclerotic (calcareous) valvular disease appears in middle and old age often superimposed *on chronic* infectious or congenital valve lesions It may occur in otherwise undamaged valves the mitral and aortic being most commonly *involved* espe-

cally at their bases At times the resulting calcification may bind one or both of the mitral cusps by solid brittle chordae ten dineae to stony masses in the papillary mus cles and rocky projections may even pro trude from a stenosed aortic valve into the lumen of the aorta or downward into the muscle of the interventricular septum Frequently only the ring of valve attachment is the site of calcification What percentage of the patients with calcareous valve changes have previously had valvular disease we have no sure means of determining at the present time but it is probable that most of the extensively stenosed valves have been deformed before the calcification has oc curred

The Effect of the Valvular Disease—The effect of chronic valvular disease on the heart muscle and cardiac cavities is of course important Aortic stenosis and aortic regurgitation throw a great strain on the left ventricle and cause hypertrophy *Aortic re gurgitation* is somewhat more important in this respect than is aortic stenosis some of the largest hearts ever recorded (900–1000 Gm and more) have been the result of it The *cor bovinum* usually indicates aortic regurgitation Not only does the left ven tricle hypertrophy when there is aortic regurgitation but its cavity becomes enlarged (primary dilatation) to take care of the reflux of blood from the aorta during dias tole Apparently dilatation and hypertrophy in these cases go hand in hand *Aortic stenosis* may produce much or little hyper trophy of the left ventricle and if uncom plicated by aortic regurgitation no primary left ventricle dilatation secondary dilata tion occurs when heart failure sets in Aortic regurgitation complicated by moderate aortic stenosis is sometimes much less of a burden for the heart than aortic regurgitation alone A fact of much interest and importance is that when the left ventricle fails slowly or repeatedly in chronic aortic valve disease the increased pulmonary blood pressure causes the right ventricle to hypertrophy also and in rare cases of aortic valve disease with this evolution the right ventricle may be relatively more enlarged than the left ventricle itself

MITRAL STENOSIS throws a strain on the left auricle and right ventricle and therefore when this valve defect is well marked there is dilatation of the left auricle with thickening of its muscular wall, and hypertrophy of the right ventricle Eventually even the right auricle may feel the burden too and respond with dilatation and hypertrophy The left auricle, being affected first may as sume enormous proportions and cases are on record in which its bulk was larger than that of all the rest of the heart its capacity in creasing even to 1000 cc or more (normally about 125 cc) The right ventricle may grow to equal or to surpass the left ventricle in weight The left ventricle is little affected

MITRAL REGURGITATION throws a strain not only on the right ventricle and left auricle but also on the left ventricle which grows heavier and dilates in order to accom modate the extra blood which it takes in to compensate for the leak back into the auricle It is often true that the heart is more enlarged by combined mitral regurgita tion and stenosis than by preponderant mitral stenosis alone for this very reason With slight degrees of mitral regurgitation however there is little change in the weight of the ventricles or in the size of their cavities

PULMONIC STENOSIS is a great burden for the right ventricle and secondarily affects also the right auricle causing both to hyper trophy and dilate often to a marked degree before failure sets in there is uncomplicated right ventricular hypertrophy PULMONIC REGURGITATION is very rare the strain which is entirely on the right heart chambers pro duces dilatation and hypertrophy

TRICUSPID STENOSIS causes right auricular dilatation and hypertrophy and if marked engorgement of liver and great veins acting almost as does chronic constrictive pericar ditis TRICUSPID REGURGITATION affects the right ventricle and right auricle producing both hypertrophy and dilatation The effects of tricuspid stenosis *per se* are practically always accompanied by those of the accom panying tricuspid regurgitation and mitral stenosis so that both right ventricle and right auricle are considerably enlarged

Pathologic changes in other organs are not usually due primarily to chronic valvu lar diseases of the heart but rather to con gestive failure (acute or chronic passive congestion) or to infectious processes (em

bolism) Pulmonary vascular engorgement is however a common finding in mitral stenosis without demonstrable heart failure, and in such cases pulmonary 'apoplexy with a variable amount of hemoptysis is not rare Furthermore chronic stenosis of the mitral or tricuspid valve if marked and even without failure of the myocardium usually causes by obstruction alone chronic engorgement of the liver which sometimes leads to cirrhosis Pulmonary or cerebral or other peripheral infarction from embolism due to intracardiac thrombosis may be the first event to reveal the presence of chronic valvular disease (especially mitral stenosis)

Symptoms —There are no symptoms characteristic of chronic valvular disease Practically all the symptoms recorded in the old textbooks are those of heart failure or irritable heart the nervous heartache in mitral stenosis or aortic regurgitation anginal pain dyspnea palpitation (due to forceful heart action premature beats paroxysmal tachycardia or auricular fibrillation) cough weakness and fainting Even extensive damage of the valves for example, well marked aortic regurgitation occasionally produces no symptoms at all In such cases the myocardium is neither fatigued nor irritable Therefore the clinical diagnosis of chronic valvular disease must depend on physical signs and the results of instrumental tests

There are five symptoms however that may be traced more or less directly to valvular disease (1) heart consciousness is often caused by marked cardiac enlargement as in aortic valve disease (2) there may be a sensation of excessive arterial pulsation throughout the body with aortic regurgitation, (3) there may be dizziness faintness or even syncope due to cerebral anemia, in some cases of marked aortic stenosis (4) there is often dyspnea on effort and there may even be attacks of pulmonary edema and of cardiac asthma due to over distention of the pulmonary blood vessels in mitral stenosis the severity of such symptoms being dependent on the degree of the stenosis and on the grade of effort or excitement or other strain such as the onset of the tachycardia of auricular fibrillation, and (5) the liver and abdomen may become uncomfortably congested when there is marked tricuspid stenosis

Signs of Chronic Valvular Disease Discovered by Physical Examination and Laboratory Tests —In the discussion of the diagnosis of chronic valvular disease the valve lesions will be considered first individually and then collectively

Mitral Valve Lesions —Mitral valve damage (STENOSIS) is proved by an apical diastolic murmur with or without a thrill which begins a brief interval after the second heart sound in the absence of aortic regurgitation or other cause of marked left ventricular dilatation * There may or may not be a presystolic crescendo murmur at the end of it This is probably the only positive evidence of a mitral valve lesion that we possess There are many signs that indicate the probability of mitral lesions but do not prove them A very loud blowing or rough systolic murmur masking the first sound heard best at the apex and transmitted well to the axilla and to the back is fair evidence of mitral damage with REGURGITATION particularly if there is also a systolic thrill palpable at the apex provided there are not present causes of cardiac dilatation to produce functional regurgitation such as anemia infection or heart failure With a rheumatic history and some enlargement of the heart a loud apical systolic murmur is practically pathognomonic of mitral damage with regurgitation in the absence of pericarditis acute rheumatic cardiac infection ventricular failure with dilatation and aortic regurgitation If there is much cardiac enlargement as in hypertension with cardiac failure such a murmur often results from functional regurgitation, *though there is less likelihood of a thrill or of as much intensity of the murmur as in the case of a valve lesion*

Roentgenologic finding of a heart enlarged transversely with prominence of the left upper border is also good evidence of mitral valve disease the prominence of the shadow at the left upper heart border is due chiefly to enlargement of the infundibulum of the

* Rarely a very large left ventricular cavity without aortic regurgitation as in chronic adhesive pericarditis or acute rheumatic myocarditis may give rise to the typical mitral diastolic murmur with undeformed mitral valve This is probably to be accounted for as may also be the Austin Flint murmur by the abnormal change in the caliber of the blood stream as it enters the dilated ventricular cavity from the auricle

right ventricle and to dilatation of the pulmonic artery rarely to left auricular dilatation

The electrocardiographic finding of pronounced abnormal right axis deviation with prominent auricular complexes (P waves) in Lead I or II is excellent evidence of mitral damage in the absence of pulmonic stenosis Both of these changes come with advanced mitral stenosis as a rule and are corroborative evidence the apical diastolic murmur proving the condition

thrill may be found in nervous overactive hearts as well as *in mitral stenosis A reduplication* of the first sound at the apex and a prominence of the third heart sound should also cause suspicion of mitral stenosis These findings and the sharpness of the apical first sound indicate the need of exercise (or amyl nitrite inhalation) to increase the speed and force of the heart to bring out the mitral diastolic murmur with or without its presystolic accentuation in early or slight grades of mitral stenosis Recently a

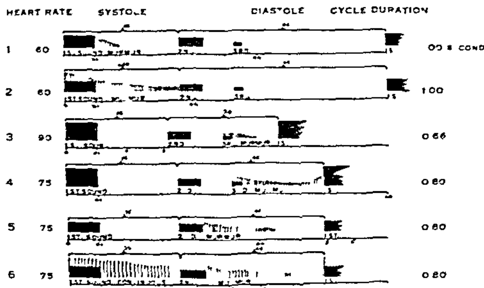

Fig 1?0—Heart sounds and murmurs graphically illustrated 1 A short systolic murmur heard at the apex indicative of mitral regurgitation When heard at the aortic area this murmur is usually indicative of slight dilatation of the aorta from hypertension or other cause When heard at the pulmonary area, it is entirely unimportant, a physiological functional murmur probably associated with some physiologic dilatation of the pulmonary artery 2 Long blowing systolic murmur masking the first sound and when heard at the apex indicative of a high degree of mitral valvular insufficiency In the aortic area, this murmur is usually harsh and may be found with aortic stenosis 3 Accentuation of the first heart sound and short mid-diastolic murmur at the apex indicative of slight mitral stenosis or dilatation of the left ventricle 4 The same as 3 except with a louder mid-diastolic murmur with presystolic accentuation indicative of a higher degree of mitral stenosis 5 A long blowing early diastolic murmur heard along the left border of the sternum, indicative of aortic regurgitation 6 Continuous murmur heard over the pulmonary valve area, indicative of patency of the ductus arteriosus

Marked accentuation of the second sound at the second left interspace near the sternum ($P_2 + +$) is usual in chronic mitral disease Auricular fibrillation constant in a young adult—under the age of forty years—generally means rheumatic heart disease with mitral involvement usually stenosis

Other signs that suggest the possibility of mitral disease include the sharp first sound at the apex with or without a very brief thrill in a heart not beating violently This short, so-called presystolic murmur and

very loud third heart sound close to the sternum in the fourth space has attracted attention the mitral diastolic murmur being found at the apex immediately following the third heart sound in many such cases this *loud third sound at the lower left sternal* border in mitral stenosis is probably due to dilatation of the right ventricle and gives rise when the heart rate is accelerated to a characteristic diastolic gallop rhythm presaging or accompanying right heart failure A pronounced presystolic murmur alone

without the mid diastolic murmur is rarely heard and unless the presystolic murmur is quite definite it should not be interpreted as *meaning mitral stenosis* Moreover, it should be remembered that when auricular fibrillation sets in, the auricles cease coordinate action so that *the presystolic* phase of the diastolic murmur of mitral stenosis disappears and leaves the telltale mid diastolic murmur behind Since auricular fibrillation is a very common condition especially in hearts with mitral stenosis this is a very important point to remember It shows the greater need of relying on the diastolic rather than on the presystolic murmur in the diagnosis of mitral stenosis Mackenzie *thought that the first murmur to appear in* mitral stenosis is presystolic in time and that an actual thrill also presystolic in time may precede the appearance of this murmur by some years it is the writer s opinion however that Mackenzie with his old fashioned monaural stethoscope failed to hear the mid diastolic murmur so characteristically found in most instances of early or slight *mitral stenosis and that he picked up only* the more advanced cases

The diastolic murmur already so frequently mentioned is of a characteristic type It begins an appreciable interval after the second sound and at once after the third sound when that is audible it is often *diminuendo* in character and is low pitched and rumbling It is best heard with the patient recumbent and by the use of the bell stethoscope The murmur is usually localized at or just inside the maximal apex impulse It is accentuated by exercise With *well marked aortic regurgitation the apical* diastolic murmur with or without presystolic accentuation may mean simply the so called "functional mitral stenosis described by Austin Flint Aortic regurgitation with a mitral diastolic murmur in a rheumatic heart should generally be considered as a combination of aortic regurgitation and organic mitral stenosis in a syphilitic heart as aortic regurgitation and 'functional mitral stenosis Thayer in 1901 reported a mitral diastolic murmur in forty five out of seventy four cases of aortic regurgitation which came to necropsy at the Johns Hopkins Hospital There was stenosis or other abnormality of the mitral valve in twenty eight of these seventy four cases so that by subtracting this number from the total figure we have a probable ratio of 17 46 or between one half and one third of the pure aortic regurgitation cases exhibiting the Austin Flint murmur

Other conditions suggesting the possibility of mitral valve damage are the history of rheumatic fever, especially if repeated attacks *have occurred cerebral or other* peripheral embolism (from left auricular thrombosis) in a young person, generally of the female sex hemoptysis in a young person without tuberculosis left recurrent laryngeal nerve paralysis and the mitral facies (cyanotic flushed face) with pulmonary congestion and in various stages of heart failure The pulse is often stated to be small and the systolic pressure low in mitral stenosis this is not infrequently so in cases of auricular fibrillation but it is certainly not always the case

Tricuspid Valve Lesions—Deformity of the tricuspid valve of any important degree is relatively rare and is usually difficult to diagnose The *frequency* of functional TRICUSPID REGURGITATION is great as compared with organic changes in the valve which produce regurgitation or stenosis Organic" regurgitation is rarely present without *stenosis its pathogenesis is the same* as that of organic mitral regurgitation Functional tricuspid regurgitation is a common *result* of right ventricular failure in very rare cases it may persist due to an irreversible dilatation of the tricuspid ring *Marked* TRICUSPID STENOSIS is manifested by a mid-diastolic murmur with or without a presystolic phase *which is localized* over the lower half of the sternum or just to the left of it Care must be taken to avoid confusion with a widely heard mitral diastolic murmur or with the early diastolic murmur of aortic regurgitation which is heard in the same place and also higher Mackenzie stated that he had heard the tricuspid presystolic *murmur* only three times Tricuspid stenosis is likely to be associated with auricular fibrillation and it *is rarely found in* advanced rheumatic heart disease without mitral stenosis Osler and Gibson stated that in a group of 173 cases of tricuspid stenosis this lesion occurred alone in only 12 it was associated with a mitral lesion in 97 with mitral and aortic

lesions in 58 with mitral and pulmonic in 3 and with pulmonic stenosis in 3

There are other signs suggestive of organic tricuspid valve disease A large liver may be present although Osler and Gibson say that it is not always enlarged with tricuspid stenosis Mackenzie looked upon pulsation of the liver with a marked wave due to the auricle as an evidence of possible tricuspid stenosis' but the auricles may fibrillate and the auricular wave will then disappear One of the features of these cases may be an enlarged nonpulsating liver without evidence either of cardiac failure or of alcoholic cirrhosis In such cases however one must consider chronic constrictive pericarditis Mitral stenosis alone may also produce chronic enlargement of the liver

Cyanosis marked in some cases and with a jaundiced tinge to the skin (the jaundice is due usually to a complicating pulmonary infarct) polycythemia dilated cervical veins increased dulness to percussion to the right of the sternum particularly in the third and fourth interspaces and a rather high abnormal prominence of the right auricular shadow with relatively clear lung fields by roentgen ray are all said to support the diagnosis of tricuspid valve disease but a fairly marked stenosis is necessary to bring out some of these findings The heart is enlarged transversely in tricuspid valve disease A superficial high pitched long rough systolic murmur maximal over the sternum at about the level of the fourth interspace and to the left rather than to the right suggests either organic tricuspid regurgitation or interventricular septal defect Electrocardiograms have shown abnormal right axis deviation partly at least because mitral stenosis is almost always associated Also when there is no auricular fibrillation the auricular complex (P wave) is increased in size The venous blood pressure is increased and there is usually a marked increase in the deep systolic jugular pulse (such pulsation is of course merely indicative of tricuspid regurgitation which may or may not be accompanied by any valvular deformity) Except for the frequency of auricular fibrillation the arterial pulse is not abnormal

Aortic Valve Lesions —A diastolic murmur beginning early and best heard down the left border of the sternum associated with the water hammer pulse is pathognomonic of AORTIC REGURGITATION This murmur may also be heard at the aortic valve area along the left border of the heart and at the apex but it should not be confused with the mitral diastolic murmur at the apex which is later in time and more rumbling in character Whether or not the cusp or cusps involved have anything to do with the variable transmission of the murmur is not known A musical diastolic murmur suddenly appearing after trauma or exertion or even spontaneously in rheumatic or syphilitic valvular disease usually means eversion of a cusp or very rarely in bacterial endocarditis a valve rupture

The marked water hammer quality of the pulse described by Corrigan is also pathognomonic of aortic regurgitation if there is an aortic diastolic murmur and if we can rule out marked peripheral vasodilatation Various suggestive phenomena such as the pistol shot heard over the great arteries for example in the groin the to and fro murmur on pressure over the great vessels (Duroziez s sign) and the visible pulsation or throbbing of the arteries of the head and extremities are dependent on the markedly increased pulse pressure due chiefly to the very low diastolic blood pressure This wide pulse pressure with very low diastolic reading is pathognomonic of aortic regurgitation except in cases of very marked peripheral vasodilatation The symptoms of ringing in the ears and vertigo sometimes complained of by patients with aortic regurgitation probably have their origin in the water hammer type of pulse An interesting phenomena observed by Hill and Rowlands in aortic regurgitation is the much higher systolic pressure in the femoral artery than in the brachial artery not dependent on hydrostatic pressure or the larger caliber of the femoral artery

Absence or weakness of the aortic second sound may be found in aortic regurgitation when it is accompanied by aortic stenosis The heart is always enlarged if there is much regurgitation and it is when regurgitation is marked that the greatest increase in heart size (*cor bovinum*) is commonly found The apex impulse is then often in the sixth or seventh space and out close to the anterior

axillary line Krehl, among others has however shown that very slight aortic regurgitation may occur without any obvious enlargement of the heart

The roentgen ray discloses a large heart increased in size downward and to the left with a rounded apex Increased excursion of the pulsation of the aortic arch is common in aortic regurgitation The aortic shadow is most increased in size if there is associated a syphilitic aortitis

In uncomplicated cases the electrocardiogram reveals markedly abnormal left axis deviation the most marked observed

Confusion of aortic with pulmonic regurgitation should be avoided by the rarity of the latter by failure to find signs of increased systemic arterial pulse pressure in pulmonic regurgitation and especially by roentgen ray and electrocardiographic study In cases previously diagnosed as having aortic regurgitation because of the finding of an early diastolic murmur along the left border of the sternum the roentgen ray may show marked prominence in the region of the pulmonary artery with marked pulsation of the hilus shadows of both lungs (the *hilus dance*) and the electrocardiogram may reveal marked preponderance of the right ventricle certainly not supporting the diagnosis of aortic regurgitation In such cases it is justifiable to make a diagnosis of pulmonic valve regurgitation but the opportunity to make such a diagnosis rarely arises except in occasional instances of marked mitral stenosis with heart failure where the pulmonic regurgitation is of functional nature I have encountered three cases in which I have felt justified in making the diagnosis of organic pulmonic regurgitation two of congenital origin and one acquired The diagnosis in the first two cases was confirmed by necropsy, the third case has not come to autopsy

A diastolic murmur heard over the sternum has been recorded as of venous origin transmitted down from a venous hum in the neck and has been encountered in exophthalmic goiter, such cases should present but little difficulty since in them the diastolic murmur is usually but part of a continuous murmur heard best in the neck

It must be added finally that a slight degree of aortic regurgitation is common and is not associated with any pulse or blood pressure changes If the diagnosis is not made until the late changes appear it is probable that at least 50 per cent of all cases of aortic regurgitation will be missed The diagnosis in many cases must be made from the murmur alone Functional regurgitation through the aortic valve was described by Corrigan and has been spoken of since by others but it is not common it may occur in cases with senile weakening of the aortic valve ring with or without hypertension

Aortic stenosis may be definitely diagnosed in the absence of any sign of an aneurysm on the discovery of a rough systolic murmur with a systolic thrill over the aortic area to the right of the sternum in the second interspace this murmur is widely transmitted especially to the vessels of the neck and to the cardiac apex Stokes noted that this murmur at times may be audible at some distance from the chest wall The pulse is generally small and anacrotic or plateau like or both a very important confirmatory finding The blood pressure is not remarkable except that there is often a low pulse pressure* if there is considerable regurgitation so that the stenotic effect is overbalanced there may be an increased pulse pressure and absence of the anacrotic and plateau characteristics The heart is usually enlarged downward and to the left as shown by palpation percussion and the roentgen ray but not to the extreme degree found in uncomplicated aortic regurgitation In aortic stenosis the aortic second sound is often absent or much diminished The electrocardiogram may show abnormal left axis deviation but mitral stenosis associated with aortic stenosis may neutralize the abnormal left axis deviation

Aneurysm and aortic dilatation may be confused with aortic stenosis of slight or moderate degree Pulmonic stenosis should not be confused with aortic stenosis because the systolic murmur of pulmonic stenosis though also loud and accompanied by a thrill is heard best to the left of the sternum and is not transmitted to the neck

Slight degrees of aortic stenosis may be

* It is however of considerable interest that an auscultatory gap is sometimes found in the process of blood pressure estimation in aortic stenosis

suspected when there is rheumatic heart disease with aortic regurgitation and a loud blowing systolic murmur at the aortic area transmitted to the neck even without a thrill Aortic stenosis overdiagnosed years ago is now quite often missed it is always to be considered as a possible and in colder climates common cause of a systolic murmur at the aortic area

Pulmonic Valve Lesions—Chronic valvular disease deforming the pulmonic valve is very rare Endocarditis of the pulmonic valve is almost invariably associated with mitral aortic or tricuspid lesions alone or combined PULMONIC REGURGITATION may be suspected by the finding of a murmur beginning early in diastole with or immediately following the accentuated second sound maximal in the second interspace just to the left of the sternum and extending down the left border of the sternum but the murmur of a slight degree of regurgitation through the pulmonic valve may be indistinguishable from that of slight aortic regurgitation since the position and character of the murmurs are almost identical and with a small amount of aortic regurgitation there may be no water hammer character to the pulse In such cases roentgenographic and electrocardiographic evidence should be helpful in indicating which ventricle shows the greater hypertrophy and which great artery—aorta or pulmonary artery—shows the greater pulsation With a moderate or marked degree of pulmonic regurgitation it is possible to observe fluoroscopically a definite water hammer pulsation in the pulmonary artery and the lung hilus shadows which at once differentiates pulmonic regurgitation from aortic regurgitation Organic pulmonic regurgitation may not be distinguishable from functional pulmonic regurgitation from the murmur alone The functional type occurs in cases of advanced mitral disease with much pulmonary engorgement The murmur of functional pulmonic regurgitation—due to the stretching of the pulmonic ring—is that described by Graham Steell Its frequency is a matter of some discussion It is said to appear and disappear with changes in the condition of the patient It may be difficult to distinguish from slight functional aortic regurgitation One should be hesitant about calling a slight early diastolic murmur heard along the left border of the sternum a Graham Steell murmur unless there is mitral stenosis of high degree and long standing Graham Steell himself found the pulmonic regurgitant murmur rarely Osler and Gibson say 'From the clinical standpoint so much that has been said about pulmonary regurgitation is either unproved or as yet incapable of proof that the subject should be approached with the greatest caution Pulmonary regurgitation is more often diagnosed than existent In several cases in which we thought it to be present in young persons the lesion proved to be aortic The rarity of organic pulmonic regurgitation should cause careful study before the diagnosis is made but functional pulmonic regurgitation (which is not diagnosable at autopsy) may as a matter of fact not be very rare I have encountered it in several cases every year its maximal audibility in the pulmonic valve area immediately following a markedly accentuated second heart sound is a most important clue

PULMONIC STENOSIS is a fairly common congenital heart abnormality but as the result of disease after birth it is exceedingly rare A loud systolic murmur in the second interspace to the left of the sternum with a systolic thrill not transmitted to the vessels of the neck is pathognomonic of pulmonic stenosis in the absence of signs of an aneurysm or of a plateau radial pulse Two types of congenital stenosis are described that occurring low and involving the infundibulum of the right ventricle and that involving the valve itself The former variety is likely to show the maximal murmur and thrill in the third left interspace and the latter in the second left space With any pronounced degree of stenosis there is considerable cyanosis chiefly as the result of the right to left shunt of venous blood through the defective ventricular septum An interventricular foramen is found in a large number of the cases of pulmonic stenosis (tetralogy of Fallot) Polycythemia and clubbing of the fingers occur with much cyanosis Enlargement of the heart to the left with the apex tilted up is shown by the roentgen ray Vaquez and Bordet call this the wooden shoe (*sabot*) shape The roentgen ray usually indicates hypoplasia of the pulmonic artery rarely a normal-sized

or dilated vessel The electrocardiogram indicates abnormal right axis deviation and it is in these cases of congenital pulmonic stenosis that the highest grades of right axis deviation are found Stenosis of the pulmonic valve acquired after birth should be distinguishable from the congenital type by the history of the case, by the evidence of other endocarditic lesions, and by the presence of pulmonic regurgitation also

COMBINED VALVE LESIONS —The combination of valve lesions causes a combination or a neutralization of the signs of the individual valve changes For example *stenosis* of the aortic valve cuts down and may completely neutralize the Corrigan pulse of aortic regurgitation Aortic regurgitation balances the right ventricular hypertrophy of *mitral stenosis so that the* whole heart may be symmetrically enlarged The characteristic murmurs of both lesions will be present in such a heart the early diastolic murmur of aortic regurgitation best heard along the left border of the sternum but often transmitted to the apex and the later rumbling diastolic murmur of mitral stenosis at the apex Sometimes an apparent difficulty may arise as to whether these murmurs represent the diastolic murmur of true mitral stenosis with the functional pulmonic regurgitant murmur of Graham Steell or the diastolic murmur of aortic regurgitation with the functional mitral diastolic murmur of Austin Flint Other data such as the type of ventricular enlargement (left or right sided) determined by electrocardiogram and roentgen ray, and the presence or absence of the Corrigan pulse or of pulmonary congestion should clear up such doubts quickly In rheumatic heart disease the two diastolic murmurs described above most often mean that there is both organic aortic regurgita*tion and organic* mitral stenosis More likelihood of error arises when one attempts to diagnose damage to three valves Osler and Gibson write As a rule the physician is in a safer position if he limits his diagnostic ambition *to two* valves Clinically when lesions of three or four valves are determined with accuracy mortifying *postmortem* disclosures are not unlikely to follow

Complications —The most common complications of *chronic* valvular disease are heart failure of the congestive type and irritability of the heart as shown by palpitation *and arrhythmia In the past* most accounts of the symptoms signs and treatment of chronic valvular disease have consisted largely of a recital of the evidence and treatment of heart failure In the case of aortic valve lesions the strain is chiefly on the left ventricle and it is that ventricle which tends first to produce such signs and symptoms of failure as edema of the lungs and Cheyne Stokes respiration Mitral stenosis exhausts the right ventricle first with the early appearance of hepatic and periph*eral stasis The pulmonary vascular conges*tion that commonly attends marked mitral stenosis either inconstant or in paroxysmal form is not to be ascribed to heart failure it is the result of the mechanical obstruction caused by the stenosed valve and so *is to be* strictly differentiated from the pulmonary vascular congestion of left ventricular failure Pulmonic stenosis is a rare cause for right ventricular failure The three valve lesions of aortic regurgitation mitral stenosis and pulmonic stenosis are the most serious of the burdens imposed on the myocardium by chronic valvular disease Even the strongest heart muscle may become exhausted eventually by such a strain Sometimes in these hearts the muscle is itself diseased and so unable to carry the burden long without trouble Neither the old view that the valve disease is the chief factor in the production of heart failure nor the modern view that weak muscle is the chief cause is sufficient Both factors play their parts inseparably though the strain due to the valve deformity is certainly the more important chronic factor and the acute or subacute rheumatic involvement of the myocardium is the more important *recurrent* acute factor

Irritability of the heart is common in chronic valvular disease Forceful uncomfortable heart beats (in aortic regurgitation particularly) paroxysmal tachycardia auricular flutter and auricular fibrillation (paroxysmal or permanent especially in mitral stenosis) and premature beats and *effort* syndrome with any of the valve lesions are frequently found but are not essential accompaniments of chronic valvular disease

Embolism into a peripheral artery is a complication which in a few cases accom

panies mitral stenosis Hemiplegia in young people may result from cerebral embolism from left auricular thrombosis in mitral stenosis Usually however embolism of cardiac origin results from infectious thrombi in subacute bacterial endocarditis or from mural thrombi over myocardial infarcts

Laryngeal paralysis with consequent hoarseness which is found rarely in marked mitral stenosis is probably the result of pressure on the left recurrent laryngeal nerve against the aorta by the pulmonary artery which is in its turn displaced by the much enlarged left auricle or right ventricle

One of the most serious complications of chronic valvular disease of congenital or rheumatic origin is the superimposed subacute bacterial endocarditis which is usually though not now invariably fatal

Differential Diagnosis —The commonest and most important conditions with which chronic valvular disease may be confused are those giving rise to the so called functional heart murmurs At this point I would like to recommend a revised nomenclature of murmurs in general Unless qualified the term functional does not distinguish between murmurs that are physiologic and murmurs that are pathologic and the term organic is customarily limited to the designation of murmurs that are the result of structural changes in the valves even though much more serious organic heart disease may be present in the myocardium with normal valves Hence the expressions physiologic and pathologic should I think be used primarily, the latter being subdivided into murmurs due to structural valvular and congenital defects and murmurs due to dilatation of heart chambers or great vessels which in turn may be the result of either cardiovascular disease or diseases of other nature such as anemia

A pathologic systolic murmur maximal at the apex without valvular disease may be heard when there is a dilatation of the mitral valve ring or dilatation of the left ventricular cavity with downward displacement of papillary muscles and chordae tendineae so that there is failure of the mitral cusps to close the left auriculoventricular ostium completely this may accompany cardiac dilatation as in primary heart failure or it may accompany adhesive pericarditis severe anemia or severe infectious diseases It is common in acute rheumatic infections which so often involve the myocardium and cause the left ventricle to dilate Sometimes a systolic murmur heard at the apex is due to the movement of air in or out of the lung tissue near the heart during systole such a murmur is intrapulmonary and should be distinguished from the other type of so called 'respiratory murmur which occurs in the heart itself only during certain phases of respiration The physiologic systolic murmur at the apex is generally less intense than the pathologic systolic murmur but not always so and slight murmurs do occur with organic mitral regurgitation of lesser degree A very loud blowing systolic murmur at the apex masking the first sound is much more likely to be evidence of organic than of functional mitral regurgitation unless the heart is large and dilated The smaller the heart the more likely it is that the *very loud* systolic mitral murmur is due to valve deformity Transmission of the apical systolic murmur to the axilla lung bases and elsewhere depends on the intensity of the murmur whether pathologic or physiologic well marked transmission of the murmur to the lung bases is evidence of its origin in mitral regurgitation in contrast to the systolic murmur of aortic stenosis Pathologic murmurs are more often transmitted because they tend to be louder However neither the time nor the intensity nor the quality of the apical systolic murmur due to mitral regurgitation determines with certainty whether or not the murmur is due to organic disease of the valve Other findings must decide that point if it can be decided at all in a given case An excellent discussion of systolic cardiac murmurs was published by Thayer in 1925

A physiologic systolic murmur maximal over the base of the heart just to the left of the sternum in the second intercostal space —the so called pulmonic area —is the commonest heart murmur of all It is heard in at least 50 per cent of all individuals in the recumbent position much less commonly in the erect position It seems to be a normal phenomenon but its cause is not known It is exaggerated in full expiration and the mechanism of its production may be related to that which normally causes reduplication

of the pulmonic second sound in full expiration—an increase in pressure in the pulmonary circulation which perhaps causes dilatation of the pulmonary artery or there may be compression or kinking of the pulmonary arteries with resultant murmur This kind of physiologic pulmonic systolic murmur is rarely if ever accompanied by a thrill probably on account of its low intensity Any circulatory weakness—particularly with severe anemia—tends to produce loud pulmonic systolic murmurs Congenital cardiac defects such as pulmonic stenosis patent ductus arteriosus and interventricular septal defect are to be differentiated from the physiologic pulmonic systolic murmur In the case of the congenital heart defects the murmur is usually intense and often accompanied by a systolic thrill while in addition with pulmonic stenosis there is generally cyanosis from birth with patent ductus arteriosus the murmur is continuous through both systole and diastole and with interventricular septal defect the maximal murmur is low in position generally at the fourth left costal cartilage close to the sternum

A pathologic systolic murmur maximal over the base of the heart just to the right of the sternum in the second intercostal space—the so-called aortic area —without valvular disease is quite common and is heard frequently when the aorta is dilated It does not come from roughening but from change in the caliber of the blood stream as it leaves the aortic valve and enters the dilated aorta Such dilatation of the aorta develops particularly in syphilitic aortitis in patients with hypertension and in cases with marked aortic regurgitation An aortic systolic murmur may not have obvious cause but it is rarely found in normal persons While aortic stenosis may occur without a systolic thrill or change in pulse pressure and shape it is something of a hazard to base this diagnosis on the murmur alone Physiologic aortic systolic murmurs do not produce thrills It should be noted that in some cases in which the aortic systolic murmur is thought to be functional there is doubtless present as its cause an actual slight aortic valve stenosis caused by calcification at the base of the valve cusps (the so called Monckeberg s aortic valve sclerosis)

A pathologic tricuspid systolic murmur which is not common should be found at the lower end of the sternum but may be masked by a mitral systolic murmur when there is dilatation of both mitral and tricuspid rings or of both ventricular cavities A tricuspid systolic murmur is not so frequent as a mitral systolic murmur although tricuspid regurgitation is common Probably the relatively low pressure in the right side of the heart accounts for the less frequent occurrence of a systolic murmur at the lower end of the sternum

A pathologic diastolic murmur maximal at the apex without valvular disease is occasionally found It resembles the mitral stenotic diastolic murmur exactly in time character and position but it is as a rule less intense and is not often accompanied by a thrill In well marked aortic regurgitation it is called the ' Austin Flint murmur and it has been thought to be due to a relative mitral stenosis resulting from the partial closing of the mitral value during diastole by the regurgitant stream of blood from the aortic valve impinging on the anterior cusp of the mitral valve But since exactly the same murmur is found now and then with left ventricular dilatation due to acute rheumatic myocarditis to severe anemia and even to heart failure in hypertension it is likely that the mechanism of its production is always the same Some patients with aortic regurgitation show the most marked dilatation of the left ventricular cavity known An unusual change in the calib the blood stream entering a dilated ventricle from a normal mitral valve account for this well known apical dias murmur *

A pathologic diastolic murmur whi heard best along the left border of sternum and at either the pulmonic aortic areas without valvular disease be due to either pulmonic regurgita (Graham Steell murmur) or aortic regu tation Both are very rare conditions an is almost always wiser to regard an e diastolic murmur which is maximal al the left border of the sternum as evidenc aortic regurgitation due to valve deform

* Heart murmurs are produced by marked cha in the caliber of the blood stream as it passes thr the heart, either forward or backward

The functional murmur is nearly always slight and is therefore not associated with much change of blood pressure but in character time and position it is indistinguishable from the organic murmur The pulmonic regurgitant murmur without pulmonic valve deformity occurs in marked mitral stenosis *with increased pressure in the* pulmonary circulation and consequently with abnormal pressure in diastole against the pulmonic valve the ring of which may itself be weak It is usually loudest in the second left interspace in contrast to the aortic regurgitant murmur which is loudest further down the left border of the sternum This type of aortic regurgitant murmur may be found in patients with systemic hyper tension and weakness of the aortic valve ring or in rare cases the latter cause alone may be responsible An important feature of the functional' diastolic murmurs at the base of the heart is that they tend to be transient appearing and disappearing with changes in the patient's condition Very rarely a Graham Steell murmur may be very loud and even accompanied by a slight thrill A pulmonic systolic murmur and accentuation of the pulmonic second sound precede the Graham Steell murmur

A pathologic tricuspid diastolic murmur without tricuspid valve deformity had not been recorded before the last edition of this work when I described such a murmur at the lower end of the sternum in a patient with a loud *Graham Steell murmur* who later showed at autopsy marked mitral stenosis pronounced dilatation of the right ventricle and a normal tricuspid valve

Other conditions to be differentiated from chronic valvular disease are *aortic aneurysm rare congenital defects such as coarctation of the aorta* and *pericardial friction rubs* An aortic aneurysm of the ascending or descending aorta may simulate to some extent aortic or pulmonic stenosis but the etiology and more marked thrills of valvular stenosis and the occasional finding of unequal pulses increased dulness at the base of the heart both by percussion and by roentgen ray occasional visible basal tumor or pulsation positive Wassermann reaction and vigorous arterial pulse sometimes seen in the neck with aneurysm help to differentiate the conditions The congenital cardiac defects mentioned above can usually be differentiated from chronic valvular disease by the history and by the unusual position and character of the murmurs Pericardial friction rubs are usually easily distinguished from the murmurs of chronic valvular disease by their scratchy near to *the ear character by their brief duration* (rarely more than a few days) and by the frequency of pericardial effusion coincident or following

Prognosis —Clinically pure *mitral regurgitation* due to valvular deformity of rheumatic origin if not of marked degree has a good prognosis Without further rheumatic infection or progressive deformity of the valve with ensuing stenosis and without the complication later in life of acute or subacute bacterial endocarditis the patient should live in full capacity for almost the normal span of life But it should be definitely stated that marked mitral regurgitation is a serious burden for the heart no less than is marked mitral stenosis and that mitral regurgitation of any degree with little or no mitral stenosis associated is not rarely complicated by fatal bacterial endocarditis

Mitral stenosis almost invariably rheumatic in origin is a very common condition in some parts of the world as in New England and it varies considerably in prognosis The lesser degrees may shorten life little if at all in fact proved cases have survived eighty years one such of my own recently died of pneumonia at eighty three Marked mitral stenosis is however serious it handicaps activity and is often fatal before or soon after the patient reaches adult life for the strain on the heart and lungs is great no matter what the condition of the muscle may be Auricular fibrillation and congestive failure with or without acute rheumatism eventually lead to death as a rule but now and then subacute (or acute) bacterial endocarditis or an intercurrent infection or pulmonary infarction is the cause of death Bacterial endocarditis rarely occurs on a markedly stenosed mitral valve it is much more common with lesser grades of deformity (regurgitation) which still permits some trauma to the valve tissue when the cusps close

Often the question comes up as to whether or not mitral stenosis or other chronic val

vular lesions should be a bar to *pregnancy* As there is no rule on which to base such a decision each case must be determined on its merits There is usually little difficulty during pregnancy and childbirth, unless the stenosis is marked or auricular fibrillation is present Both of these conditions—*i e* very marked mitral stenosis and auricular fibrillation—contraindicate pregnancy Auricular fibrillation especially is a serious complication Most serious of all is of course congestive heart failure, the pregnancy should not be terminated until after the congestive failure has been controlled, a well treated case may go on to term but should never be allowed to become pregnant again

Almost the same may be said of *rheumatic aortic regurgitation* of slight extent as of slight rheumatic mitral regurgitation, the prognosis is reasonably favorable The higher degrees of aortic regurgitation are however a great strain on the heart The victim usually does not attain middle age and he rarely survives it Death is caused by heart failure often induced by acute rheumatism or by acute or subacute bacterial endocarditis in youth

Syphilitic aortic regurgitation is always a serious sign—generally of advanced cardiovascular syphilis Patients with this lesion do not often survive more than a few years Death may ensue from rapidly progressive failure twelve to thirty six months after the discovery of the lesion but in occasional cases it is delayed much longer

Arteriosclerotic aortic regurgitation or aortic stenosis (Monckeberg s sclerosis) is usually but part of a general arteriosclerosis which may lead to death within a few years it can add a considerable burden to a heart often poorly supplied with blood

Rheumatic aortic stenosis has a better prognosis than a similar grade of aortic regurgitation and may allow survival to old age The presence of aortic stenosis if not marked may improve the prognosis of aortic regurgitation Once the heart begins to fail however the prognosis is poor

Tricuspid valvular disease is practically always complicated by disease of either the mitral or aortic valve or both and its prognosis depends mainly on that of the other valvular defects It is of interest that tricuspid stenosis when marked actually decreases the strain on the heart and reduces the gravity of the immediate prognosis

Pulmonic valvular disease is a serious condition whether congenital or acquired By far the most common lesion of this type is congenital pulmonic stenosis This condition even though compensated by some other defect like patency of the ductus arteriosus or interventricular septal defect is generally fatal early in life it may rarely allow survival to youth or even to middle age or beyond It handicaps activity very much and patients who do not succumb to acute infectious disease in childhood die as a rule of heart failure or subacute bacterial endocarditis in early adult life

Chronic valvular disease is thus a serious handicap and very often limits both the duration and activity of life Death comes generally because of heart failure often secondary to acute rheumatic myocarditis but may result from the complication of subacute bacterial endocarditis or other acute infectious disease against which the resistance is lowered

The most valuable prognostic sign in valvular disease is the size of the heart the larger the heart the worse the prognosis

Treatment—Very little need be said about the treatment of chronic valvular disease We are not concerned here with the treatment of its complications (such as heart failure either congestive or anginal) or of cardiac irritability represented by the arrhythmias

The treatment of chronic valvular disease itself to date has proved futile An attempt has been made to cut and thus to enlarge the stenosed mitral valve by *operation* but this method of treatment has been ineffective Only one or twice has such an operation been successful or even been followed by survival the mortality in a small group has been very high Actually there is little to be gained anyway in changing mitral stenosis into mitral regurgitation

No operative attempt has yet been made to correct the valve defects in the other more serious conditions—aortic regurgitation and pulmonic stenosis and it seems unlikely that such measures would be possible

There is no *drug therapy* yet devised to improve the condition of the scarred valves Only in the progressive changes in the aortic

valve which are due to syphilis is there hope from drugs at present and even in cardio vascular lues the antisyphilitic treatment may afford little benefit, sometimes in large dosage it may do harm and lead to early death Nevertheless careful therapy with potassium iodide and bismuth or arsenic should be attempted whenever possible that is in the absence of heart failure for life is sometimes prolonged thereby

Of course the prevention of further infections which are likely to damage the valves is of prime importance in individuals with chronic valvular disease Tonsillectomy avoidance of exposure to cold and wet and early use of salicylates in rheumatic fever and of the sulfonamides in bacterial endocarditis are worth while A change of residence from an unfavorable (cold and wet) to a favorable (warm and dry) climate is generally helpful in rheumatic heart disease and may be life saving Recently it has been demonstrated that the use of the sulfonamides during the winter and spring in children subject to recurrent rheumatic fever is protective by preventing infection with hemolytic streptococcus

Of the greatest importance of all is the campaign now under way to prevent the factors which produce chronic valvular disease The wiping out of rheumatic fever and chorea scarlet fever syphilis subacute bacterial endocarditis and presenile arteriosclerosis is more important than the discovery of surgical or any other methods of treatment

DISEASES OF THE CORONARY ARTERIES

THE coronary arteries are subject to the same types of pathologic changes as are other arteries These comprise sclerosis due to atheroma and that associated with hypertension arteritis of various forms such as rheumatic and the common lesions of syphilis involving the coronary mouths (ostial narrowing) periarteritis nodosa thrombo angiitis obliterans rarely verrucous endarteritis aneurysms rupture and injury Sclerosis and syphilitic ostial narrowing are the only conditions which are at all common

C EGGLESTON

CORONARY SCLEROSIS

The great majority of lesions are due to (1) arteriosclerosis (atheroma) or (2) to the vascular thickening associated with chronic hypertension Often both types of vascular change are present to different degrees in the same heart This is almost always true following long standing hypertension Atheroma is common in the main coronary arteries the anterior descending branch of the left coronary (so called artery of occlusion) and only somewhat less frequently in the right coronary or its circum flex branch But narrowing or even obliteration of the lumen due to atheroma with

calcification may occur anywhere in the coronary bed Points of bifurcation are sites of predilection Several points of extensive narrowing or complete obliteration may be present simultaneously In such hearts the sclerotic process presumably has been of gradual development and as the local vascular narrowing progressed toward closure of the lumen at a given point anastomoses between neighboring coronary branches were *developing sufficiently to maintain a blood* supply adequate to preserve part or most of the myocardium Functionally the normal coronaries are end arteries as the intercoronary communicating arterioles of less than 40 microns in diameter are incapable *of carrying enough blood to maintain the* vitality of the myocardium when a larger branch is shut off acutely

Etiology—The cause of coronary atheroma *is* not yet known with certainty It appears often to be related to a disorder of cholesterol metabolism and is one of the natural concomitants of the aging process Although it may occur precociously it becomes increasingly prevalent in persons more than fifty years of age in whom it is the commonest of all causes of heart disease Whatever its ultimate cause it is generally regarded as a degenerative process associated *with physiologic aging It is irreversible and* gradually progressive

The etiology of hypertension as well as the pathologic vascular changes is discussed in a separate chapter As found in the coronaries these changes involve predominantly the smaller divisions and especially the arterioles Unless an associated atheroma is also present the intima is usually smooth and not likely to be the site *of thrombus formation*

Morbid Anatomy—The pathologic changes in the myocardium are much the same in both types and are the result of continued and usually progressive partial anoxemia and ischemia hence of impaired myocardial nutrition Whether because of atheromatous *narrowing or of the sclerosis* of hypertension the coronary circulation becomes less and less responsive to the demands of increased work The muscle fibers tend to lengthen and to hypertrophy as described in Diseases of the Myocardium (p 1048) These muscular changes are at first compensatory to increase the heart s contractile power The hypertrophy of the individual muscle fibers is not *accompanied* by an increase in their blood supply however and the larger fibers require both more oxygen and greater nutrition to perform their work The benign compensatory process soon becomes harmful and ultimately destructive through increase in the disproportion between blood supply available and the work performed so that either anginal or congestive heart failure begins to appear

Hypertrophy and dilatation of the heart may be absent or insignificant even when coronary atheroma is advanced in degree and present in multiple foci Commonly there is a moderate enlargement of the heart Occasionally this may be pronounced but in some cases there is usually some *additional* factor such as a valvular lesion or hypertension to explain the enlargement In the hypertensive form of coronary sclerosis on the other hand dilatation and hypertrophy are early and prominent pathologic features Such hearts may be truly enormous weighing 700 grams or more even without structural changes in a valve

The myocardium in either type of coro*nary sclerosis may appear normal upon* gross examination even where death was caused by myocardial failure This is commoner in the hypertensive form than in the atheromatous Frequently there is some visible scarring as shown by scattered areas of fibrosis Where atheroma has been the dominant cause with one or more *points of great* coronary narrowing or even complete obliteration of the lumen the areas of gross fibrosis are likely to be both large and widespread The fibrosis is seen microscopically to lie in and between the muscle fibers or to replace them not to be perivascular in distribution

Infarction of the myocardium is common in atheroma of the coronaries When fresh or *recent* the infarcted area is usually dark and hemorrhagic often with areas of yellow The tissue is soft and the area may be depressed below the surrounding muscle Later during healing the color changes to grayish or yellowish because of the invasion of

fibrous tissues or due to fatty changes Old or healed infarcts are seen as white usually depressed scars or when large they may be thin and extend through the entire thickness of the myocardium The latter may bulge and are then called cardiac or myocardial aneurysms An infarcted area occasionally ruptures Then a tear through the ventricular wall is usually readily visible The microscopic findings are those common to the several stages of necrosis and replacement fibrosis

The frequent sites of infarction lie in the areas supplied by the anterior descending branch of the left coronary, the right coronary or the circumflex branch of the left They are therefore to be seen in the anterior wall of the left ventricle the anterior portion of the interventricular septum or near the apex of the left ventricle in the posterior wall of the left ventricle and adjoining part of the septum or in the mesial portion of the same ventricle Infarctions may be single or multiple When multiple they may be of different ages from fresh to healed Infarction of the right ventricle alone is almost unknown but some extension of the infarct into the right ventricle is not infrequent specially where the apex or septum is involved

Incidence —Coronary sclerosis may occur even in advanced form without discoverable sclerosis in other arteries Some degree of sclerosis is usually to be found however in the retinae the peripheral arteries the aorta the kidneys or elsewhere if carefully sought Sclerosis of the coronary arteries has been found at all ages but it occurs mainly in the sixth decade of life and later It is more than three times as common in the male as in the female except in association with chronic hypertension when there is a relatively high incidence in women Both obesity and diabetes seem to predispose to coronary sclerosis possibly because of the disturbed lipoid metabolism in these conditions There appears to be a rather definite familial or hereditary tendency to coronary sclerosis so that several cases are often found in a single family One striking example from the author s practice showed three brothers to have died of acute myocardial infarction between the ages of forty and fifty years the only sister was hypertensive the father and one of his brothers were known to have died acutely of heart disease after having suffered from angina pectoris The mother succumbed acutely after a history suggestive of chronic hypertension, and two of the four grandparents also suffered acute death from heart disease while a third died of chronic Bright s disease and a terminal dropsy ' The average age at death decreased with each succeeding generation Chronic nephritis with hypertension appears to be an important predisposing factor in a smaller number of instances Few or no other factors are known materially to influence the occurrence of coronary sclerosis

Symptoms —Coronary sclerosis may be asymptomatic and is a fairly common necropsy finding in persons whose histories showed no symptoms pointing to disturbances related to the heart or circulation It is not rare to find one or more points of marked coronary narrowing or even complete atherosclerotic occlusion in the absence of a history of disability A few asymptomatic cases may be suspected on the discovery of changes in the electrocardiogram or upon x ray changes in heart or aorta Acute infarction may be painless and manifested only by an attack of acute edema of the lungs or of acute collapse apparently developing spontaneously Electrocardiograms may reveal the true cause and should be taken routinely

Gastro intestinal symptoms are often prominent and coronary disease may be overlooked when the major complaints are of indigestion or dyspepsia with eructations and flatulence or epigastric discomfort or pain *Hiatus hernia* must be kept in mind and excluded by appropriate roentgenologic examination because its symptoms may closely resemble those associated with coronary sclerosis including attacks of angina or even of myocardial infarction In some cases the symptoms suggest *disease of the gallbladder* Paroxysms of *spontaneous dyspnea* or nocturnal attacks resembling *asthma* sometimes of pulmonary edema may dominate the clinical picture and mislead the physician at least for a time The routine use of both x ray and the electrocardiogram will obviate many errors in diag

nosis Lastly among those without cardiovascular symptoms are persons past middle age who complain of progressive loss of energy, unexplained weakness and fatigability, and poor nutrition often combined with insomnia

The great majority of cases of coronary sclerosis are productive of symptoms of cardiac pain (angina pectoris or myocardial infarction) or of those due to congestive heart failure In the anginal group the pain is an expression of a transient local relative ischemia and, in accord with its cause is of short duration seldom lasting more than five to twenty minutes Where angina has been the dominant clinical syndrome extensive coronary sclerosis is usually found at autopsy There may be several healed scars of infarction and collateral coronary channels may be abundant But while these may be adequate to maintain enough circulation for moderate activity they may not be sufficient to meet extra demands The anginal syndrome as described occurs characteristically in response to conditions which increase the heart s work It may also be induced by tachycardia which is of rather frequent occurrence as a result of coronary sclerosis Anemia is often present in conjunction with arteriosclerosis and increases the susceptibility to angina Attacks of angina are frequently forerunners of acute infarction

C EGGLESTON

MYOCARDIAL INFARCTION

(*Coronary Thrombosis Coronary Occlusion*)

Advancing knowledge has made it desirable to revise our nomenclature by adopting the term myocardial infarction instead of the older and commoner ones of coronary thrombosis or occlusion Cardiac infarction is a satisfactory alternative term Myocardial infarction is most often the result of coronary thrombosis usually developing on the bed of an atheromatous abscess or on the surface of a calcified plaque but complete obstruction may occur without giving rise to any symptoms when collateral coronary circulation is adequate to prevent infarction Moreover infarction rarely may be caused by *coronary embolism* by the rupture of an atheromatous abscess in the wall of a coronary artery or by massive hemorrhage into such an abscess and from *too prolonged local ischemia due to the combination of focal coronary narrowing plus prolonged excessive work of the heart* as from tachycardia, and so on When the onset *of symptoms is sudden and apparently spontaneous* which is most common one may be correct in amplifying the diagnosis of acute myocardial infarction by the qualification *due to coronary thrombosis or acute coronary occlusion*

Symptoms—When acute cardiac infarction usually produces a group of symptoms *more or less typical* which permit its diagnosis The *sexes* are affected in the proportion of about seven males to three females The *onset* is spontaneous with *severe pain* in *the precordium* beneath the upper sternum or about the ensiform and upper epigastrium The pain is often described as constricting or in terms conveying the idea of weight pressure or compression The pain may remain rather localized or may radiate to the same regions as does the pain of angina namely to the sensory areas supplied by the first five thoracic segments of the spinal cord The pain is rarely relieved by rest or vasodilators and when severe morphine may not completely abolish it Accompanying the pain there are sweating pallor and often cyanosis causing an ashen appearance of the face The phenomena of shock or collapse are common appearing within a few minutes or hours Nausea and vomiting may ensue but it sometimes is hard to decide whether they are caused by the infarction or the opiate which usually is given promptly Untreated the pain persists for hours and even for a day or two

The *pulse rate* is usually increased well above 100 per minute and often the pulse is feeble and thready *Arrhythmias* may appear usually premature beats less often ventricular tachycardia auricular fibrillation or flutter Fibrillation and flutter are usually paroxysmal and vary in duration from a few heart beats to attacks lasting for several hours or days Rarely auriculoventricular heart block is an early event and

Adams Stokes attacks may result The blood pressure usually begins to fall within a few hours and may reach very low levels Both the systolic and diastolic pressure decline but the systolic falls proportionately more than the diastolic resulting in a lowered pulse pressure Occasionally the fall may be delayed for one or two days and very uncommonly there is a transient initial rise followed by a fall

Evidences of *destruction of tissue* appear on the first or second day They are fever of low grade only infrequently above 102° F by rectum which generally subsides within a week a moderate leukocytosis usually not over 15 000 a mild polynucleosis with a relative rise in the proportion of immature forms and an increase in the sedimentation rate of the red cells The elevated sedimentation rate usually persists much longer than the others of these phenomena and is considered to be one of the best guides to the progress of healing The other evidences of tissue destruction usually disappear within seven to ten days In 10 to 15 per cent of cases a transient pericardial friction rub may be heard

Examination of the heart reflects the pulse changes in rate and rhythm The apex impulse may be feeble or not felt at all The heart sounds are usually slapping and the first sound especially may lack its normal sustained tonal quality The sounds sometimes are loud and sharp More often they are faint and may even be scarcely audible The first sound may be split or reduplicated resulting in a gallop rhythm The second sound may also be split A systolic murmur is frequently heard at the apex but is not of special significance other than confirming myocardial weakness The lungs may remain clear throughout or they may show signs of any degree of congestion from a few basal rales on inspiration to a rapidly developing edema with profuse pink frothy sputum in which the patient may literally drown Secondary infection may take place in the lungs with a resultant pneumonia usually of the confluent lobular type or at times frankly lobar and due to one of the fixed strains of pneumococci When the infarcted area underlies the endocardium the resulting inflammation often leads to the formation of mural thrombi from which fragments may be broken off and cause embolization The brain the spleen the kidneys and upper or lower extremities are the usual sites

Diagnosis —Although diagnosis generally can be made on purely clinical evidence from the appearance of some combination of the symptoms given above electrocardiograms may be of the utmost assistance They may establish the diagnosis within less than twenty four hours in many cases They may provide decisive evidence when recorded serially in questionable cases They aid in localizing the site of infarction They establish the nature of the disturbances in the heart s rhythm or mechanism And often they are of much help in following the course of healing One or more of the precordial leads should be recorded routinely in addition to the conventional leads When a single precordial lead is used it is customary to take CFIV When taken very shortly after the onset the record may show no distinctive abnormalities

Localization of Infarct—When the infarcted area involves the anterior and apical portions of the heart including the left lateral wall it is likely to produce changes in the electrocardiogram of the Q_1T_1 pattern Lead I shows low potential of QRS and large Q wave There may be a Q in lead II and there are usually large S waves in leads II and III In recent infarction the R T junction and segment are displaced upward from the isoelectric level As healing begins the junction and segment return to normal and the T wave in lead I becomes a sharp V shaped inverted wave The precordial lead which corresponds to the Q_1T_1 pattern usually shows a large negative initial deflection or Q wave and the R T junction segment and the T waves are progressively altered exactly as described for lead I Such infarctions are commonly located in the course of the anterior descending branch of the left coronary artery *Infarction of the posterior and diaphragmatic walls* yields the Q_3T_3 pattern There is a large Q wave in lead III often also present in lead II QRS is of low amplitude in lead II In recent cases there is elevation of the R T junction and segment in lead II This is followed during healing by their return to the isoelectric level and by progressive change in T_3 which becomes V shaped and nega

nosis Lastly among those without cardio vascular symptoms are persons past middle age who complain of progressive loss of energy unexplained weakness and fatigability, and poor nutrition often combined with insomnia

The great majority of cases of coronary sclerosis are productive of symptoms of cardiac pain (angina pectoris or myocardial infarction) or of those due to congestive heart failure In the anginal group the pain is an expression of a transient local relative ischemia and in accord with its cause is of short duration seldom lasting more than five to twenty minutes Where angina has been the dominant clinical syndrome extensive coronary sclerosis is usually found at autopsy There may be several healed scars of infarction and collateral coronary channels may be abundant But, while these may be adequate to maintain enough circulation for moderate activity they may not be sufficient to meet extra demands The anginal syndrome as described occurs characteristically in response to conditions which increase the heart s work It may also be induced by tachycardia which is of rather frequent occurrence as a result of coronary sclerosis Anemia is often present in conjunction with arteriosclerosis and increases the susceptibility to angina Attacks of angina are frequently forerunners of acute infarction

C EGGLESTON

MYOCARDIAL INFARCTION

(*Coronary Thrombosis Coronary Occlusion*)

Advancing knowledge has made it desirable to revise our nomenclature by adopting the term myocardial infarction instead of the older and commoner ones of coronary thrombosis or occlusion ' Cardiac infarction is a satisfactory alternative term Myocardial infarction is most often the result of coronary thrombosis usually developing on the bed of an atheromatous abscess or on the surface of a calcified plaque but complete obstruction may occur without giving rise to any symptoms when collateral coronary circulation is adequate to prevent infarction Moreover infarction rarely may be caused by *coronary embolism* by the rupture of an atheromatous abscess in the wall of a coronary artery or by massive hemorrhage into such an abscess and from too prolonged local ischemia due to the combination of focal coronary narrowing plus prolonged excessive work of the heart as from tachycardia and so on When the onset of symptoms is sudden and apparently spontaneous which is most common one may be correct in amplifying the diagnosis of acute myocardial infarction by the qualification ' due to coronary thrombosis or acute coronary occlusion '

Symptoms —When acute cardiac infarction usually produces a group of symptoms more or less typical, which permit its diagnosis The *sexes* are affected in the proportion of about seven males to three females The *onset* is spontaneous with *severe pain* in the precordium beneath the upper sternum or about the ensiform and upper epigastrium The pain is often described as constricting or in terms conveying the idea of weight pressure or compression The pain may remain rather localized or may radiate to the same regions as does the pain of angina namely to the sensory areas supplied by the first five thoracic segments of the spinal cord The pain is rarely relieved by rest or vasodilators and when severe morphine may not completely abolish it Accompanying the pain there are sweating pallor and often cyanosis causing an ashen appearance of the face The phenomena of shock or collapse are common appearing within a few minutes or hours Nausea and vomiting may ensue but it sometimes is hard to decide whether they are caused by the infarction or the opiate which usually is given promptly Untreated the pain persists for hours and even for a day or two

The *pulse rate* is usually *increased* well above 100 per minute and often the pulse is feeble and thready Arrhythmias may appear usually premature beats less often ventricular tachycardia auricular fibrillation or flutter Fibrillation and flutter are usually paroxysmal and vary in duration from a few heart beats to attacks lasting for several hours or days Rarely auriculo-ventricular heart block is an early event and

Adams Stokes attacks may result The blood pressure usually begins to fall within a few hours and may reach very low levels Both the systolic and diastolic pressure decline but the systolic falls proportionately more than the diastolic resulting in a lowered pulse pressure Occasionally the fall may be delayed for one or two days and very un commonly there is a transient initial rise followed by a fall

Evidences of *destruction of tissue* appear on the first or second day They are fever of low grade only infrequently above 102° F by rectum which generally subsides within a week a moderate leukocytosis usually not over 15 000 a mild polynucleosis with a rela tive rise in the proportion of immature forms and an increase in the sedimentation rate of the red cells The elevated sedimen tation rate usually persists much longer than the others of these phenomena and is con sidered to be one of the best guides to the progress of healing The other evidences of tissue destruction usually disappear within seven to ten days In 10 to 15 per cent of cases a transient pericardial friction rub may be heard

Examination of the heart reflects the pulse changes in rate and rhythm The apex im pulse may be feeble or not felt at all The heart sounds are usually slapping and the first sound especially may lack its normal sustained tonal quality The sounds some-times are loud and sharp More often they are faint and may even be scarcely audible The first sound may be split or reduplicated resulting in a gallop rhythm The second sound may also be split A systolic murmur is frequently heard at the apex but is not of special significance other than confirming myocardial weakness The lungs may remain clear throughout or they may show signs of any degree of congestion from a few basal rales on inspiration to a rapidly developing edema with profuse pink frothy sputum in which the patient may literally drown Sec ondary infection may take place in the lungs with a resultant pneumonia usually of the confluent lobular type or at times frankly lobar and due to one of the fixed strains of pneumococci When the infarcted area underlies the endocardium the resulting in flammation often leads to the formation of mural thrombi from which fragments may be broken off and cause embolization The brain the spleen the kidneys and upper or lower extremities are the usual sites

Diagnosis —Although diagnosis generally can be made on purely clinical evidence from the appearance of some combination of the symptoms given above electrocardiograms may be of the utmost assistance They may establish the diagnosis within less than twenty four hours in many cases They may provide decisive evidence when recorded se rially in questionable cases They aid in lo calizing the site of infarction They establish the nature of the disturbances in the heart s rhythm or mechanism And often they are of much help in following the course of healing One or more of the precordial leads should be recorded routinely in addition to the conventional leads When a single precordial lead is used it is customary to take CFIV When taken very shortly after the onset the record may show no distinctive abnormal ities

Localization of Infarct —When the in farcted area involves the anterior and apical portions of the heart including the left lat eral wall it is likely to produce changes in the electrocardiogram of the Q_1T_1 pattern Lead I shows low potential of QRS and large Q wave There may be a Q in lead II and there are usually large S waves in leads II and III In recent infarction the R T junc tion and segment are displaced upward from the isoelectric level As healing begins the junction and segment return to normal and the T wave in lead I becomes a sharp V shaped inverted wave The precordial lead which corresponds to the Q_1T_1 pattern usu ally shows a large negative initial deflection or Q wave and the R T junction segment and the T waves are progressively altered exactly as described for lead I Such infarc tions are commonly located in the course of the anterior descending branch of the left coronary artery Infarction of the pos terior and diaphragmatic walls yields the Q_3T_3 pattern There is a large Q wave in lead III often also present in lead II QRS is of low amplitude in lead II In recent cases there is elevation of the R T junction and segment in lead II This is followed during healing by their return to the iso electric level and by progressive change in T_3 which becomes V shaped and nega

tive T_2 may follow T_3 The precordial lead is less consistently altered and may remain normal When altered there is likely to be a negative displacement of the R T junction and segments during the acute stages

Many changes in the electrocardiogram may result from coronary sclerosis with and without the occurrence of acute cardiac infarction These are seldom pathognomonic although they may be of great diagnostic value when related to the several clinical and other phenomena *A diagnosis should not be made on the basis of the electrocardiogram alone* Serial records are especially valuable when acute or recent infarction is suspected, both with relation to diagnosis and the progress of healing Many of the phenomena are transient some may remain more or less permanently Ectopic premature beats the tachycardias and auricular flutter or fibrillation of the auricles occur frequently Various grades of auriculoventricular block are to be found the lesser degrees being revealed only by graphic records Greater degrees often may be diagnosed from clinical changes in the heart rate and rhythm but even in these tracings are useful for confirmation or correction

The more significant features are to be found in the ventricular complexes These include waves of low potential involving either the first ventricular complexes the T waves or both Large Q waves may be found especially in lead III where they are suggestive when right axis deviation is absent Notching or splitting of the QRS group with its duration lengthened to $1/10$th of a second or over reveals some degree of defect in the spread of impulses through the Purkinje system There may be block of one branch of the bundle of His either left or right or a mixed type may be found Left bundle branch block is the type usually seen The R T junction may be displaced above or below the isoelectric line and so may be the R T segment The T wave may be inverted and of coveplane type or it may be of large amplitude and sharply peaked whether positive or negative It must be repeated that the value of such graphic records is greatest when they are considered in relation to the patient s history and other clinical findings and is least when they are considered alone an error too often made

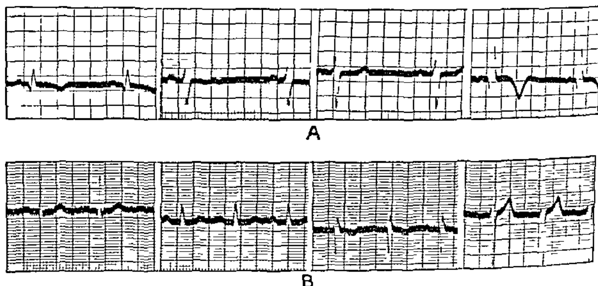

Fig 121 —Typical four lead electrocardiograms Leads read from left to right A is Q_1 T_1 type representing anterior or apical lesion B is Q_3T_3 type representing basal or posterior lesion

The development of roentgenkymography has provided a means by which it may be possible to demonstrate graphically *the location of an infarct* The destroyed area is revealed by a reversal of the direction of the movements of the margin of *the ventricular* shadow During ventricular *contraction* the infarcted region either moves outwardly or shows little or no motion Recently Master and others have stated that these same phe-

nomena can be seen by careful fluoroscopy This may prove of value but it is not yet well established

Attacks due to prolonged localized myocardial ischemia may appear in coronary sclerosis and present a clinical syndrome similar to that just described but different enough in fundamental features to be distinguished from infarction There is usually some closely related precipitating cause such as surgical or other type of shock acute severe hemorrhage operation, prolonged anesthesia or other condition which lowers blood pressure and lessens coronary blood flow Or they may be induced by increased work of the heart in excess of available increased blood supply for example by paroxysmal tachycardia intense emotion excessive physical effort and others Attacks of this type last longer than those of angina pectoris and unlike those due to myocardial infarction *they are not accompanied by evidences of destruction of tissue* The diagnosis of infarction should not be made in the absence of fever leukocytosis relative polynucleosis relative increase in immature polynuclear cells or elevated sedimentation rate in any combination This syndrome has been called coronary failure but a better term should be found since coronary failure has been applied to other syndromes with equal justification If an attack is believed to be of such nature treatment should be instituted at once to assure as efficient as possible a coronary flow relative to the patient s needs The suggested measures are given under treatment It is believed that effective treatment carried out promptly may at times prevent actual infarction During an attack of coronary failure the electrocardiogram may show transitory abnormalities similar to those seen in infarction but these are usually fleeting and often are missed entirely

The majority of patients with acute infarction survive the first two or three days to enter the second period which includes the remainder of the first two to three weeks The clinical features during this period are quite variable but it is nevertheless a period of real or potential danger The processes of liquefaction and absorption of the destroyed muscle are taking place and scar tissue is being laid down by invading fibroblasts Clinically the symptoms are usually subsiding Pain has usually stopped or lessened greatly and the evidences of tissue destruction ameliorate During this period the greatest hazards are embolism rupture of the ventricle or the development of serious disorder of the heart mechanism

Premature beats are common They may arise in the auricle the a v node or the ventricle They often are unimportant but if very frequent or if they appear consecutively and arise in the ventricle they may portend ventricular paroxysmal tachycardia or even ventricular fibrillation either of which may prove fatal Fibrillation of the ventricles is seldom survived and often kills so rapidly that there is no time for treatment Auricular flutter or fibrillation may develop but is much less dangerous and generally can be controlled or stopped Brief paroxysms of auricular fibrillation terminating spontaneously are particularly common and of relatively little moment Auriculo-ventricular heart block with or without the Adams Stokes syndrome is seen occasionally Varying degrees of intraventricular block are seen in electrocardiograms they are evidence of extensive myocardial damage and sometimes make prognosis unfavorable

Rupture of the left ventricle through a recent infarct is unusual It leads to very rapid death generally from cardiac tamponade If the tear be very small bleeding may be so gradual that death is delayed for hours The author recently saw an example of this in which hemorrhage had been so gradual that portions of the clot in the pericardium were undergoing fibrosis The rent in the heart muscle was very small and the channel through it very tortuous

Embolism is usually secondary to the formation of mural thrombi in the heart It may involve the lungs brain spleen kidney one or more extremities or some other part of the body Pulmonary embolism may be acutely fatal or it may constitute a serious complication from which recovery is slow In the earlier stages of pulmonary embolism there may be alterations in the electrocardiogram which are transient but aid in diagnosis The most important of these are the development of large S waves in leads one and two depression of the S T segments in the same leads and diphasic or

inverted T in lead I They should not be confused with the changes which may result from additional cardiac infarcts Embolism to the brain is likely to cause hemiplegia, and to other structures or organs the typical and easily recognizable manifestations described elsewhere

Congestive failure may begin at any time during this early period and produces the usual train of symptoms It may prove rapidly fatal, but generally tends to become chronic Its response to treatment appears to be determined by the extent of myocardial injury and the amount of coronary reserve remaining At times recovery is rapid and nearly complete so that the patient is left with but little handicap In such instances progressive failure usually develops as the terminal phase of the disease

The course in the majority of patients is one of more or less rapid recovery with subsidence of symptoms during the initial three weeks Thereafter the patient is well started upon convalescence and is not usually in much danger During the later weeks clinical recovery is accompanied by the return of the electrocardiogram toward normal but some patients do not manifest this change their records remaining abnormal for years By the end of about six weeks healing is complete enough in most cases to allow the patient to begin some mild activity However risky it may have been patients sometimes recover fairly well despite lack of proper early rest and treatment

Differential Diagnosis—Acute myocardial infarction may be confused with acute perforation of a peptic ulcer or rupture of the gallbladder acute pancreatitis and rarely with other surgical emergencies Prompt and correct diagnosis is most important since surgical intervention is a life saving measure in the foregoing condition while it is almost uniformly fatal in cardiac infarction The electrocardiogram is often of the greatest aid in differentiation Rarely the early stages of a dissecting aneurysm of the aorta may cause confusion in diagnosis but an error is not immediately dangerous as the early treatment of both conditions is the same The electrocardiogram may be the same in both conditions although the electrocardiographic changes are usually more transient in aneurysm The pain in dissecting aneurysm frequently is severe in the lower abdomen and lower extremities due to involvement of the abdominal aorta and its major branches Sensory changes, usually variable are prone to occur in the same areas and the pulsations may be reduced in the femoral arteries Further the dissection may extend along one or more of the branches of the aorta and be reflected in symptoms referable chiefly to the kidneys or to the gastrointestinal tract

Prognosis—This varies widely in myocardial infarction Death may be sudden or very rapid in the initial attack The great majority of patients however recover Statistics vary but about 80 per cent of all patients survive In some series the mortality has been as low as 8 per cent Efforts to establish criteria to improve prognosis have yielded some data of definite value Patients may recover after the severest symptoms while on the other hand death may occur with few or no preceding symptoms nevertheless among large groups of patients the mortality is definitely greater in those with severe initial symptoms This is especially true of early severe shock marked cyanosis pronounced dyspnea high fever greatly increased heart rate and high leukocytosis Other phenomena suggesting a prognosis less favorable than average include gallop rhythm and congestive heart failure When such complications as infarction of the lung pneumonia cerebral embolism or peripheral embolism appear the gravity of outlook is increased Any type of irregularity exercises some unfavorable influence but this is slight except for patients with ventricular tachycardia or ventricular fibrillation in whom the prognosis is much worse because of the abnormal rhythm Cardiac infarction is somewhat graver in women than in men The prognosis becomes less favorable with increasing age In general the younger subjects have a better outlook and longer life expectancy than older persons

Despite the help sometimes afforded by the preceding considerations prognosis in myocardial infarction is often difficult to determine particularly early in the course of the disease and should therefore be guarded as mistakes are common In the end death is almost always due to heart

disease The majority succumb within five years but a few may survive for ten to twenty years or longer Somewhat more than half of the survivors are able to return to their previous work at least to some extent if not fully

Men survive longer than women and more of them are able to resume full activity Women are more prone to subsequent congestive heart failure than men possibly because of the high incidence of underlying hypertension More than one third of the survivors die of a subsequent infarction and less than one third of congestive failure most of the remainder die suddenly from causes related to the heart

Treatment —Complete physical and mental rest should be required from the onset even if the diagnosis is merely suspected This should preclude the patient s feeding himself or turning without help and is intended to relieve the heart of all extra strain and if possible to bring its work down to a level which can be met by the curtailed coronary blood flow Marked apprehension and pain require the use of morphine 0 015 to 0 03 Gm (gr 1/4–1/2) by hypodermic The acute infarction may be productive of reflex spasm in other portions of the coronary tree Atropine sulfate 0.8 to 1.25 mg (gr 1/80–1/50) preferably by the intravenous route *may diminish or check* the spasm Somewhat smaller doses may then be given subcutaneously at intervals of about four hours Aminophylline (theophylline with ethylene diamine) is also effective when injected slowly into a vein in a dose up to about 0.5 Gm (gr 7½) repeated if required every four to six hours These agents may be continued for one to three or more days as indicated Papaverine has been used for the same purpose The usual dose is 0 065 Gm (gr 1) every four hours by vein

The prompt administration of oxygen either by nasal catheter suitable face mask or in a tent often lessens the load on the heart overcomes cyanosis and dyspnea and diminishes pain In those cases in which there is pulmonary congestion or shock immediate provision of an oxygen enriched atmosphere may maintain cardiac function until such a time as collateral circulation is established When 100 per cent oxygen is given the physically dissolved oxygen is increased as much as 2 5 cc per 100 cc of blood and it is this increase in physically dissolved oxygen in the capillaries which are adjacent to the occluded artery that is responsible for maintenance of cardiac function In these instances the continuous administration of oxygen in concentrations of 50 to 100 per cent may be the most effective method of treatment Shock or collapse requires prompt application of heat and the slow intravenous infusion of 5 per cent glucose in physiologic saline solution may be valuable particularly where there has been profuse sweating or repeated vomiting Occasionally it suffices to administer the glucose by hypodermoclysis or rectal drip When acute pulmonary edema is present the same measures should be instituted except that glucose should be given in 50 per cent solution From 50 to 100 cc are administered into a vein and injected slowly The same volumes of 50 per cent sucrose or sorbitol may be used but glucose seems preferable and is usually available promptly Epinephrine should not be used for there is danger of causing serious or fatal accident by throwing the heart into ventricular fibrillation Epinephrine is also contraindicated in collapse with hemoconcentration

A small porportion of cases show congestive heart failure almost *from the onset* these patients may be given digitalis as described (p 1151) Otherwise digitalis is not indicated and should not be given

During the first few days diet is not a matter of concern The patient should be given enough fluids by mouth to compensate for losses if he can retain them Such food as is permitted should be bland and not productive of gaseous distention Individual meals should be small and frequent Later the diet should be light digestible tasty and of low caloric value especially where the patient is overweight The bowels may be neglected entirely at the onset After two or three days mineral oil simple saline laxatives or cascara may be prescribed in doses just sufficient for a daily easy evacuation Suppositories or enemata may be required At times the strain of using a bedpan may be much greater than that involved in having the patient helped to a bedside commode

After the need for opiates has passed, usually by the second or third day, sedation should be provided by one of the barbiturates or by bromide with or without chloral These may also be used to promote sleep when necessary

Disturbances of heart rhythm may arise at any time and require treatment Premature systoles may be ignored unless very troublesome or very numerous They are often suppressed by phenobarbital but are more effectively controlled by quinidine in doses of 0 25 to 0 5 Gm (gr 4–8) given four or five times daily Paroxysmal auricular fibrillation usually does not require treatment because of its transient character If it persists the use of quinidine in the preceding doses may check it Occasionally doses up to a total of 3 to 4 Gm (gr 45 to 1 drachm) per twenty four hours may be required Paroxysmal ventricular tachycardia should be checked promptly by quinidine for it may lead to ventricular fibrillation and death or induce congestive heart failure The routine use of quinidine as a preventative of both ventricular tachycardia and ventricular fibrillation has been advocated The author prefers the plan of testing each patient s reaction to quinidine as early as possible after the attack of infarction and then reserving its further use until need for it arises

Heart block is rare and the lesser grades need no therapy Occasionally it produces seizures of Adams Stokes syndrome The oral use of ephedrine in doses of 0 045 to 0 1 Gm (gr ¾–1½) repeated as often as every two to three hours may prevent the attacks When this fails the intramuscular injection of 0.5 to 0 1 cc (minims 7½–15) of a 1 1000 solution of epinephrine may be required Rarely it may be necessary to try barium chloride by mouth This drug should be given cautiously The usual dose lies between 0 03 to 0 06 Gm (gr ½–1)

Aminophylline and theophylline because of their ability to dilate the coronaries are used by many in the hope of improving cardiac nutrition hastening recovery and preventing acute local ischemia The evidence as to their value remains somewhat conflicting They are commonly administered in doses of 0 1 to 0 2 Gm (gr 1½–3) of aminophylline or 0 2 to 0.3 Gm (gr 3–5) of theophylline three or four times daily They are given by mouth and enteric coated tablets may be ordered if nausea be produced

During convalescence after the third week has passed the patient may begin to feed himself may turn in bed without help may have occasional visitors and usually requires little more than symptomatic treatment It may of course be necessary to continue digitalis if it had been required because of congestive heart failure Many advocate the long continued use of aminophylline Convalescence may have to be prolonged where there has been extensive damage congestive failure or other complications The average favorable course usually permits the patient to resume nearly normal activity within three months from the onset Less favorable cases may require a year of carefully guided convalescence and some of these never regain more than a limited degree of physical capacity Some patients remain chronic invalids Throughout the entire course every effort should be made to maintain high morale and an optimistic attitude on the part of the patient

C EGGLESTON

SURGICAL TREATMENT OF CARDIAC PAIN

The development of our understanding that actual or relative localized myocardial ischemia is the mechanism by which heart pain is produced has led to many efforts to relieve the condition surgically Three general plans of approach have been suggested First to reduce permanently the amount of work required of the heart For this purpose total ablation of the thyroid gland was proposed It has been tried in a sufficiently large number of cases to justify its virtual abandonment in favor of other procedures The pain was more or less effectively controlled in a considerable number of patients but in many of these the symptoms of myxedema were about as incapacitating as had been the cardiac pain or the congestive failure Either or both of these would generally return if enough thyroid were given to control the myxedema

The second type of operation seeks to

increase the blood supply to the myocardium Various measures for increasing vascularization through the production of sterile adhesions between the two layers of the pericardium have been tried but proved inadequate They have been abandoned by most surgeons Omental or muscle grafts were proved in animal experiments to produce some revascularization of the heart but only when the need for it was caused by reduction in the normal coronary flow The operation has been performed in a relatively small number of patients by Feil and Beck using portions of the pectoral muscles and by O Shaughnessy who employed omental grafts The results are not yet convincing and the procedure is still in the experimental stage

The third surgical approach has been to cut or destroy the nerves carrying impulses from the heart to the spinal cord thus severing the reflex arc for the production of referred pain and that leading to reflex arrest of the heart or the production of ventricular fibrillation and death The afferent fibers of these arcs pass through the upper five thoracic sympathetic ganglia and the corresponding rami communicantes They may be broken by the paravertebral injection of alcohol or by surgical section of the dorsal nerve roots Both methods have their advocates and both require particular training skill and experience Alcohol block which does not necessitate a surgical operation consists in the injection through long needles of 5 cc of 85 per cent alcohol into the immediate region of each of the upper five thoracic sympathetic ganglia and their rami communicantes to destroy the nerves In the hands of an expert the injection usually succeeds and carries almost no mortality However a severe alcohol neuritis of the intercostal nerves occurs in a majority of patients It usually subsides entirely in one or two months but while present may cause intense discomfort Pleurisy is produced in a few patients and occasionally a temporary pneumothorax Coronary pain is relieved in nearly half of the cases and the relief is lasting The relief is temporary in about 30 per cent more who then may be re injected or subjected to dorsal root section In these either nerve regeneration has taken place or destruction was originally incomplete There is failure in 10 to 20 per cent of cases Horner s syndrome may occur

Dorsal root section is far more certain in its results but also requires high surgical skill and entails an extensive surgical operation involving laminectomy Despite its extent the operation carries a minimal degree of risk It is perhaps more likely to produce enophthalmus narrowing of the palpebral fissure and contracted pupil (Horner s syndrome) than is alcohol block but the results are permanent

Choice of procedure rests with the physician and the patient after the merits and complications of both procedures have been well understood White and Smithwick say

Among the 74 patients treated by surgical and chemical denervation we have now followed a large number in whom all sensation of pain has been removed Yet these patients always have the sensation of an attack either from a sense of thoracic oppression without pain or from palpitation flushing or shortness of breath Direct surgical denervation should therefore be the method of choice for the patient with severe cardiac pain who is a reasonably good surgical risk Unfortunately the number of patients with the severest forms of angina pectoris who fall into the operable group is limited The author has observed several dramatic recoveries by posterior root section

C Eggleston

CARDIAC ANEURYSM

This is a sequel to myocardial infarction in about 85 per cent of all instances in which it is found It may be produced by the degeneration and healing of other lesions which cause destruction of the muscular wall of the heart such as gummas focal mycotic abscesses localized rheumatic necrosis and trauma or it may arise congenitally in a membranous septum It has been noted in less than 10 per cent of necropsies in patients who have had myocardial infarction The aneurysm is most frequent in the left ventricle near the apex or on the lateral wall The posterior wall is seldom involved The great preponderance of cases occurs in males more than forty five years of age that

is in the same age groups in which myocardial fibrosis coronary sclerosis and myocardial infarction occur

Pathology —*Pathologically* the wall of the aneurysm is thin and composed of fibrous scar tissue but occasionally a few muscle fibers are found There is *usually* a lining blood clot which *may* be *laminated* and organized This may contain *calcium or the* fibrous scar itself may be the site of calcification *The aneurysm* may be only a shallow bulge of the ventricular wall a larger protruding cavity or a prominent sac connected with the ventricular cavity by a neck or narrow opening Rarely the aneurysm may rupture and cause sudden or very rapid death, but intraventricular and systemic blood pressures are usually too low for this to occur

Symptoms are infrequent and not diagnostic There may be an increased area of precordial pulsation increased area of precordial dulness, and occasionally a pericardial friction rub A gallop rhythm or systolic murmur sometimes both a systolic and a diastolic murmur may be heard at the apex Auricular fibrillation is fairly common and paroxysms of ventricular tachycardia may occur Both of these arrhythmias are however frequent in coronary sclerosis hence are not helpful in diagnosis The electrocardiogram generally reflects the previous apical or anterior infarction hence is of the Q_1T_1 pattern Often there is little or no disability Congestive failure or angina pectoris is occasionally present

Diagnosis rests chiefly on the history of a previous infarction combined with one or more of the following x ray findings (1) enlargement of the left ventricle with deformity of its silhouette (2) a localized shadow not separable from that of the heart by rotation of the patient (3) absent or abnormal pulsations of the margins of the shadow, (4) calcium in the margin of the shadow X ray study should include examination of the heart in oblique as well as in postero anterior positions A large gas bubble in the stomach may reveal an aneurysm on the diaphragmatic surface of the heart which would otherwise not be seen Fluoroscopy is often more helpful than films but both should be used Roentgen kymograms are at times of value

Cardiac aneurysm usually does not develop in less than one to two months after an infarction Death usually follows within two years after aneurysm has been discovered It may be sudden or due to congestive heart failure or may result from a complication such as cerebral embolism There is no treatment for cardiac aneurysm but proper care of the patient with acute infarction may possibly prevent its formation

C EGGLESTON

SYPHILIS OF CORONARY ARTERIES

Syphilis of the coronary arteries is due to extension of syphilitic aortitis of the proximal portion of the aorta into the sinuses of Valsalva The coronary lesion involves their mouths and the adjacent 0.5 to 1 5 cm of the vessel wall Usually the lesion is confined to the ostia themselves which are narrowed or even obliterated by extensive infiltration and fibrosis of the intima and to a lesser extent of the media The adventitia is less often involved The process is seldom seen in congenital syphilis Prior to the development of modern antisyphilitic treatment ostial syphilis of the coronaries was a common late manifestation of the disease The *frequency* of its occurrence has been materially reduced, but it is still far commoner than it should be Its incidence varies so widely among different groups of the population that figures are misleading It is much commoner in Negroes than whites in males than females and in the poor than the well to do Syphilitic ostial stenosis is unusual in the absence of aortitis but often accompanies aortic insufficiency Either of these conditions reduces coronary blood flow more or less significantly and together they may cause marked reduction This reduced coronary blood supply is responsible for such diffuse myocardial fibrosis as may be found postmortem Further the hypertrophy associated with aortic regurgitation increases the demand for greater blood supply to the myocardium There is some increase in coronary circulation however through the development of collateral coronary *anastomoses* during the gradual *narrowing* produced by the productive inflammation about

the coronary orifices Both ostia are usually involved but where only one is affected it is almost twice as likely to be the right as the left Similarly the right is usually the more severely stenosed

Incidence —The incidence of syphilitic coronary and aortic disease in the adult lies between less than 5 per cent and more than 15 per cent There is usually a latent period of nearly twenty years between the chancre and clinical signs of coronary syphilis making the decade between forty and fifty years that of highest incidence of the disease Rarely the period of latency is less than five to ten years and it may even be as short as three years Serologic tests are positive in 80 to 95 per cent depending upon the efficiency of the laboratory but a single negative test does not exclude the diagnosis

Symptoms —It should be the goal of the physician to recognize syphilitic aortitis with or without coronary involvement before the advent of symptoms This appears possible as yet in only a very few cases The use of a serologic test should be routine in the first examination of each new patient A positive test or history should be followed by special study of the circulatory system clinically and roentgenologically to detect or exclude such signs as accentuation of the aortic second sound or of a hollow or ringing quality of that sound The diastolic murmur of aortic insufficiency should be sought carefully along with the vascular signs of that lesion Minor degrees of widening of aortic dulness *are very hard to detect The x ray* should be employed regularly using both the fluoroscope and teleoroentgenograms with the patient in several positions Special attention *should be given to the supracar*diac portion of the aorta Unfortunately this cannot be visualized clearly because of its location so that when widening of the shadow can be made out the process is already rather advanced But such routine careful investigation may detect the damage early enough to permit effective antisyphilitic treatment

The *development* of *symptoms* is usually abrupt Spontaneous paroxysmal dyspnea frequently nocturnal is a common initial manifestation or the onset may be with pain of anginal type and location This may occur spontaneous*ly or follow* excitement or exertion The pain may remain localized over the upper precordium or it may radiate just as the common pain of angina Radiation through the chest to the back seems to be more likely than is the case in angina due to other causes Response to rest and the nitrites may be prompt The pain is probably due to myocardial ischemia and anoxemia Some patients complain of a more or less constant dull boring or gnawing substernal pain which has been attributed to active syphilitic inflammation of the root of the aorta rather than of the coronaries The paroxysmal type of pain is always associated with narrowing of the coronary mouths

The common signs of aortic insufficiency are often present and marked enlargement of the heart is usually evidence that the coronary ostia are not completely obstructed Attacks of so-called cardiac asthma and of more advanced degrees of pulmonary edema are seen frequently Sudden unexpected death often closes the chapter even before the development of any signs of congestive heart failure It is presumably caused by reflex arrest of the heart or by ventricular fibrillation There are no characteristic changes to be found in the electrocardiogram but left axis deviation is usually present with aortic insufficiency

Congestive failure is a late development in most cases and is evidence of marked exhaustion of the heart s reserve For this reason as well as because of the irreversible *nature of the coronary lesions the response* to treatment is likely to be of short duration or it may be very limited from its beginning

Course —*Untreated patients usually die* within less than five years of the earliest positive diagnosis and in less than two years after the onset of symptoms

Treatment —Theoretically it should be possible to prevent the development of syphilis of the coronary arteries and aorta by the prompt and adequate treatment of primary syphilis This is a goal which has not yet been reached but one toward which we should continually strive Some patients do not seek treatment in the stage of the chancre or even after secondary manifestations have developed Some who accept *treatment in these* most favorable stages

refuse to continue to the completion of a cure After the passage of the primary and secondary stages treatment of the syphilis can still do much to prevent irreparable damage to the heart, provided it can be started before cardiovascular symptoms have appeared If they have appeared the course of the disease is usually but little influenced by specific treatment In a few cases the syphilitic process may be arrested and several years added to the patient's life

Specific antisyphilitic therapy instituted after signs and symptoms of aortic and coronary lesions have appeared must be administered cautiously and in modified form The iodides may be used alone for a few weeks Then small and slowly ascending doses of mercury or bismuth are to be given for about two months If these have been tolerated well neoarsphenamine or bismarsen may be administered on a corresponding scale of slowly ascending dosage No attempt should be made to use full doses at any time and arsphenamine is better not used at all Attempts at either rapid treatment or maximal therapy may be disastrous from the production of a Jarisch Herxheimer reaction in the root of the aorta or the coronary ostia with resulting acute closure and death Or too radical therapy may eradicate the syphilis but cause fatal scarring in the aortic root This has been called the Therapeutic Paradox by Wile

C EGGLESTON

CORONARY ARTERITIS AND EMBOLISM

Rheumatic coronary arteritis cannot be recognized unless it is accompanied by rheumatic lesions elsewhere The active form most often shows Aschoff bodies in the adventitia with the localized collection of polynuclear leukocytes and lymphocytes in and about the fragmented collagen Typical giant cells may be found in the older lesions Healing takes place with the formation of a dense scar Thrombosis is rare Healed lesions leave thickening of the vessel wall involving all three coats but the intima and adventitia are usually the most severely scarred The lumen is often much narrowed Where Aschoff bodies are present on opposite walls of a coronary they may narrow the lumen greatly but this is of rare occurrence

Sometimes rheumatic coronary arteritis and aortitis are responsible for clinical manifestations identical with those produced in syphilis The anginal syndrome may occur particularly in the more acute stages of rheumatic arteritis

Arteritis of the coronaries also is found in other diseases than rheumatic fever Among the commoner of these are diphtheria and scarlet fever the septicemias pneumonia and so on Its occurrence is of little clinical importance as it is seldom sufficient to produce symptoms and those which may be present are not distinctive Occasionally in pneumonia and somewhat more often in septicemia mycotic aneurysms may arise in the coronaries Any type of arteritis when affecting the coronaries may lead to the symptoms of angina pectoris or cause thrombosis and cardiac infarction but such accidents are rare

Periarteritis Nodosa —This is an acute or subacute inflammatory disease the etiology of which is unknown It affects chiefly arteries of medium size anywhere in the body including the coronaries which are estimated to be involved in as high as 70 per cent of cases The lesions in the coronaries are the same as have been described in other arteries When the coronary lesions produce symptoms they are the same as those already described for other forms of coronary arteritis They may be more or less masked by the other symptoms of this bizarre disease

Embolism of the coronaries may occur but it is quite rare The emboli are derived from endocardial lesions on the mitral or aortic valves in most instances but may arise almost anywhere in the body If the emboli are infected they may cause local abscesses or produce mycotic coronary aneurysms Occasionally such aneurysms rupture into the pericardial sac More frequently embolism into a coronary produces the characteristic picture of an acute myocardial infarction The clinical diagnosis of embolism demands the recognition of some source of emboli It is usually little more than inferential until and unless established at the necropsy table

MISCELLANEOUS PATHOLOGIC CONDITIONS

SYPHILIS OF THE HEART

In this presentation only tertiary syphilis of the myocardium will be considered as syphilitic aortitis with its complications aortic regurgitation involvement of the orifice of the coronary arteries and aortic aneurysm are discussed in another section (p 1166)

History.—The first gumma of the heart was reported in 1845 by Philippe Ricord an American born French syphilodermatologist Subsequently Virchow described tertiary syphilis of the heart as either fibrous or gummatous in type however the former is probably indistinguishable from fibrosis due to coronary artery disease Warthin found myocardial lesions in 40 to 60 per cent of the hearts of syphilitic patients and spirochetes in the heart muscle of the majority of these cases but these findings in acute syphilitic myocarditis have not been confirmed by other investigators

Morbid Anatomy.—Gummatous myocarditis occurs in two forms (1) diffuse miliary or submiliary gummatous myocarditis and (2) localized gummatous myocarditis the so-called cardiac gumma Both occur in congenital as well as in acquired lues Sohval has collected all the authentic cases and found that there were only seven reported instances of the diffuse form, and ninety seven of the localized gummatous type The *pathology* of the gummatous lesion in the heart does not differ from that of gummas in general The gumma may be solitary or multiple Remnants of degenerated muscle fibers in the central necrotic area may help to differentiate the gumma from a tuberculous lesion of the heart The gumma may involve the bundle of His or its branches causing various grades of heart block it may interfere with valvular function by direct invasion or may cause a pseudo stenosis of the valvular orifices by pressure upon them The gummas may caseate excavate and thus form cavities in direct communication with the chambers of the heart They may cause epicarditis rupture of the papillary muscles perforation of the interventricular septum or rupture of the heart through aneurysm of the heart wall In that way they may be a cause of sudden death

DIAGNOSIS.—Clinically syphilis of the heart is rarely diagnosed with certainty but under favorable conditions its presence may be suspected and the patient be given the benefit of treatment As the most frequent site of the gumma is in the left ventricular myocardium (Stockman) and usually at the base of the interventricular septum it may cause heart block of any grade by involvement of the A V bundle or its branches and thus the diagnosis may be suspected in a syphilitic patient Again the gummatous process may compromise or by extension invade a valvular or subvalvular region thus causing valvular pseudostenosis or insufficiency this has occurred in the region of the pulmonic aortic tricuspid and mitral valves—in order of frequency If a bizarre stenotic murmur is heard in a syphilitic patient and especially if this is associated with unexplained roentgenographic shadows along the cardiac margins a gumma may be suspected A positive Wassermann reaction

is not necessarily present in this condition Sohval states that when atypical cardiac findings are discovered in a condition known or suspected to be syphilitic, tertiary cardiac syphilis should be considered and one may add, appropriate antiluetic treatment should be instituted

Treatment —In treatment one should remember that the patient is a heart patient and that rest is important to avoid heart failure As in any case of cardiovascular syphilis it is wisest to begin specific antisyphilitic treatment with bismuth or mercury injections combined with sodium or potassium iodide in order to avert therapeutic shock later to select the arsenical least likely to give any untoward reaction and to postpone the use of the arsenical preparation until there has been time for heart muscle and elastic tissue to regenerate

TUBERCULOSIS OF THE HEART

Tuberculosis may affect any part of the heart The most common type of involvement tuberculous pericarditis is generally secondary to tuberculosis of the lungs bronchi mediastinum or to general miliary tuberculosis The pericarditis may be fibrinous or fibrinocaseous in which case a pericardial friction rub will be a prominent sign or there may be an effusion either serofibrinous hemorrhagic or purulent The disease frequently runs a slow chronic course with formation of pericardial adhesions and partial or even total obliteration of the pericardial sac More detailed discussion will be found in the section on Pericarditis (p 1039)

Tuberculosis of the myocardium is relatively rare The heart muscle like other muscle seems to have a high degree of immunity to tuberculosis In overwhelming severe miliary tuberculosis especially in young people and children the myocardium may occasionally be involved and on post mortem examination may reveal miliary tubercles large tubercles or even diffuse tuberculous infiltration Infection of the bronchial and mediastinal lymph nodes or of the pericardium may progress by direct extension to the myocardium and involve any part of the auricles or ventricles Myocardial tuberculosis is not known to produce ulcerative lesions The *signs* and *symptoms* depend on the structures affected and the extent of involvement Generally the cardiac involvement is of a minor nature and is so overshadowed by the active tuberculous process elsewhere that diagnosis is made only at necropsy

Tuberculosis of the endocardium is very rare Occasionally in acute miliary tuberculosis autopsy discloses miliary tubercles in the endocardium or more rarely in the valves Very rarely a nonulcerating vegetative or fibrocalcareous lesion may be found There are no characteristic signs or symptoms *Treatment* consists of care of the tuberculous infection

WOUNDS OF THE HEART

Wounds of the heart belong more to the domain of surgery They may be caused by *cutting instruments* as in stab wounds of the thorax by sharp objects such as paracentesis needles by bullets fractured bones etc Exploratory needles penetrating the wall of the heart do not usually cause fatal hemorrhage but may do so especially if the wall of the auricle is torn The whole cardiac wall need not necessarily be penetrated to produce severe symptoms The *chief danger is hemorrhage* not merely because of the large loss of blood but because overdistention of the pericardial sac may compress the auricles and prevent filling of

the heart during diastole resulting in tamponade of the heart Other serious complications are hemopneumopericardium purulent pericarditis empyema pyopneumothorax adhesive pericarditis and mediastinitis heart failure and possibly ventricular fibrillation The *symptoms* which lead one to suspect a wound of the heart complicating a wound of the thorax are those of precordial pain at times also abdominal pain and spasm of the abdominal muscles a pulsating stream of blood from the wound which may be foamy from admixture of air from the lung or the evidence of severe hemorrhage

The *physical examination* may reveal a pericardial friction rub a rapidly enlarging area of cardiac dulness due to hemopericardium or the presence of the characteristic water wheel murmurs of pneumohemopericardium With these there is usually all the evidence of severe internal hemorrhage With the development of cardiac tamponade the heart rate increases while the blood pressure and pulse pressure fall and the venous pressure rises The heart sounds become fainter and the area of cardiac dulness increases Stereoscopic x ray examination or fluoroscopy may locate a foreign body or missile in the heart

The *treatment* is largely surgical consisting of suture of the heart wound Recovery results in about 35 per cent of the operated cases Small transfusions of blood are also indicated Large branches of the coronary artery have been ligated with recovery as in a case recently reported by Davenport and Smith

CONTUSIONS OF THE HEART

Contusions of the heart may be the result of direct trauma to the heart itself but are generally the result of trauma to the chest wall without any necessary penetration of the skin or any obvious superficial injury External violence such as a sharp or heavy blow on the precordium is capable both in experimental animals and in human beings of producing definite areas of contusion in the heart muscle by a process analogous to the mechanism which causes cerebral concussion The heart muscle is bruised with resulting hemorrhage and myomalacia and the pathologic characteristics of the scars of myocardial changes produced by coronary artery occlusion In recent years the so called steering wheel injury has become fairly common Here as the result of an automobile accident the driver is thrown forcibly forward so that his chest strikes against the steering wheel and his heart is bruised without any permanent injury to the bony thorax The *clinical signs* of such myocardial damage are very similar to those following coronary artery closure and may include the electrocardiographic changes characteristic of damaged heart muscle as well as the changes in heart rate heart sounds blood pressure temperature and leukocyte count which are associated with classic coronary occlusion Extrasystoles auricular fibrillation or other types of arrhythmia may result Within a period of a few hours to a few days following the trauma the patient generally experiences symptoms of cardiac pain and circulatory weakness which may gradually improve or may go on to eventual cardiac failure

The *diagnosis* rests on the combination of a history of trauma to the thorax with the development within a few days of symptoms and signs of myocardial injury

The *treatment* consists of rest sedation and the same general measures that apply in acute coronary artery closure Surgical interference is indicated only if hemorrhage or rupture occurs

TUMORS OF THE HEART

Tumors of the heart are rare They may be divided into primary and secondary new growths *Malignant cardiac tumors* are rarely primary but usually attack the heart by extension from neighboring structures or by metastatic involvement The *primary neoplasms* reported have been sarcoma fibroma myxoma myxofibroblastoma, lipoma lymphangioma cavernous myoma melanoblastoma and rhabdomyoma The last mentioned is multiple and has been found associated with sclerosis of the brain and malformation of the kidneys The other tumors are more commonly found in the auricles (Link) The secondary metastatic growths found have been those originating from renal tumors melanosarcoma xanthosarcoma osteosarcoma chondroma thyroid tumors, and carcinoma New growths may invade the heart by direct extension along the pericardial sac *e g* sarcoma of the thymus carcinoma of the lung pleura or esophagus

Clinically tumors of the heart give no characteristic symptoms Occasionally a neoplastic growth in the left auricle may cause a narrowing of the mitral orifice and thereby simulate a mitral stenosis Evidence of pericarditis dry hemorrhagic or purulent may be found In a few cases the tumors have compromised the bundle of His and given rise to bradycardia and heart block A case reported by Krause and another by Ehrenberg gave evidence of their presence by x ray examination The diagnosis may be suspected if cardiac signs or symptoms such as auricular fibrillation develop in the course of malignant disease elsewhere in the body with signs of pericardial effusion especially hemopericardium obstruction of a large vessel and x ray evidence The prognosis of malignant cardiac tumors is hopeless

PARASITES

The parasites which may occur in the heart are the echinococcus the *Cysticercus cellulosae* of *Taenia solium* and perhaps the *Trichina spiralis* They are all rare and their diagnosis almost impossible The echinococcus (hydatid cyst) occurs most commonly in the right ventricle and produces no symptoms unless the cyst bursts and thus gives rise to embolic infarcts in the lungs pneumonia or pleurisy or to a blocking of the pulmonary artery Sudden death has resulted from such rupture The cysticercus which is next in frequency to the echinococcus has been found in the myocardium but produces no symptoms whatever or only such general symptoms—dropsy, pectoral pain and evidence of hypertrophy—as are not sufficiently characteristic to lead to a diagnosis Trichinosis may result in an acute interstitial myocarditis and parenchymatous degeneration with clinical evidence of circulatory failure in the fourth to the seventh week In the fatal cases however the embryos are not found in the heart muscle. The prolonged hypotension is vasomotor in origin The treatment is prophylactic and symptomatic

FOREIGN BODIES

Foreign bodies occasionally penetrate the heart from without through injury or reach the heart through the great veins the

bronchi esophagus or stomach Various foreign bodies have been found such as fragments of projectiles needles bullets broken ends of swords files knives tooth picks splinters of wood etc The embolic route is very rare Foreign bodies have wandered through the heart and great vessels They cause little reaction hardly any clinical symptoms and are usually accidental necropsy findings Thrombi more especially the ball thrombi and pedunculated thrombi cannot strictly be included among the foreign bodies

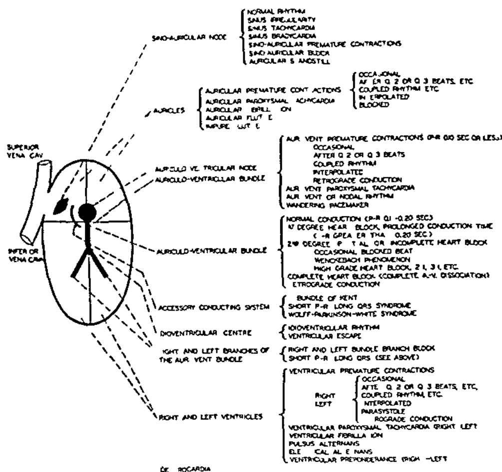

Fig 122—Here is shown a diagram of the heart and its areas of specialized tissue with an outline of the rhythms to which each part may give rise

Functional Disorders of the Heart

CARDIAC ARRHYTHMIAS

Cardiac rhythm connotes the sequence of the heart beats It may be regular or irregular The irregularity may be perpetual as in auricular fibrillation or may disturb the normal sequence occasionally or at regular intervals and the cardiac rate may be rapid or slow The heart with its areas of specialized tissue together with the related rhythms is shown in Fig 122 The normal stimulus initiating the heart beat arises in the sinus node which lies in the right auricle in the region of the opening of the superior vena cava It spreads in a radical fashion over the auricles and induces their contraction and

arriving at the auriculoventricular node which lies at the lower part of the inter auricular septum proceeds rapidly down the auriculoventricular bundle and over the

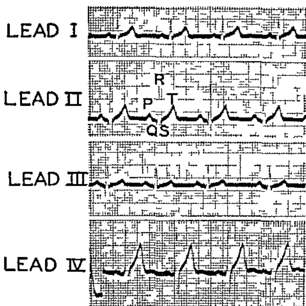

Fig 123—This figure shows the three standard leads and the chest lead of a *normal* electrocardiogram The leads and waves are identified The P waves the major part of the QRS deflections and the T waves are upright in all leads and P R is 0 17 seconds QRS_ 0 06 seconds rate 75 per minute Lead I is derived from the electrodes placed on the right and left arms Lead II from the right arm and left leg and Lead III from the left leg and left arm To obtain chest Lead IV the precordial electrode is placed 1 cm outside the apex beat and the indifferent electrode on the left leg Using Lead III selector of the gal vanometer control box the left leg wire is attached to the precordial electrode and the left arm electrode to the left leg in order to secure upright T waves in normal curves The P R interval measures the time for passage of the excitation wave from the sinus node through the auricles to the auriculoventricular node down the auriculoventricular bundle to the beginning of ventricular activity and normally does not exceed 0 20 seconds The QRS interval represents the time of spread of the excitation wave through the ventricles by way of the special conduction system and is normally not greater than 0 10 seconds The Q T time from the beginning of QRS to the end of T measures ventricular systole The three standard leads of the electrocardiogram obey the laws of the Einthoven equi lateral triangle namely that the amplitudes of any waves of the complexes in Lead II equal the sum of those in Lead I and *Lead III Standardization in all* records unless specifically mentioned is such that one millivolt produced 1 cm deflection of the string Divisions of the ordinates equal 10^{4} volts Divisions of the abscissae equal 0 04 seconds

right and left branches in the ventricular septum simultaneously and finally is distributed by the Purkinje fibers to the ventricular muscle and results in synchronous contraction of the two ventricles

The sinus discharge is usually more rapid than the inherent rate of the auriculoventricular node and the idioventricular center over which it takes precedence as the pacemaker Normally, conduction is forward from auricles to ventricles but occasionally may be retrograde The activity of the sinus node is affected by the vagus and the accelerator nerves Most of the fibers of the right vagus are distributed to the sinus node and most of the fibers of the left vagus to the auriculoventricular node and a few to the bundle The heart beat is the expression of a physiologic mechanism and has no histologic counterpart that can be discovered at present except in heart blocks

The **physiologic properties** of heart muscle concerned with its rhythms are (1) *excitability or contractility* it responds to a stimulus by contracting (2) *refractory period* having contracted a recovery period is necessary before it can respond to the next stimulus (3) *automaticity or rhythmicity* the property of initiating impulses, (4) *conductivity* it conducts an impulse that it receives

Method of Examination—Orderly examination facilitates the clinical recognition of arrhythmias 1 The jugular bulbs and external jugular veins which become dis*tended if the patient lies flat* are observed for pulsations which are magnified by using as a lever a narrow strip of paper bent at a right angle near one end and applied to the moistened skin overlying the vessel The a (auricular contraction) c (ventricular contraction) and v' (ventricular filling) waves can usually be identified by this technic when the heart is beating normally 2 The sequence of beats in the radial pulse is analyzed 3 The rhythm is analyzed on auscultation correlating it with radial and carotid pulses auricular contractions may be heard in complete heart block and in auricular flutter 4 The apex and radial rates are counted simultaneously for one minute to estimate the pulse *deficit* 5 The physician may tap one foot as a metronome to accompany the basic rhythm and then detect deviations from it If careful clinical examinations are made and then checked with electrocardiograms whenever possible a skill is acquired which permits proceeding without them when they are not available Elec

trocardiograms record the electrical activity of the heart accompanying contraction The normal cardiac cycle consists of a P wave indicating auricular activity followed by the QRS complex recording the spread of the excitation wave through the ventricles and in turn by the T wave coinciding with the retreat of electrical activity associated with contraction after which there is an isoelectric pause before the onset of the next P wave (Fig 123)

varies and sinus irregularity is present The rate may wax and wane in a repetitive pattern When the irregularity is respiratory it is easily diagnosed because the rate may increase with inspiration and decrease with expiration (Fig 124B and C) It is a physiologic phenomenon It is most common in children and young individuals It may disappear during rheumatic carditis It may occur after digitalis It may be confused with auricular fibrillation with a slow ven-

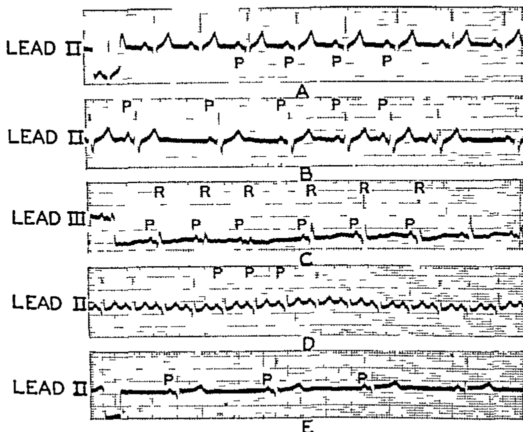

Fig 124—Here are reproduced electrocardiograms showing variations in discharge from the sinus node In A the discharge is regular and the complexes are equally spaced (Lead II) In B there is sinus irregularity (Lead II) and in C there is sinus irregularity with marked respiratory variation in the amplitudes of the QRS complexes (Lead III) D records sinus tachycardia (15 per minute) (Lead III) and E sinus bradycardia (37 per minute) (Lead II) P = auricular complexes R = ventricular complexes

Sinus Node—Normal Rhythm—The heart beat controlled by the sino auricular node is called normal or regular (sinus) rhythm or normal (sinus) mechanism The discharge of impulses may be quite regular (Fig 124A) or may have the following variations

Sinus Irregularity or Sinus Arrhythmia—When the sinus discharge is irregular (Fig 124B and C) the length of the cycle

tricular rate (Fig 129A) however in sinus irregularity there is no pulse deficit and increasing the heart rate with exercise dispels the irregularity but might elicit a pulse deficit in fibrillation The sequence of P QRS T waves in the electrocardiogram is normal but the P P interval varies (Fig 124B and C) In pericardial effusion chronic constrictive pericarditis labored respiration of asthma and in certain normal individuals

there may be *pulsus paradoxus* the *pulse volume decreases in inspiration* instead of *increasing and increases in expiration* instead of decreasing This may be verified when taking the blood pressure

Sinus tachycardia occurs when the discharge of impulses from the sinus node is over 100 per minute The rate may be 200 but the lower ranges above 100 are more common

ETIOLOGY —Sinus tachycardia is normal in a few individuals It may result from depression of vagus activity or from stimulation of the accelerator nerves and may be induced by atropine or by adrenalin It is a physiologic response to exercise eating, excitement and fear It occurs in neurasthenia neurocirculatory asthenia anemia pulmonary tuberculosis hyperthyroidism infections (except typhoid fever) especially rheumatic fever active rheumatic carditis coronary occlusion heart failure and following hemorrhage

PATHOLOGIC PHYSIOLOGY —The normal heart augments its output in response to exercise and increased oxygen consumption by increasing its rate In experiments which eliminate the effects of exercise and metabolism accelerating the heart by atropine increases the cardiac output per minute In cardiac patients tachycardia resulting from atropine does not alter the arterial but increases the venous oxygen saturation The effects of prolonged tachycardia are not known

SYMPTOMS —There may be no symptoms or there may be palpitation or pounding of the heart especially in neurasthenia and hyperthyroidism

DIAGNOSIS —In sinus tachycardia the rate usually accelerates and retards gradually in contrast to the sudden onset and offset in paroxysmal tachycardia In electrocardiograms the normal sequence of P QRS T is observed but the P-P interval is short (Fig 124D)

TREATMENT —The heart rate accelerated by exercise retards on resting as well as when other precipitating factors are alleviated Sedatives may be effective

Sinus bradycardia occurs when the sinus impulses are fewer than 50 per minute

ETIOLOGY —Sinus bradycardia is not unusual in athletes and young adults It occurs during sleep It may be associated with malnutrition jaundice and increased intracranial pressure due to brain tumor, meningitis or intracranial hemorrhage It may result from digitalis or from carotid sinus pressure

PATHOLOGIC PHYSIOLOGY —In sinus bradycardia the cardiac output per minute may decrease *because of the slow rate the stroke* volume however may be increased

SYMPTOMS —There are usually no symptoms

DIAGNOSIS —The diagnosis of sinus bradycardia is not difficult unless the rate is slow enough for confusion with complete heart block It accelerates with exercise If very slow the auriculo ventricular node assumes pacemaking or there may be ventricular escape In electrocardiograms there is normal sequence of P QRS T but the P P interval is long (Fig 124E)

TREATMENT —Sinus bradycardia requires no specific treatment except for the underlying condition which at times may be responsible for it It is rarely necessary to use atropine

Sino-auricular Premature Contractions — It is unusual for the sinus node to initiate premature contractions They cannot be differentiated clinically from other premature beats (p 1116) In electrocardiograms the P waves are similar in form to the normal ones indicating their mutual origin but they occur early and are not followed by a compensatory pause

Sino auricular block sinus pause or arrest occurs when the discharge of impulses from *the sinus node is interrupted* It may be occasional frequent or in a recurrent pattern or there may be longer periods of block

ETIOLOGY —Sino auricular block may result from *increased vagal activity* It may be precipitated by quinidine potassium salts or digitalis When the sinus node is quiescent for a few seconds syncope may result It may follow carotid sinus stimulation *If this tissue is hypersensitive* attacks may be precipitated by sudden turning of the head a tight collar bending forward One carotid sinus is usually more sensitive than the other

PATHOLOGIC PHYSIOLOGY — Occasional sino auricular block does not affect the func

tional capacity of the heart When it is prolonged the cardiac output and the blood pressure fall to zero until the ventricles escape

SYMPTOMS.—Occasional sinus pause is usually without symptoms If there are longer periods of block with asystole Stokes Adams like attacks occur with giddiness or even syncope and convulsions because of cerebral anemia

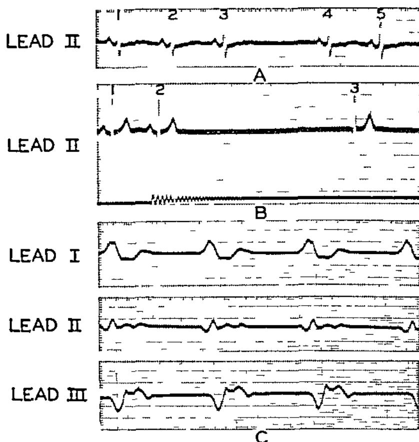

Fig 125—A is reproduced (Lead II) to show sino auricular block The interval from 3 to 4 equals twice the interval from 1 to 2 or equals interval 1 to 3 B shows sinus arrest with cardiac standstill (asystole) for 8 sec resulting from right carotid sinus pressure (Lead II) Ventricular escape occurs at 3 The signal at the bottom indicates the onset of carotid sinus pressure C records three leads showing auricular standstill with idioventricular rhythm and bundle branch block which probably resulted from toxic effect of potassium chloride The patient exhibited normal rhythm before the onset of this rhythm

DIAGNOSIS —Single sino auricular block can occasionally be detected because the pause equals two usual intervals It is to be differentiated from auriculoventricular block When the pause is of longer duration as in carotid sinus hypersensitivity the diagnosis should be suspected because of asystole which can be recognized on auscultation In testing for carotid sinus sensitivity (see p 1119 point 4) pressure may be applied for 5 to 15 seconds asystole may last for 7 to 8 seconds before the ventricles escape (Fig 125B) In electrocardiograms single sino auricular block is recognized by the absence of auricular and ventricular activity and the interval covering the block approximately equals two normal intervals (Fig 125A) and longer periods of sinus arrest may be recorded with ventricular escape (Figs 125B and 137B)

TREATMENT —Occasional sino auricular block requires no specific therapy If it is due to carotid sinus hypersensitivity and associated with symptoms atropine 0 0006 Gm (1/100 gr) three times a day Tr Belladonna 0 6 to 1 0 cc (10 drops) three times a day ephedrine 20–30 mg (1/3 to 1/2 gr) three times a day or luminal 0 015 Gm (1/4

gr) four times a day orally may be used If these measures are ineffective one or both carotid sinuses may be denervated If due to digitalis and infrequent digitalization may be continued if the drug is necessary

Auricular Standstill —In this rhythm the sinus node is quiescent the auricles fail to contract and there is ventricular escape with

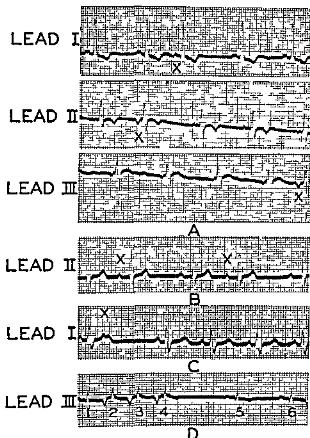

Fig 126—In A are shown the three standard leads in which auricular premature contractions (X) are recorded in each lead In B the auricular premature contractions (X) recur and give rise to coupling In C there is an auricular premature contraction (X) superimposed on the T wave and it occurs so early that it is blocked (ventricles refractory) In D the first complex (1) is normal followed by a run of 3 auricular premature contractions in succession (2 3 4) giving rise to a short run of auricular paroxysmal tachycardia followed by reversion to normal rhythm in the fifth and sixth complexes

idioventricular rhythm It occurs transiently in carotid sinus hypersensitivity As a persistent rhythm only a few instances have been reported Death results if the idioventricular center fails to initiate ventricular contractions Auricular standstill may occur as a toxic effect of potassium salts and quinidine on the sinus node and auriculoventricular system Calcium chloride 0.5 Gm (7½ gr) intravenously or barium chloride 30 to 40 mg (½ to ⅔ gr) orally may increase cardiac irritability In the electrocardiogram P waves are not seen and there is idioventricular rhythm (Fig 125C)

Premature contraction is the best term for an irregularity resulting from contractions which are derived from abnormal stimuli arising in various parts of the heart *Extrasystole* implies an extra feat of the heart, because of the pause following the premature contraction the number of beats per minute is not increased The term extrasystole applies only when the premature contraction is interpolated between two normal beats without disturbing the sequence (p 1139) The terms ectopic' and 'aberrant' imply an unusual place of origin and manner of spread of the excitation wave and would not include sino auricular premature contractions without assuming that they arose from a different part of the sinus node *Dropped* beats are seen in heart block. *Intermittent* pulse is vague The occurrence and volume of the pulse accompanying a premature contraction depend on its time in the cardiac cycle Premature contractions may arise from areas of increased irritability The mechanism might be the reentry of a previous excitation wave by way of an area of muscle which was refractory when the impulse first approached it but had recovered when the same impulse came to it slightly later by another route

Auricular Rhythms —*Auricular premature contractions* are occasioned by abnormal stimuli arising in one of the auricles which causes them to contract prematurely and also passing down the auriculoventricular system initiates ventricular contraction Auricular premature contractions may occur occasionally (Fig 126A), several in a sequence (Fig 126D) or according to a pattern (Fig 126B)

Etiology —Auricular premature contractions occur more frequently in younger than in older individuals and are not as common as ventricular ones They may not be significant They may be associated with active rheumatic fever and other infections especially pneumonia they occur in organic heart disease especially mitral stenosis coronary artery disease chronic constrictive pericarditis during pericardiectomy and fol

lowing coronary occlusion They are frequent during periods of stress and may result from coffee alcohol tobacco

Pathologic Physiology —Occasional auricular premature contractions do not disturb the circulation significantly when they cause coupling the cardiac output decreases

Symptoms —Patients may be unaware of the irregularity They may complain of palpitation the pause after the premature contraction the prematurity the quick beat the forceful beat following the premature one the heart turning over fluttering in the heart fulness of the neck veins a catch in the throat and cough Their persistency may cause fatigue

Diagnosis —Auricular premature contractions are detected by their prematurity both on auscultation of the heart and on palpation of the pulse They cannot always be differentiated from ventricular or auriculoventricular ones The dominant rhythm is disturbed if the foot taps synchronously with the heart beat it will not automatically get in step after the premature contraction The sounds accompanying the premature beat approach the usual ones The premature complex in the electrocardiogram consists of a P wave of different contour a P R time exceeding 0 10 seconds and a QRS complex of supraventricular form which may differ from the usual ones (Fig 126A)

Prognosis —Their occurrence may be fleeting They may occur for years without significance They may precede the onset of auricular fibrillation in mitral stenosis and are common in patients subject to auricular paroxysmal tachycardia

Treatment —Treatment is usually not necessary for they may disappear when the precipitating factors are alleviated Attention should not be directed to them because it may induce symptoms Patients are reassured Cigarettes coffee and alcohol are eliminated when implicated When treatment is required triple bromides 1 0 Gm (15 gr) three times or twice a day orally may dissipate them and are usually more effective than luminal 0 015 Gm (¼ gr) three times a day The patient is warned of drowsiness and drug rash If the irregularity disappears the drug is decreased and frequently may be discontinued without recurrence If sedation fails digitalis in full therapeutic amounts (see auricular fibrillation) is the most effective drug Quinidine 0 2 Gm (3 gr) three times a day (see auricular fibrillation) is less effective than in the relief of ventricular ones Occasionally potassium chloride or phosphate 2 Gm (30 gr) three times a day by mouth is beneficial Auricular standstill as a toxic effect of potassium must be kept in mind Papaverine 0 06 Gm (1 to 5 gr) three to four times a day at three to four hour intervals may abolish them

Blocked Auricular Premature Contractions —Occasionally an auricular premature contraction may be blocked if it arises early in diastole because the ventricles are still refractory This irregularity is detected in electrocardiograms (Fig 126C)

Auricular paroxysmal tachycardia is a rapid *regular* beating of the heart controlled by stimuli arising from a focus in the auricles and characterized by sudden onset and sudden offset It may be considered a succession of auricular premature contractions It may persist for a few beats only or for days The rate is usually rapid around 150 per minute but is frequently up to 250 per minute and very rarely less than 100

Etiology —It is more common in younger individuals than the ventricular type There may be a single attack or recurrences at rare or frequent intervals It occurs without organic heart disease It may be precipitated by excessive alcohol intake cigarettes gastro intestinal upsets or sudden change in position It may be associated with acute infections acute rheumatic fever being the most common and pneumonia next It occurs in mitral stenosis thyrotoxicosis during precardiectomy acute coronary occlusion during pregnancy and in patients with Wolff Parkinson White syndrome

Pathologic Physiology —During auricular paroxysmal tachycardia the cardiac output per minute decreases and the amount per beat from the normal average of 60 cc to a few cubic centimeters only The heart dilates the circulation time increases The vital capacity decreases The oxygen saturation of both the arterial and venous blood decreases If prolonged heart failure may occur especially in mitral stenosis *Transient* electrocardiographic changes have been re-

ported, presumably due to the anoxemia of heart muscle from decreased coronary flow There may be cyanosis A few rales at the lung bases, fall in blood pressure fever and leukocytosis are not unusual

SYMPTOMS —Patients are usually aware of the disturbed rhythm They complain of fluttering of the heart that started suddenly rapidity of the heart, palpitation throbbing or fullness of the neck vessels Common complaints are weakness faintness shortness of breath and sensation of the heart stretching There may be apprehension and nervousness Cardiac distress may simulate the symptoms of coronary occlusion Nausea and vomiting a sense of fulness dizziness fainting and loss of consciousness may be experienced When the blood pressure falls the picture may be one of shock

DIAGNOSIS —*Paroxysmal tachycardia* may be diagnosed from the *history* of sudden onset and offset but the type cannot be decided unless the patient is examined during an attack since auricular nodal and ventricular tachycardia and auricular fibrillation and flutter may be paroxysmal Awareness of an irregularity suggests fibrillation The rapidity and regularity are apparent both on auscultation and on tapping the rhythm with one foot The rate is not influenced by respiration or exercise but may change in several hours Pulsations in the jugular veins are rapid and "c" waves may be identified The pulse is rapid of small volume and rarely alternating If carotid sinus pressure or ocular pressure terminates the attack it is likely to be supraventricular In electrocardiograms P waves of abnormal form are detected with P R exceeding 0 10 second and usually a supraventricular form of the QRS complex (Figs 127A B and C) There may be 2 1 block.

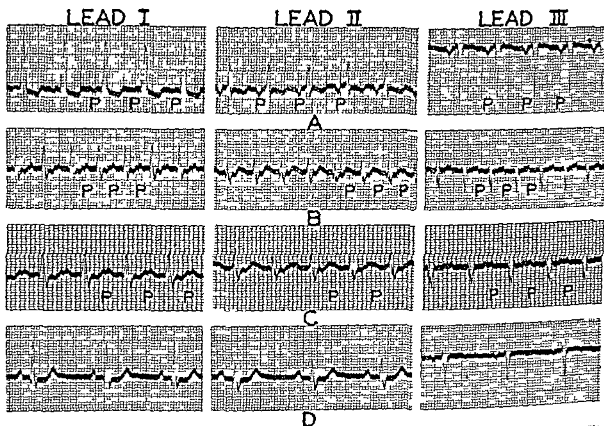

Fig 127—In A are shown the three leads recording auricular paroxysmal tachycardia rate 107 per minute (P = P waves) In B is shown another example of auricular paroxysmal tachycardia rate 16? per minute In C is shown the same paroxysm with the speed of the electrocardiographic film increased to spread out the complexes and aid in identifying the P waves D shows the electrocardiogram after reversion to normal rhythm (rate 61 per minute) from the auricular paroxysmal tachycardia recorded in B and C

PROGNOSIS —Auricular paroxysmal tachycardia frequently indicates heart disease but may recur for many years without other abnormalities there may be a single attack

Its occurrence increases the hazards of the underlying disease

TREATMENT—The first problem is to stop the attack and the second to prevent recurrence The patient should be reassured and kept in bed especially when mechanical stimuli or drugs are used If possible electrocardiograms should be taken before and during attempts to stop the paroxysm Patients may report measures that have stopped previous attacks

Attacks are usually terminated by inducing vagal or parasympathetic effects (1) Holding the breath as long as possible or expiring against the closed glottis (*Valsalva*) or inspiring after closing the glottis (Muller) (2) bending forward or lying down with feet in the air or (3) mechanical induction of *nausea* may terminate the attack. (4) *Carotid sinus pressure* is frequently effective Effects which were formerly attributed to vagal pressure were due to carotid sinus pressure The patient should be recumbent during this maneuver and atropine 0 0006 Gm ($\frac{1}{100}$ gr) for intravenous use or adrenalin 1 cc. (15 minims) 1 1000 (hypodermic) should be ready for immediate injection should asystole persist too long The right and then the left carotid sinus is pressed after which both may be stimulated Pressure for five to ten seconds is effective in suitable cases The carotid bulb which is easily identified in the bifurcation of the common carotid is compressed against the cervical spine This procedure should not be taught the patient Auscultation warns of asystole.

(5) In the long run the most effective drug is *digitalis* With the patient in bed digitalization is carried out rapidly in twenty four hours (p 1122) 1 8 Gm (27 gr) is the average digitalizing amount of the powdered leaf (U.S.P XII) if given orally in twenty four hours and the subject has had no digitalis within three weeks If reversion does not occur during the twenty four hours of digitalization as is common (Fig 127B C D) 0 2 Gm (3 gr) three times or twice a day are given the next day If the clinical strength of the preparation is not known smaller amounts are used 1.5 Gm (22½ gr) in twenty four hours It is not necessary to give the drug intramuscularly or intravenously (6) Acetyl beta methylcholine (*mecholyl*) subcutaneously is frequently effective 10–20 mg ($\frac{1}{6}$ to $\frac{1}{3}$ gr) are given subcutaneously to those ten to twenty years of age 30–40–50 mg (½ to ¾ gr) to those more than fifty years 30 mg (½ gr) being the average dose It should not be given without having atropine 0 0006 Gm ($\frac{1}{100}$ gr) ready for intravenous use if asystole is prolonged or if the side effects are marked Gentle massage of the site of injection enhances the effect The patient should be lying down in case fainting or asystole occurs Because the drug induces increased bronchial secretions profuse expectoration asthmatic breathing due to bronchospasm urticaria and involuntary stools it should not be used without preparations beforehand to meet them History of such allergic manifestations as asthma and hay fever or of sensitivity to sea food and strawberries are contraindications to its use Mecholyl results in auriculoventricular block long periods of ventricular quiescence or auricular standstill before reversion to normal rhythm occurs The synchronous use of mecholyl and carotid sinus pressure may be effective (7) If these measures fail *quinidine sulfate* orally is occasionally effective (p 1123) The use of quinidine hydrochloride 0.2 Gm to 0.3 Gm (3–5 gr) intravenously is limited to those instances when other measures have repeatedly failed and the persistence of the rhythm is deleterious When electrocardiograms are not available and the diagnosis is not established and drug treatment has to be instituted it is better to use quinidine than digitalis because of the danger of digitalis inducing ventricular fibrillation if the rhythm should be ventricular paroxysmal tachycardia. (8) Unilateral ocular pressure is very painful and is too rarely effective to use routinely (9) Apomorphine 5 mg ($\frac{1}{12}$ gr) hypodermically or syrup of ipecac 4 to 8 cc (1 to 2 drachms) by mouth which may be repeated are used to induce vomiting during which the attack may stop They are not resorted to often (10) Occasionally triple bromide 1 0 Gm (15 gr) three times a day by mouth or morphine 16 mg (¼ gr) hypodermically may terminate the attack although the latter is not recommended because paroxysmal tachycardia recurs.

Prevention of attacks is more difficult

Elimination of the precipitating factors may be sufficient if attacks occur at wide intervals If they occur at weekly or ten day intervals the most effective therapy is full digitalization followed by ration doses In other instances quinidine 0 2 Gm (3 gr) once or twice daily is effective although it is usually not desirable to give it over long periods Electrocardiograms are taken occasionally to detect prolongation of P R and of QRS conduction

Auricular Fibrillation—Auricular fibrillation is an irregularity in which the sinus node no longer controls the rhythm of the heart It is characterized by absence of coordinated auricular contraction tumultuous rapid twitching of auricular muscle fibers and total irregularity of the ventricular beats Instead of the usual origin and spread of the sinus stimulus an excitation wave courses continuously through the auricular muscle over a circular pathway about the opening of the great veins The great speed of the excitation wave 400–600 occurring per minute, and the continual variation in the length and course of the pathway account for the irregularity in the auricular action in the electrocardiogram Not all of these stimuli traverse the auriculoventricular bundle because of its refractoriness nor can the ventricles respond to all arriving there because of their refractoriness consequently the ventricular rate before digitalization is usually rapid and irregular (Fig 128A), but slower than auricular activity

Etiology—Auricular fibrillation is the most common rhythm requiring therapy Though commonly associated with organic heart disease, both transient and permanent types occur without it It may follow excessive intake of alcohol oversmoking, over eating food poisoning surgical operations It occurs transiently in acute rheumatic fever, pneumonia, particularly in the older decades coronary occlusion and pulmonary infarction It is frequently associated with chronic rheumatic heart disease especially mitral stenosis, less frequently with the arteriosclerotic and hypertensive types infrequently with luetic and congenital forms extremely infrequently with subacute bacterial endocarditis occasionally with diphtheria and chronic constrictive pericarditis and transiently during pericardiectomy After mitral stenosis its most frequent occurrence is in thyrotoxicosis frequently reverting to normal rhythm after operation It has been observed in a child three and one half years of age but is more common in later years

Pathologic Physiology—*On observation of the fibrillating heart the auricles* appear dilated and coordinated contraction is replaced by quivering of the auricular surfaces while the ventricles beat at totally irregular intervals There is decrease in car

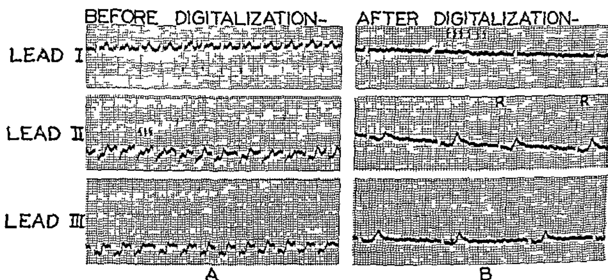

Fig 128—In A are recorded three leads showing auricular fibrillation before digitalization showing the irregular fibrillation waves (fff) the rapid ventricular complexes (R R) (ventricular rate approximately 175 per minute) which occur irregularly B shows the effect of digitalization in this same patient the slower ventricular rate (59 per minute) and the change in T waves

diac output per minute and dilatation of the heart irrespective of whether or not heart disease is present and the state of compensation Due probably to the slow circulation rate permitting a longer time for oxygenation of the blood in the lungs there is *increase* in the arterial oxygen saturation until heart failure supervenes and decrease in venous oxygen saturation

During tachycardia there is little blood in the ventricles when systole occurs so that contraction fails either to open the aortic valve or to expel enough blood to form a radial pulse accounting for the *pulse deficit* at the next systole there will be a greater accumulation of blood so that the radial pulse is barely palpable or will be larger accounting for variations in pulse volume The pulse deficit represents expenditure of cardiac energy which is wasted The blood pressure changes from beat to beat Fibrillation may be accompanied by fever due to decreased elimination of heat with the retardation of the blood flow Leukocytosis may occur The onset of fibrillation may be beneficial in some patients exhibiting mitral stenosis because the ventricular rate can be satisfactorily controlled

The presystolic murmur of mitral stenosis is due to auricular contraction If the presystolic murmur and thrill have been present during normal rhythm the timing of the murmur and thrill change with the onset of fibrillation so that they appear early in diastole or in mid diastole when the intra auricular pressure is greatest because of the absence of orderly contraction of the auricles to promote ventricular filling Occasionally during tachycardia the sequence of sounds makes a mid diastolic murmur appear presystolic this discrepancy disappears when the rate is retarded

Symptoms —Patients may be unaware of the rhythm or of the date of onset Paroxysmal fibrillation is more likely to give symptoms Patients may be unable to separate the symptoms of heart disease from those of arrhythmia They may complain of irregular beating of the heart described as fluttering palpitation skipping pounding or of fulness and fluttering of the neck veins In both the chronic and paroxysmal forms apprehension and irritability may be present for a short time after onset as well as dizziness or faintness Exertion may provoke dyspnea and the persistence of tachycardia may precipitate heart failure Angina pectoris is uncommon

Diagnosis —The clinical diagnosis is not difficult and is easier if the ventricular rate is rapid or before digitalization On auscultation the rhythm is usually totally irregular If the foot is tapped synchronously with contractions a regular sequence cannot be detected The pulse is usually slower and is irregular and of variable volume Simultaneous auscultation of the heart and palpation of the pulse reveals the magnitude of the *pulse deficit*. The ventricular rate and pulse deficit increase with moderate exercise while the irregularity due to premature contractions is likely to disappear The ventricular rate may be 180 but usually is 130–160 and occasionally is as low as 70 or 80 even without digitalis Carotid sinus pressure retards the ventricles transiently With slower ventricular rates or after digitalis the irregularity may be less marked and the pulse deficit small Occasionally the ventricular beats are regularly spaced (Fig 129A) and clinical recognition may be impossible unless exercise increases the rate and elicits irregularity With a slow rate it may be confused with sinus irregularity or frequent premature contractions The electrocardiogram is characterized by absence of definite P waves the presence of fibrillation waves and irregular sequence of the QRS complexes (Fig 128)

Prognosis Complications and Course —When the ventricular rate is slow patients maintain an adequate circulation for years without progressive cardiac enlargement or failure Others carry on satisfactorily when the rate is controlled The paroxysmal form may lead to no apparent harm in the course of years Chronic fibrillation does not in itself carry serious prognosis but as a complication of heart disease it comes on usually toward the end of the natural history of the disease Its onset may precipitate failure especially in organic heart disease or pneumonia Sluggishness of blood flow in the auricular appendages plus lack of coordinated contractions promote formation of mural thrombi and their dispersal in the blood stream Infarction of the brain spleen kidneys and occlusion of peripheral arteries

may occur Pulmonary infarcts result from thrombi from the right auricle or by paradoxical embolism (congenital communication) from the left side of the heart Patients tolerate surgical procedures when adequately digitalized

TREATMENT —If the ventricular rate is slow if it accelerates only moderately on exercise, and if the patient is without symptoms *special treatment is not indicated* although the use of quinidine should be considered If the rate is rapid especially if the patient has heart disease, rest in bed is indicated if possible until it is retarded and is required if there is failure If the patient is in bed and digitalis has not been given in three weeks *digitalization* may be undertaken rapidly by giving in twenty four hours by mouth a total of 1 8 Gm (27 gr) of the powdered leaf (U S.P XII) Experience *has shown that this is the average* amount which if given in twenty four hours *to patients with auricular fibrillation and* rapid ventricular rates will retard the rate to 70 or 80 per minute without nausea and vomiting If digitalization is accomplished in twenty four hours excretion during this time may be neglected The 1 8 Gm (27 gr) may be distributed as follows 0 8 Gm (12 gr) as the first dose 0 5 Gm (7½ gr) four to five hours later 0 3 Gm (5 gr) four to five hours after this and 0 2 Gm (3 gr) four to five hours later still (Fig 128A B) If the clinical strength of the preparation is not known, smaller amounts are used Stand*ardization of digitalis by the cat method* (U S P XII) aims to supply digitalis preparations of *uniform potency The amount of* such uniform preparations required to induce certain effects *in* patients *must* then be ascertained Experience has shown that the clinical strength of digitalis can be gauged by its effect in slowing the ventricular rate in auricular fibrillation The digitalizating amount of the preparation which is available may be ascertained therefore by establishing the amount required to slow the rapid ventricular rate in auricular fibrillation to 70 or 80 per minute If the patient is partially digitalized 0 2 to 0 3 Gm (3 to 4 gr) twice or three times a day may be given Cardiac rate and pulse deficit are counted frequently during digitalization Successive doses are withheld if nausea or vomiting occur or if the rate falls below 60 to 70 or ventricular premature contractions appear Digitalization should be accomplished without toxicity Nausea vomiting and ventricular premature contractions however may be due *to heart failure and* may disappear on digitalization The ven*tricular rate is a reliable clinical guide to* digitalization in fibrillation and the aim *should* be to reduce it to around 70 per minute (Fig 128A B) Slightly more or slightly less than 1 8 (27 gr), which is the average amount may be necessary Having reduced the rate it is maintained around this level by ration amounts The average ration is 0 2 Gm (3 gr) a day using the rate as a guide, 0 1 Gm (1½ gr) alternating with 0 2 Gm (3 gr) or 0 2 Gm (3 gr) alternating with 0 3 Gm (5 gr) daily and occasionally more may be required Experience has *shown that a resting apical rate of* 60 to 70 is satisfactory and allows for moderate increase with exercise

If the patient is nauseated and vomits digitalization may be accomplished by giving the drug by rectum as microenemata in the same dosage as by mouth It is rarely necessary to use digitalis intravenously or intramuscularly It should be established that the patient has not had digitalis for three weeks before giving it intravenously If there is urgency strophanthin K (0 25 mg) or digitoxin 0 4 mg q 4 h for three doses may be given intravenously or digifoline intramuscularly There has been however *insufficient experience under varied* circumstances with the highly purified digi*talis glucosides* to warrant their routine use although they hold promise

If the patient remains ambulatory digitalization is accomplished more slowly Knowing the average *amount of the* preparation required for digitalization in twenty four hours (1 8 Gm [27 gr]) *and the daily* maintenance amount (0 2 Gm [3 gr] alternating with 0 1 Gm [1½ gr]) *and the number of* days it is appropriate to take for digitalization the total amount *required for digitaliza*tion in this number of days is calculated If digitalization is spread over one week the regime may be as follows 1 8 Gm (27 gr) required to digitalize +0 9 Gm (15 gr) to maintain digitalization (0 1 Gm [1½ gr] alternating with 0 2 Gm [3 gr] *for 6 days*)

amounts to 2.7 Gm (42 gr) to be given during the week which may be spread somewhat as follows (Table 1)

TABLE 1 DIGITALIS ADMINISTRATION FOR ONE WEEK

Day	*Digitalis (U.S.P. XII)* AM	PM	*Amount for the day*	*Total to date*
1	0.3 Gm (5 gr)	+0.3 Gm (5 gr)	=0.6 Gm (10 gr)	0.6 Gm. (10 gr)
2	0.3 Gm (5 gr)	+0.2 Gm (3 gr)	=0.5 Gm (8 gr)	1.1 Gm (18 gr)
3	0.2 Gm (3 gr)	+0.2 Gm (3 gr)	=0.4 Gm (6 gr)	1.5 Gm (24 gr)
4	0.2 Gm (3 gr)	+0.1 Gm (1½ gr)	=0.3 Gm (4½ gr)	1.8 Gm (28½ gr)
5	0.2 Gm (3 gr)	+0.1 Gm (1½ gr)	=0.3 Gm (4½ gr)	2.1 Gm (33 gr)
6	0.2 Gm (3 gr)	+0.1 Gm (1½ gr)	=0.3 Gm (4½ gr)	2.4 Gm (37½ gr)
7	0.2 Gm. (3 gr)	+0.1 Gm (1½ gr)	=0.3 Gm (4½ gr)	2.7 Gm (42 gr)

Toxic symptoms are not expected after the first doses but would be more likely to occur toward the end of the week accordingly the last doses are smaller and the patient warned of toxic symptoms If the clinical potency of the preparation is not known smaller amounts than those listed above are recommended Digitalization by 0.2 to 0.3 Gm (3 to 5 gr) daily takes too long to attain an adequate effect Occasionally in terminal heart disease digitalis fails to reduce the rate or sufficient amounts can not be given without inducing ventricular premature contractions If there is heart failure digitalization commonly results in diuresis which may be sufficient to restore compensation

The reversion of *chronic* fibrillation to normal rhythm with *quinidine* is now undertaken infrequently Reversion should not be attempted (1) if fibrillation has been present for a long time because mural thrombi may be dislodged when the auricles begin contracting regularly (2) if the heart is large (3) during heart failure—compensation should be restored first (4) if failure has been of long duration because the formation of thrombi may have been encouraged (5) without taking into consideration that some patients feel better and the heart rate is more easily controlled during fibrillation. During attempts at restoration the patient should be in bed The ventricular rate is first reduced with digitalis and compensation is restored Digitalis is then discontinued and test made for quinine idiosyncrasy with two doses of quinidine 0.2 Gm (3 gr) at two hour intervals The drug may then be given as follows 0.4 Gm (6 gr) four times a day at four hour intervals the first day normal rhythm may recur at any time If fibrillation persists 0.4 Gm (6 gr) quinidine is given five times a day the second day and 0.4 Gm (6 gr) six times a day the third day If reversion has not occurred larger amounts should not be given at this time but digitalis is resumed and the ventricular rate reduced again If reversion is urgently desired a second attempt may be made attention being given to the occurrence of ventricular premature contractions If normal rhythm is restored maintenance doses 0.2 Gm (3 gr) twice a day are given for a week longer If normal rhythm is restored once but fibrillation recurs while quinidine is being given further attempts are not recommended If it recurs after being discontinued another attempt may be made It is not advisable to use quinidine daily over long periods to prevent recurrence

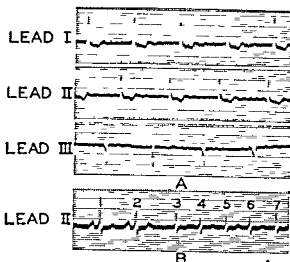

Fig 129 —In A is shown auricular fibrillation in which the ventricular sequences are regularly spaced, ventricular rate 60 per minute In B is shown the transition from normal rhythm (88 per minute) to auricular fibrillation (ventricular rate 125 per minute) Complexes 1 and 2 are normal rhythm and 3 to 7 inclusive auricular fibrillation

Paroxysmal Auricular Fibrillation—

Treatment —If paroxysms are infrequent and brief in an otherwise well subject *specific treatment is not required* beyond avoidance of precipitating factors (Fig 129B) If however the attack has persisted *for several hours or days* if tachycardia prevails if the patient is uncomfortable or if signs of failure are apparent treatment is indicated The patient should be in bed and the ventricular rate reduced with digitalis There is no evidence clinically that digitalis fixes the rhythm and prevents reversion to normal since (1) paroxysmal fibrillation may revert to normal rhythm on digitalization (2) maintenance amounts of digitalis may prevent recurrent fibrillation and (3) *normal rhythm recurs while digitalis is being* given after thyroidectomy If normal rhythm is not restored during preliminary digitalization and if the signs of failure have not been present or have disappeared quinidine may be given (p 1123) If the patient has been treated effectively with quinidine and has no idiosyncrasy instructions may be given about taking the drug on recurrence Ration doses of quinidine are usually not given daily over months or years controlling the ventricular rate with digitalis is more satisfactory Recurrent fibrillation is occasionally prevented by digitalization followed by maintenance doses when quinidine has been ineffectual In acute rheumatic fever it is transient and usually does not require therapy In pneumonia or coronary occlusion prompt slowing of the ventricular rate is necessary the use of quinidine is then considered Occasionally following quinidine fibrillation changes to flutter which persists in spite of large amounts of quinidine or digitalis

The benefits of digitalis are more dramatic in auricular fibrillation than in normal rhythm because of marked slowing of the ventricular rate Digitalis exerts certain other effects on the heart which can be recorded in *patients* 1 An effect on heart muscle is observed objectively in changes in the form and amplitude of T waves of the electrocardiogram (Fig 128A B) This effect however cannot be interpreted in terms of benefit or degree of digitalization 2 Digitalis increases the auriculoventricular block and in adequate dosage prevents most of the fibrillation impulses from passing to the ventricles those passing relatively infrequently find the ventricles containing more blood The ventricular rate is retarded (Fig 128A B) and the pulse deficit is decreased or abolished The blocking effect of digitalis can be pushed to complete heart block Atropine abolishes the vagal effects so that the ventricular rate and pulse deficit increase 3 Digitalis decreases the size of the dilated, fibrillating heart and increases its volume output The failing and the digitalized heart as well as the normal heart appear to obey Starling s law of the heart 4 The extent of ventricular contraction is also increased in roentgenkymograms These effects contribute toward increase in cardiac output per minute and per beat decrease of the circulation time toward normal and fall in venous pressure, if it has been elevated When normal rhythm is restored spontaneously or by quinidine still further increase in cardiac output may occur with other appropriate changes

Quinidine brings about restoration of normal rhythm in fibrillation by increasing the refractory period of auricular muscle As the excitation wave moving in its circuit reaches a certain point it finds that tissue still refractory and unable to transmit it the circus ends and the sinus node assumes control Quinidine also slows the speed of conduction of the impulse and thereby tends to perpetuate the circus motion accordingly when the effect on the refractory period is greater than its contrary effect on conduction normal rhythm supervenes

Quinidine is to be discontinued should there occur ringing in the ears deafness diarrhea nausea vomiting rash fever interventricular heart block ventricular premature contractions rapid regular rhythm or episodes of irregular rhythm suggesting ventricular fibrillation Cerebral accidents or death occurring during quinidine therapy are in some instances due to embolism associated with dislodgment of mural thrombi on restoration of coordinated contraction of the auricles Other instances of *death have* been attributed to cardiac standstill resulting from depression of both the sinus and auriculoventricular nodes *leaving no center* available for pacemaking when the auricles stop fibrillating

When it occurs in *hyperthyroidism* the

ventricular rate is reduced with digitalis Larger than the average amounts may be required to attain adequate slowing Maintenance doses are continued during treatment with iodine and after thyroidectomy In most instances a few days to many weeks after operation the rhythm reverts to normal spontaneously When this occurs digitalis is discontinued if heart failure does not require its continued use If normal rhythm has not recurred after an adequate postoperative period the use of quinidine is considered

Auricular flutter is a rhythm in which the auricles contract regularly at a rate of 200-360 or more per minute and in which the ventricles contract in response to some of these stimuli Flutter is due to the passage of an excitation wave in a circus motion about the opening of the great veins in the right auricle The passage is over a constant pathway and only one impulse is given off from the circumference of the circular pathway with each circuit the auricular impulses occur *regularly* the rate ranging between 200 and 400 per minute but commonly around 320 (Fig 130) which is slower than in fibrillation These impulses spread through the auricular muscle down the auriculoventricular node and bundle to the ventricles but are so rapid that the conducting system cannot readily transmit nor the ventricles respond to so many and auriculoventricular block usually develops The ventricular rate is usually regular and slower than the auricular rate and usually has a constant ratio to it two auricular contractions to one ventricular designated 2 1 auricular flutter is common before treatment (Fig 130) A 1 1 ratio is occasionally observed The most frequent ventricular rate is 150 to 165 per minute Ratios of 3 1 4 1 or 5 1 occur after digitalization (Fig 131B and C) and occasionally before treatment If the ratio fluctuates the ventricular sequence is irregular (Fig 131A) Auricular flutter is more commonly paroxysmal than chronic It may be transient (Fig 131E) but usually persists for hours days or weeks and rarely for many years

ETIOLOGY—Auricular flutter is more commonly associated with heart disease than not It occurs in chronic rheumatic heart disease especially when mitral stenosis is present in hyperthyroidism pneumonia active rheumatic infection hypertensive and arteriosclerotic heart diseases coronary occlusion, and less rarely in congenital heart disease It is far less common than fibrillation and occurs more frequently in the older than in the younger age group It has been reported during pericardiectomy

PATHOLOGIC PHYSIOLOGY—When there is tachycardia as in 2 1 block the cardiac output per minute is markedly decreased so

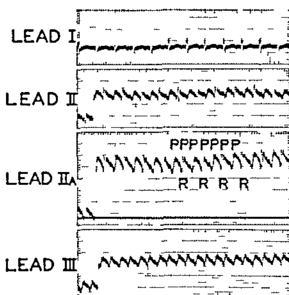

Fig 130—Here are shown the three standard leads recording 2 1 auricular flutter (ventricular rate 187 auricular rate 374) The flutter waves are poorly seen in Lead I but are easily identified in Leads II and III (PPP) of which there are two to one ventricular complex (RRR) In Lead IIA the galvanometer string was standardized for 2 cm instead of 1 cm in order to magnify the flutter waves

that the stroke volume may fall to 13 cc. per beat (normal 60 cc) together with prolongation of the arm to tongue circulation time and cardiac dilatation Rise in venous pressure may be recorded Reversion to normal rhythm is accompanied by restoration of these functions toward normal levels When the ventricular rate is moderately slow the cardiac output may be normal

SYMPTOMS—The patient may complain of rapid heart beat or palpitation which may be described as a fluttering sensation Heart failure may be precipitated or aggravated by its onset Rarely its onset may

be accompanied by syncope due to cerebral anemia and by sweating apprehension and fall in blood pressure

DIAGNOSIS —The ventricular rate is usu

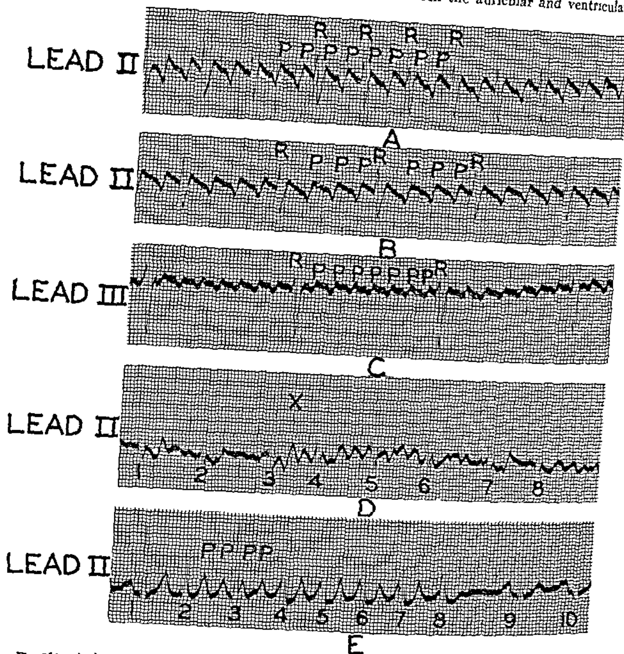

Fig 131 —A shows auricular flutter with the *ratio of auricular* waves (PPP) to ventricular ones (*RRR*) changing from 2 1 to 3 1 (ventricular rate 110 *auricular rate 240*) B 4 1 auricular flutter is recorded (ventricu lar rate 57 auricular rate 228) and in C *the ratio is* 7 1 (ventricular rate 42 auricular rate 294) In D is shown auricular fibrillation 1-2-3 changing *at* Y *to* impure flutter for 4-5-6 and then auricular fibrillation again *for* 7 and 8 In E the first *complex 1 is normal* rhythm followed by 7 complexes (2 to 8) of auricular flutter (PP) in which the position of the ventricular contraction changes and is then followed by reversion to normal rhythm *for complexes 9 and 10*

ally rapid 150 to 160 per *minute* and is not influenced by exercise or holding the breath Block is increased transiently by carotid sinus pressure If block varies the ventricular sequence is irregular When audible, approximately 300 auricular con tractions may be counted per minute and a ratio between the auricular and ventricular rates is detected Occasionally rapid auricu lar waves and *slower larger* ventricular waves are identified in the jugular pulse During 4 1 block when the ventricular *rate*

is around 75 per minute the rhythm may escape recognition The detection of regularly spaced flutter waves in the electrocardiogram establishes the diagnosis (Figs 130 131A B C and E) The auricular rate is greater than in auricular paroxysmal tachycardia but the differentiation is difficult if there is 1 1 ratio

Impure flutter is intermediate between fibrillation and flutter (Fig 131D) Clinically it resembles fibrillation in irregularity of the ventricular sequence but in the electrocardiogram there is a fairly but not absolutely regular spacing of flutter waves at a faster rate than definite flutter interspersed with runs of fibrillation waves

Prognosis—Auricular flutter is usually associated with heart disease It is commonly of short duration if treated but may be chronic

Treatment—Treatment is directed to restoration of normal rhythm The patient should be in bed Digitalis is the most effective drug If the clinical strength of the preparation is known and the ventricular rate is rapid digitalization may be accomplished in twenty four hours by giving 1 8 Gm (27 gr) the average amount in this time (p 1122) As it becomes effective the ventricular rate falls as block increases to 3 1 or 4 1 and may reach 75 per minute during the day Reversion may occur during the first twenty four hours On the other hand if the rate has not retarded sufficiently 0 3 Gm (5 gr) twice during the second day may be required Maintenance doses are given when satisfactory slowing results nausea and vomiting being avoided During this time the rhythm may become normal When the ventricular sequence is irregular it may be due to changing block or to the onset of fibrillation After the onset of fibrillation normal rhythm may follow It may be restored directly from flutter or often there is an intervening period of fibrillation It is not necessary to discontinue digitalis at the onset of fibrillation to insure reversion to normal rhythm

After restoration of normal rhythm digitalis is discontinued unless it is required because of heart failure If normal rhythm is not occasioned by digitalis or if the rhythm has changed to fibrillation which persists without giving way to normal rhythm quinidine sulfate may be used orally digitalis being continued if necessary to keep the ventricular rate slow Fibrillation is more satisfactory as a chronic irregularity than flutter because the ventricular rate is more easily controlled If quinidine is effective maintenance amounts are given for a few days Occasionally, these measures are not successful it may be impossible even to retard the ventricles Recurrent flutter may be prevented by digitalization followed by ration doses If ration doses of quinidine are used for this purpose which is not recommended toxic effects should be foreseen This drug should not be used intravenously unless there is urgency

The use of digitalis to restore normal rhythm is based on its vagal effects Vagal stimulation by the drug shortens the refractory period of auricular muscle and increases the transmission rate This action tends to maintain the gap in the circus shortens the time to make a circuit and the auricular rate increases The direct action of the drug on the auricular muscle on the other hand lengthens its refractory period and slows conduction which tends to close the gap and slow the auricular rate Although the vagal and direct effects are opposite the vagal effect overrides the direct action and converts flutter to fibrillation from which normal rhythm may follow The action of quinidine effective in breaking up the circus motion is the same as in fibrillation it fails when the effect on conduction over balances that on the refractory period

Auriculoventricular Tissue—*Auriculoventricular Nodal or Junctional Premature Contractions*—If an abnormal stimulus arises in the auriculoventricular node or bundle a premature contraction results In a large series of electrocardiograms they are frequently encountered They may occur occasionally or in a pattern

Etiology—Nodal premature contractions occur in normal as well as in diseased hearts especially during active rheumatic carditis and coronary occlusion

Pathologic Physiology—Occasional auriculoventricular premature contractions do not embarrass the circulation appreciably but when frequent may decrease the cardiac output

Symptoms—If infrequent they give rise

to no symptoms There may be symptoms similar to those associated with auricular premature contractions

DIAGNOSIS —They cannot be differentiated clinically from auricular premature contractions The pause after the premature beat *is relatively short The diagnosis is* electrocardiographic The impulse arising in the auriculoventricular tissue passes back

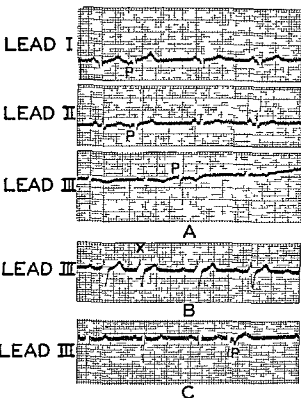

Fig 132 —A records the three standard leads of the electrocardiogram *in which one auriculoventricular premature* contraction (P) arising high in the tissue is recorded in each lead so that the P wave is in front of the QRS complex and the P R time of them 0 08 to 0 09 seconds In B the auriculoventricular premature contraction (X) arises near the middle of the tissue and a P wave is not seen In C the auriculoventricular premature contraction (P) arises low in the auriculoventricular bundle and ventricular contraction precedes auricular activity so that the P wave follows the QRS complexes

ward by retrograde conduction to the auricles and initiates their contraction and simultaneously downward to the ventricles stimulating them If the stimulus arises high up in the junctional tissue the auricles contract first followed in 0 10 seconds or less by the ventricles if it arises in the middle of this tissue *it arrives simul*taneously at the auricles and ventricles and they contract synchronously if arising at the lower part of the junctional tissue the stimulus arrives at the ventricles first causes them to contract, and arriving later at the auricles results in their contraction accordingly, in the electrocardiograms the P wave falls in front of (Fig 132A) during (Fig *132B*) or after the QRS complex (Fig 132C)

One auriculoventricular premature contraction occasionally initiates two ventricular contractions The stimulus traverses the auriculoventricular bundle and initiates the ventricular contraction and in passing backward to the auricles, stimulates their contraction this auricular impulse spreads through the auricular muscle and arriving at the auriculoventricular tissue passes down the bundle if this tissue is no longer refractory is distributed again to the ventricles and causes another ventricular systole provided the ventricles have also recovered from their refractoriness (Fig 149A and B)

TREATMENT —When treatment is required it is similar to that given for auricular premature contractions namely sedation or *digitalis*

Auriculoventricular Paroxysmal Tachycardia —This term designates a rapid regular beating of the heart controlled by stimuli arising in the junctional tissue and characterized by sudden onset and *sudden* offset It may be looked upon as a succession of auriculoventricular premature contractions The excitation wave passes upward to the auricles initiating their contraction and also downward to the ventricles stimulating them The rate is usually around 150-200 per minute but may be slower or more rapid

ETIOLOGY —It occurs in all age groups both in subjects with normal hearts and in those with organic disease It occurs in acute rheumatic fever and coronary occlusion and in patients with Wolff Parkinson White syndrome It may be transient or persist for days

PATHOLOGIC PHYSIOLOGY —*Auriculoventricular* paroxysmal tachycardia is associated with decreased cardiac output per minute and the stroke volume may fall as low as 12 cc from a normal level of 60 cc the circulation time may be prolonged and the heart dilates The blood pressure may fall and heart failure may appear

SYMPTOMS—Symptoms are similar to those associated with auricular paroxysmal tachycardia

DIAGNOSIS—Clinically this cannot be differentiated from auricular paroxysmal tachycardia although the rate may be more rapid The diagnosis is made in the electrocardiogram the P wave falls before (0 10 seconds or less) (Fig 133A and B) during (Fig 133C) or after the QRS complex (Fig 133D) Occasionally supraventricular paroxysmal tachycardia is diagnosed if the origin cannot be more accurately localized

PROGNOSIS—Attacks may occur for many years without the appearance of signs of cardiac disease Electrocardiographic changes may persist several weeks after an attack

TREATMENT—Treatment is similar to that for auricular paroxysmal tachycardia Digitalization is the most effective means

Auriculoventricular or nodal rhythm occurs when pacemaking is dislocated from the sinus node to the auriculoventricular tissue so that a focus in this tissue controls the beating of auricles as well as ventricles The rate is usually slower around 40 per minute than the discharge from the sinus node The sequence is usually regular

ETIOLOGY—The dislocation of pacemaking to this node is precipitated either by factors depressing the sinus discharges by

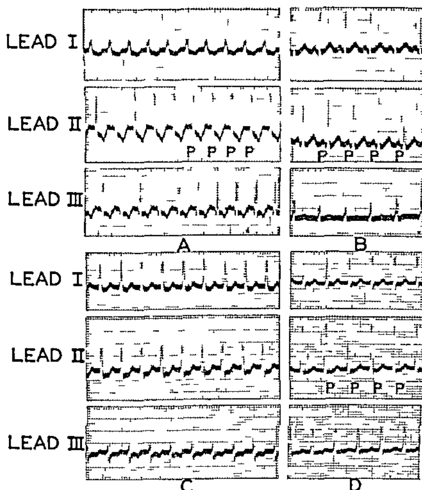

Fig 133—In A and B are shown the three standard leads illustrating auriculoventricular paroxysmal tachycardia (rate 206 and 150 per minute respectively) in which the P waves (PPP) fall in front of the QRS In C are shown the three standard leads illustrating auriculoventricular paroxysmal tachycardia (rate 176) in which the P waves are not seen and are presumably concealed in the QRS complexes and in D the P waves (PPP) follow the QRS complexes (rate 172 per minute) Increasing the speed of the electrocardiograph film or loosening the galvanometer string may aid in identifying the P waves

vagal stimulation or those increasing the irritability of the auriculoventricular tissue by sympathetic nerve stimulation The rhythm occurs more commonly in subjects having heart disease It may result from digitalis, sometimes in doses less than the full therapeutic amount and also after atropine On the other hand atropine may restore sinus pacemaking It is encountered in acute infections

Pathologic Physiology —Studies of the circulation during this rhythm have not been reported

Symptoms —The rhythm causes no symptoms unless the rate is very slow

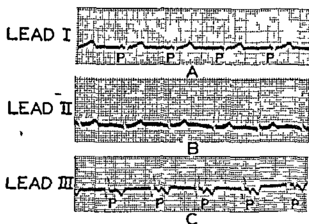

Fig 134 —In A is shown Lead I illustrating nodal rhythm (rate 66 per min) in which the P waves (PPP) precede the QRS the P R time is 0 08 to 0 09 sec In B is shown Lead II illustrating nodal rhythm (rate 79 per min) in which the P waves are not seen and it appears that the P and QRS occur simultaneously In C is shown Lead III of nodal rhythm in which the focus for pacemaking is low in the bundle so that the ventricular complexes (QRS) (65 per min) occur first followed by the auricular contractions (PPP)

Diagnosis —The diagnosis should be suspected when the rate is slow and large pulsations occur in the jugular veins resulting from simultaneous contraction of auricles and ventricles *Electrocardiograms differentiate it from complete block and sinus bradycardia* The stimuli may arise in any part of the auriculoventricular tissue so that the P waves in the electrocardiogram precede (Fig 134A) occur simultaneously with (Fig 134B) follow the QRS complex (Fig 134C) or shuttle up and down (Fig 135A)

Prognosis —Normal rhythm is restored when the precipitating factors are eliminated

Treatment —It is usually very transient but may persist for days It requires no special therapy If digitalis is implicated normal rhythm follows its elimination Heart failure, however takes precedence in therapy

Wandering Pacemaker —When pacemaking shifts back and forth from the sinus to the auriculoventricular node the rhythm is designated as *wandering pacemaker* It is commonly transient but may be persistent It very rarely follows digitalization It is frequently observed in normal individuals especially athletes with bradycardia and during deep breathing It may be evidence of carotid sinus hyperactivity In electrocardiograms the P waves shift location with respect to the QRS complex indicating that the site of impulse formation shifts from the sinus node to the upper part of the auriculoventricular node then moves gradually down the auriculoventricular tissues after which it retraces its course up the junctional tissue back to the sinus node (Fig 135B)

Conduction Defects —*Heart block* refers to auriculoventricular heart block and occurs when stimuli arising in the sinus node or auricles are delayed or obstructed in their passage down the auriculoventricular bundle Defect in the main bundle is more common than in its right and left branches

When there is delay in conducting the sinus impulse the interval from the beginning of auricular activity to the onset of ventricular activity in the electrocardiogram exceeds 0 20 seconds *This is designated prolonged P R conduction time or first degree heart block* (Fig 136A) When impulses are blocked from reaching the ventricles so that ventricular contractions fail to occur there is *second degree partial* or *incomplete heart block* which may assume several patterns In the *Wenckebach phenomenon* the delay in conduction increases progressively until an impulse is blocked and a "dropped beat" occurs the bundle transmits the next sinus impulse after which the progressive increase in P R time recurs (Fig 136B) Every third (3 2 heart block) fourth fifth sixth seventh or eighth stimulus may be blocked At other times every second or every second and third impulses are blocked giving rise to 2 1 (Fig 136C) and 3 1 (Fig *136D*) block in which there are two and three auricular contractions to one ventricular beat respec

tively These are *high grade heart block* Finally when obstruction to the passage of sinus impulses is total *complete heart block* or *complete auriculoventricular dissociation* is present (Figs 136E F, 137A) When this occurs the ventricles escape and contract at their own inherent rhythm which is usually slow thirty to forty per minute and rarely rapid *idioventricular rhythm* prevails (Figs 136E F 137A) The auricles may beat regularly (Figs 136F 137A) or fibrillate (Fig 136E)

Etiology—Alterations in the conducting system resulting in heart block may be occasioned by (1) structural damage (2) toxic effect of drugs (3) nutritional changes and (4) vagal effects Conduction changes are accepted as criteria of rheumatic activity which may cause all degrees of transient or permanent block Any degree of block occurs in arteriosclerosis and in coronary occlusion it may be transient or chronic Likewise diphtheria may cause any degree of block chronic or transient especially complete block Congenital heart block especially when complete may be associated with interventricular septal defect Digitalis results in any grade of block which is not necessary for a therapeutic effect Acetyl beta methylcholine chloride induces conduction defects through its stimulation of parasympathetic nerve effects Nutritional or functional changes probably cause the alterations in uremia and in myxedema Carotid sinus pressure may induce any grade block and cardiac standstill (Fig 137B and C)

Morbid Anatomy—In functional or nutritional block pathologic lesions are not expected In organic block anatomic lesions

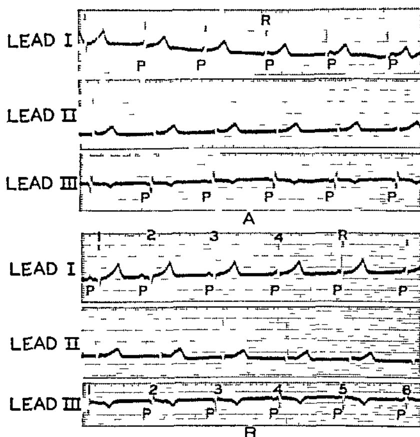

Fig 135—In A is shown three leads of nodal rhythm (rate 50 per min) in which the focus for pacemaking shuttles up and down the junctional tissue indicated by the changing position of the P waves (PPP) to the QRS complexes In B is shown three leads of *wandering pacemaker* Complexes 1 and 2 arise in the sinus node (58 per minute) 3 shifts to high up in the junctional tissue (rate 48 per min) the place of origin of the excitation wave then gradually moves down the bundle (shifting position of P waves) in Leads I and II and in Lead III the site is again high up (complexes 2 and 3) then in 4-5-6 activity is restored to the sinus node

are detected very frequently, but may not be greater than in another heart in which defects are not recorded The lack of correlation between the presence of block and the microscopic picture is not surprising since the integrity of a few fibers may be sufficient to transmit the excitation wave Inflammatory changes in rheumatic fever may involve

First degree heart block causes no symptoms and probably no marked alterations in cardiac function The P R interval in the electrocardiogram exceeds 0 20 seconds (Fig 136A)

Second Degree Heart Block—PATHOLOGIC PHYSIOLOGY—Occasional block is probably associated with no marked change in cardiac

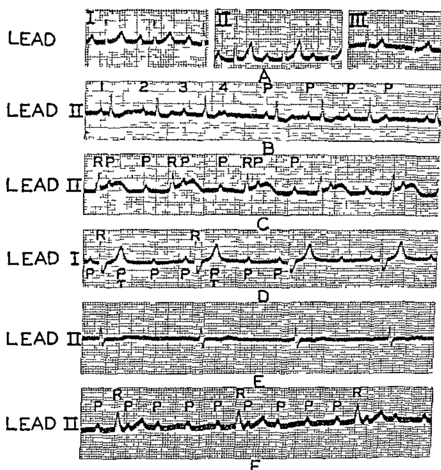

Fig 136—In A is shown three standard leads with P R conduction prolonged to 0.32 sec in Lead II In B is shown in Lead II gradual prolongation of P R from 0 20 in 1st to 0 27 in 2d to 0 39 in the 3rd complex and the fourth P wave is blocked this pattern is then repeated (Wenckebach phenomenon) In C is shown Lead II of 2 1 heart block (P=P waves R= ventricular waves) with prolonged P R time to 0 41 seconds (ventricular rate 48 auricular rate 96) *The blocked P wave appears on the hump of the T waves* In D is shown Lead I of 3 1 heart block (PPP=P waves and R=ventricular complexes) (ventricular rate 37 auricular rate 111) In E is shown auricular fibrillation with complete heart block and idioventricular rhythm the ventricular rate 37 in Lead II In F is shown Lead II of complete heart block with the auricles (PPP) continuing to contract at the rate of the sinus node discharge (ventricular rate 30 auricular rate 120) *Idioventricular rhythm with bundle* branch block is present (QRS prolonged to 0 12 seconds)

the conduction system although the changes are also attributed to vagal effects Arteriosclerosis causes block either by myocardial fibrosis involving the bundle or by decrease in blood supply by narrowing or closure of coronary vessels supplying this tissue There may be diffuse syphilitic involvement or gumma formation

function *2 1 block results in decrease in* cardiac output per minute with prolongation of the circulation time

SYMPTOMS—Patients are usually unaware of occasional block when occurring frequently they may complain of the pause of the forceful beat after the pause or palpitation In 2 1 block they may complain of

the slow forceful beating dyspnea and rarely exhibit other signs of failure

DIAGNOSIS —During digitalis therapy or rheumatic fever the diagnosis is frequently possible When there is occasional block a sequence of regular beats followed by a pause will be detected on auscultation then the regular sequence recurs The pause is also apparent in the pulse The irregularity differs from a premature contraction in not being preceded by an early beat The pause may equal two regular cycles When high grade block is present the ventricular rate may be slow around forty per minute when the ventricular rate suddenly halves 2 1 heart block should be considered (Fig 136C) Auricular contractions may be heard in the middle of the long pauses and one or two a waves may be seen in the jugular pulse The electrocardiogram shows the relationship between P and QRS complexes (Fig 136B C and D)

PROGNOSIS OF FIRST AND SECOND DEGREE HEART BLOCK —In rheumatic fever block usually disappears with recovery when resulting from digitalis normal conduction is restored with its elimination In luetic and arteriosclerotic heart diseases or after coronary occlusion block indicates myocardial damage and makes the prognosis more serious

TREATMENT —Incomplete block usually requires no treatment Digitalis when implicated is omitted for a few days or the dose diminished If the patient complains of irregularity atropine 0 0006 Gm 1/100 gr) may abolish it Digitalis can usually be given when necessary even though high grade block is present without increasing the block

Complete Heart Block —ETIOLOGY —Complete block is most common in arteriosclerotic heart disease with or without coronary occlusion less common in congenital heart disease following diphtheria or digitalis intoxication

PATHOLOGIC PHYSIOLOGY — Complete block is usually associated with marked decrease in the cardiac output *per minute* but the stroke volume is usually increased and may be as much as 90 cc per beat The circulation time may be prolonged In complete block the heart rate cannot increase appreciably to provide increase in cardiac output As a compensatory mechanism the organism decreases its basal metabolic rate The systolic blood pressure may be elevated

SYMPTOMS —When complete block has become established patients may be without symptoms when at rest but experience dyspnea and dizziness on exertion They may be unaware of the rhythm or may complain of the slow forceful beating of the heart Other patients suffer the Stokes Adams syndrome characterized by syncope with convulsions or milder symptoms of dizziness and faintness because there may be several seconds of ventricular asystole at the onset of complete block before the idioventricular center becomes active During this time the circulation is at a standstill In recurrent complete block the Stokes Adams syndrome may recur with each onset When complete block has become established and adjustments have been made the cardiac output is usually sufficient to supply the body needs and the patient recovers from syncope and convulsions and may remain without symptoms On further slowing of the rate however to 15 or 20 per minute syncope will recur Asystole and syncope may be transient or persist for several seconds Occasionally patients complain of headache weakness and fatigue Heart failure may result

DIAGNOSIS —Complete heart block is to be suspected when the heart beats regularly around thirty five per minute and the patient complains of syncopal attacks It is to be differentiated from 2 1 heart block and sinus bradycardia Exercise does not increase the rate appreciably The cardiac and radial rates correspond Auricular beats may be heard at a more rapid rate than the ventricular ones a waves may be identified during the ventricular intervals and a ratio is not apparent The first heart sound changes due to the shifting relationship of auricular to ventricular systole (Fig 137A) Fluoroscopy reveals independent auricular and ventricular contractions Electrocardiograms confirm the diagnosis (Figs 136E F 137A) When digitalis is being given in auricular fibrillation the onset of a slow *regular* ventricular sequence suggests complete block (Fig 136E)

PROGNOSIS —Complete block usually disappears with recovery from rheumatic car

ditis and diphtheria Persistence after diphtheria is compatible with longevity In luetic and arteriosclerotic heart disease and after coronary occlusion it indicates progressive damage to heart muscle and makes the prognosis more serious Bundle branch block increases the hazards Compensated patients tolerate surgical operations Death follows prolonged ventricular asystole or too great ventricular slowing Complete block occasionally disappears after being present for many months

TREATMENT —When complete block has become established treatment is usually not required Patients lead active lives with not only because it is not known whether the patient will suffer another seizure shortly after recovery, but also on the chance that the idioventricular center will take over promptly If the attack is prolonged intracardiac injection of adrenalin is indicated In chronic complete block, patients may require adrenalin every two to three hours for many days due to sudden decline in rate below that established For more prolonged effect ephedrine sulfate 20 to 30 mg (⅓ to ½ gr) three times a day orally may be beneficial In other instances barium chloride 30 to 40 mg (½ to ⅔ gr) three or four times a day orally increases ventricular irritability

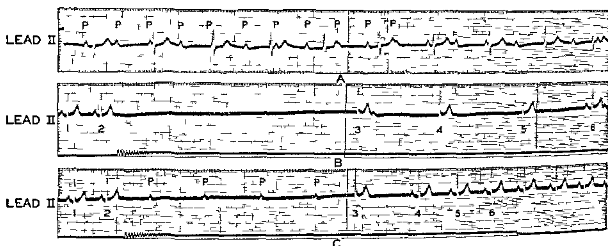

Fig 137 —In A is shown a long strip of Lead II showing complete heart block with idioventricular rhythm, auricular rate 75 and the ventricular rate 43 per minute At times 3 1 or 4 1 heart block may be diagnosed unless a long enough strip is taken for the P waves and QRS complexes to get out of step The R R interval in which the QRS falls may be short B shows in lead II asystole for 6 sec resulting from right carotid sinus pressure ventricular escape finally occurring at 3 with three complexes of idioventricular rhythm and reversion to normal sinus rhythm at 6 while pressure is still maintained The signal at the bottom indicates the application of pressure C shows in Lead II complete heart block with ventricular asystole for 6 sec on the application of pressure to the left carotid sinus The auricular rate (PPP) is 43 per minute There is ventricular escape at 3 followed by return to normal sinus rhythm at 4 while pressure is still maintained The signal indicates onset and release of pressure

restriction of overexertion If heart failure occurs digitalis is used It is unusual for its vagal effects to retard the ventricles further When due to digitalis normal conduction follows its elimination

When Stokes Adams attacks occur frequently 0 5 cc to 1 0 cc (7½ to 15 minims) adrenalin 1 1000 is given hypodermically Its effect lasts one to two hours It increases the irritability of the ventricular pacemaker and of ventricular muscle and may prevent long periods of asystole as well as increase the rate Although it may be useless to give adrenalin during Stokes Adams syncope it is advisable to give it at once nevertheless

Thyroid extract 0 1 Gm (1½ gr) once to three times a day may be tried It is used cautiously not only because it is inadvisable to increase the basal metabolic rate in patients with coronary artery disease but also because fall in basal metabolic rate is one of the compensatory mechanisms in complete block Atropine 0 5 to 1 0 mg (½₀ to ⅟₆₀ gr orally or hypodermically several times daily may decrease vagal block

Bundle branch block or intraventricular block occurs when the excitation wave is impeded in its passage down the right or left branch of the auriculoventricular bundle an abnormality recorded in electrocardio

grams (Figs 138A C and D) Excitation of the ventricle supplied by that branch is delayed and asynchronism of ventricular contraction results The rhythm is unaffected

ETIOLOGY—It occurs most commonly in arteriosclerotic and hypertensive heart diseases and is most common in older individuals It follows myocardial infarction Left bundle branch block is more common than right probably because sclerotic changes are more common in the descending branch of the left coronary artery It occurs occasionally in rheumatic carditis and bolic phenomena (Fiedler's or isolated myocarditis)

MORBID ANATOMY—Myocardial fibrosis involving the bundles has been found when bundle branch block was recorded electrocardiographically It is however frequently impossible to differentiate microscopically the blocked from the unblocked side or from the bundles in hearts not exhibiting this defect In them block may be due to decreased blood supply to the affected bundle Structural changes are not expected if the defect was transient.

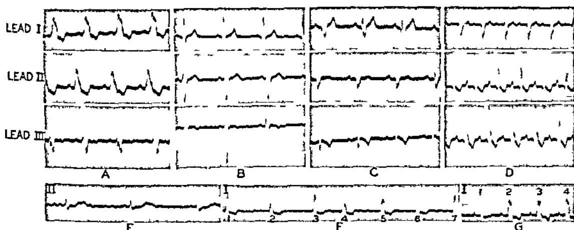

Fig 138—A illustrates three leads of left bundle branch block, concordant type in which the major QRS is upward in Lead I and T waves opposite in direction to the major deflection The QRS interval is 0 17 to 0 18 sec in Lead II B illustrates three leads of left bundle branch block discordant type in which T waves are in the same direction as the major QRS deflection and the QRS interval is 0 14 sec C illustrates three leads of bundle branch block of the wide S wave type (QRS time 0 13 sec) and in D three leads of right bundle branch block of the wide S wave type (QRS time 0 13 sec) and in D three leads of right bundle branch block concordant type T waves in opposite direction to the major QRS deflection (QRS time 0 12 sec) The discordant type in which the T waves are in the same direction as the major QRS deflection is not recorded In E is shown Lead II illustrating bundle branch block (QRS time 0 12 sec) with complete heart block in auricular fibrillation (ventricular rate 34 per minute) (see Fig 136F for bundle branch block with complete heart block in which the sinus node is operative) In F is shown Lead I of auricular fibrillation in which in complexes 1-2-3 the QRS time is 0 09 to 0 10 seconds (normal) followed in 4-5-6 by bundle branch block (QRS 0 11 to 0 12 seconds) and then by normal conduction in 7 In G is shown Lead I normal sinus rhythm with transition from normal QRS (0 08 sec) in 1 to bundle branch block (QRS 0 12 to 0 13 sec.) in complexes 2-3-4

in chronic valvular disease (aortic stenosis and insufficiency) Gumma and diffuse syphilitic involvement as well as diphtheria are less commonly implicated Bundle branch block is occasionally functional in uremia and a fatigue manifestation during tachycardia It may be a toxic effect of quinidine and rarely has been attributed to digitalis It occurs in association with a short P R conduction (Wolfe Parkinson White syndrome) (Fig 139) It is seen in acute myocarditis of obscure origin associated with cardiac enlargement heart failure and em

PATHOLOGIC PHYSIOLOGY—The effect of onset of bundle branch block on cardiac function is not known The lesion occurs most frequently in hearts subject to myocardial damage in which the functional capacity may be already reduced

SYMPTOMS—There are no symptoms attributable to bundle branch block

DIAGNOSIS.—The clinical diagnosis cannot be made with certainty Gallop rhythm a bifid apex thrust and reduplication of one or both heart sounds suggest its presence A bifid apex beat may be exaggerated by a

strip of paper applied as a lever at the point of maximal impulse Pulsus alternans may be present The QRS time exceeds 0 10 seconds usually 0 12 seconds or longer (Fig 138) Occasionally every other beat shows block There may be normal P-R conduction or any degree of auriculoventricular block (Figs 138D and 136F)

Prognosis—Bundle branch block carries a grave prognosis It is more commonly permanent than transient (Fig 138F and G) Prognostic significance appears to derive from electrocardiographic patterns The annual death rate for all types is highest in the first year after discovery being greatest for the *concordant* types (Fig 138A and D) less for the *discordant* types (Fig 138B)

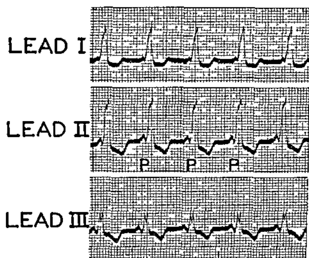

Fig 139—In this figure is shown an example of the short P R (0 07 to 0 08 sec) and the long QRS (0 12 sec) or Wolff Parkinson White syndrome

still less for the *wide S wave* types (Fig 138C) From then on the earliest and greatest mortality is found in those with the concordant types the longest survival and lowest death rate are found in those exhibiting the wide S wave types and intermediate length of survival in those showing the discordant types After the first year the life expectancy curve in the wide S wave type roughly parallels that of the normal population Ten years after discovery more than one third of the wide S wave type patients are still alive but only one sixth of the concordant types and one quarter of the discordant types These statements do not apply to the short P R long QRS syndrome (Fig 139)

Treatment—In most instances specific treatment is not indicated It may disappear in uremia when hypertonic glucose is given intravenously It may disappear with recovery from heart failure

Wolff Parkinson White syndrome is a conduction defect in the electrocardiogram characterized by a *short P R interval and prolonged QRS time* (Fig 139) It is usually an accidental finding in individuals without evidence of organic heart disease A few patients have other congenital defects such as interventricular septal communication Patients are prone to attacks of paroxysmal rhythms most commonly auricular or nodal and less frequently ventricular tachycardia and rarely to auricular flutter and fibrillation One explanation of this syndrome is the presence of a congenital accessory pathway of conduction such as the bundle of Kent bridging the auricles and ventricles The short P R time would be accounted for if this accessory pathway offered a shorter and more rapid route for conduction from auricles to ventricles the long QRS would be explained by asynchronous contraction of the two ventricles one ventricular contraction being initiated by the stimulus which has bridged the gap by the bundle of Kent and the other one contracting a later time by the excitation wave traversing the usual pathway down its bundle Restoration of normal P R and QRS intervals may take place with atropine and exercise suggesting that vagal affects underlie this phenomenon Both digitalis and quinidine have restored normal relationships in others

Prognosis—This defect does not appear to carry a serious prognosis except that it predisposes to paroxysmal rhythms and may be associated with other congenital cardiac defects

Ventricular Rhythms—*Idioventricular Rhythm*—With the onset of complete heart block or auricular standstill the ventricles beat in response to stimuli from the idioventricular center which is located in the auriculoventricular bundle just before its bifurcation It discharges impulses usually at a slow rate around thirty five per minute The QRS complex in the electrocardiogram has a supraventricular form (Figs 136E 137A) unless there is a bundle branch de

fect (Fig 136F and 139F) Rarely when the site of origin is in the ventricular muscle below the bifurcation the complexes resemble ventricular premature contractions Due to the block the impulses do not pass backward to the auricles Idioventricular rhythm differs from auriculoventricular rhythm in which stimuli arising in the auriculoventricular tissue control both auricular and ventricular activity

Ventricular Escape—Occasionally when the sinus discharges are greatly retarded and the auriculoventricular node is also depressed there may be ventricular escape and one or more beats arise from the idioventricular center It occurs in normal individuals and after carotid sinus stimulation The QRS complex is usually of the supraventricular form without a preceding P wave (Figs 125B 137B and C) because of retrograde block it may however be of aberrant form

Ventricular Premature Contractions—If an abnormal stimulus arises in the right or left ventricle a ventricular premature contraction results The impulse spreads over the ventricles and up to the auriculoventricular bundle and node but *usually* not back to the auricles so that the dominant rhythm is uninterrupted occasionally however retrograde conduction to the auricles occurs The normal impulse from the sinus node passing down the auriculoventricular system usually finds the ventricles refractory having just contracted prematurely

ETIOLOGY—Stimuli causing ventricular premature contractions have been elicited in man *mechanically* (1) by tapping over the ventricle which lies directly under the skin and muscle in a defect of the thoracic cage caused by previous removal of ribs and (2) during pericardiectomy They have been induced *electrically* during drainage of the pericardial cavity They occur more commonly in the older individuals Forced respiration breath holding or excitement may incite them They are common in organic heart disease but more frequently no other cardiac signs are detected They occur in acute infections especially acute rheumatic fever acute tonsillitis and pneumonia in arteriosclerotic hypertensive and chronic rheumatic valvular heart diseases and following coronary thrombosis They may result from nervous tension loss of sleep coffee and cigarettes and from overdigitalization when coupled rhythm may appear (p 1142) On the other hand they may be a manifestation of heart failure and may disappear with digitalization They may precede ventricular paroxysmal tachycardia

PATHOLOGIC PHYSIOLOGY—Occasional ventricular premature contractions do not alter the functional capacity of the heart but when they occur frequently and persistently the cardiac output is probably decreased

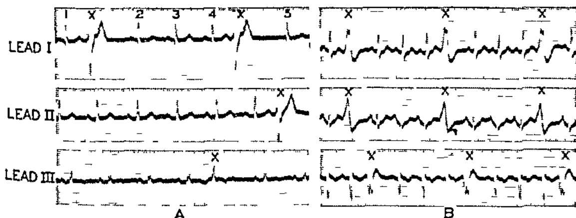

Fig 140—In A are shown three leads illustrating left ventricular premature contractions (X) There is compensatory pause In Lead I the interval 1 to 2 equals twice the regular intervals 2–3 or equals 2 to 4 In B are shown three leads illustrating right ventricular premature contractions (X) after every third normal contraction The pause after the ventricular premature contractions is compensatory If the main QRS deflection is upward in Lead I the premature contraction arises in the right ventricle (B) and if downward, in the left ventricle (A) The form of QRS in Leads II and III is dependent upon the origin of the premature contractions in the apical middle or basal part of the heart

strip of paper applied as a lever at the point of maximal impulse Pulsus alternans may be present The QRS time exceeds 0 10 seconds usually 0 12 seconds or longer (Fig 138) Occasionally every other beat shows block There may be normal P R conduction or any degree of auriculoventricular block (Figs 138D and 136F)

PROGNOSIS—Bundle branch block carries a grave prognosis It is more commonly permanent than transient (Fig 138F and G) Prognostic significance appears to derive from electrocardiographic patterns The annual death rate for all types is highest in the first year after discovery being greatest for the *concordant* types (Fig 138A and D) less for the *discordant* types (Fig 138B)

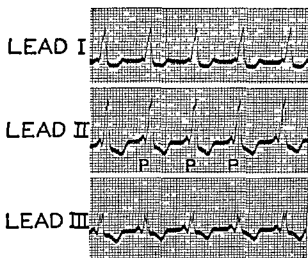

Fig 139—In this figure is shown an example of the short P R (0 07 to 0 08 sec) and the long QRS (0 12 sec) or Wolff Parkinson White syndrome

still less for the *wide S wave* types (Fig 138C) From then on the earliest and greatest mortality is found in those with the concordant types the longest survival and lowest death rate are found in those exhibiting the wide S wave types and intermediate length of survival in those showing the discordant types After the first year the life expectancy curve in the wide S wave type roughly parallels that of the normal population Ten years after discovery more than one third of the wide S wave type patients are still alive but only one sixth of the concordant types and one quarter of the discordant types These statements do not apply to the short P R long QRS syndrome (Fig 139)

TREATMENT—In most instances specific treatment is not indicated It may disappear in uremia when hypertonic glucose is given intravenously It may disappear with recovery from heart failure

Wolff Parkinson White syndrome is a conduction defect in the electrocardiogram characterized by a *short P R interval and prolonged QRS time* (Fig 139) It is usually an accidental finding in individuals without evidence of organic heart disease A few patients have other congenital defects such as interventricular septal communication Patients are prone to attacks of paroxysmal rhythms most commonly auricular or nodal and less frequently ventricular tachycardia and rarely to auricular flutter and fibrillation One explanation of this syndrome is the presence of a congenital accessory pathway of conduction such as the bundle of Kent, bridging the auricles and ventricles The short P R time would be accounted for if this accessory pathway offered a shorter and more rapid route for conduction from auricles to ventricles the long QRS would be explained by asynchronous contraction of the two ventricles one ventricular contraction being initiated by the stimulus which has bridged the gap by the bundle of Kent and the other one contracting a later time by the excitation wave traversing the usual pathway down its bundle Restoration of normal P R and QRS intervals may take place with atropine and exercise suggesting that vagal affects underlie this phenomenon Both digitalis and quinidine have restored normal relationships in others

PROGNOSIS—This defect does not appear to carry a serious prognosis except that it predisposes to paroxysmal rhythms and may be associated with other congenital cardiac defects

Ventricular Rhythms—*Idioventricular Rhythm*—With the onset of complete heart block or auricular standstill the ventricles beat in response to stimuli from the idioventricular center which is located in the auriculoventricular bundle just before its bifurcation It discharges impulses usually at a slow rate around thirty five per minute The QRS complex in the electrocardiogram has a supraventricular form (Figs 136E 137A) unless there is a bundle branch de

10 Gm (15 gr) twice or three times a day is very frequently effective and is the drug of choice. If the premature contractions result from digitalis the drug is stopped for a few days or the ration decreased Except is used over long periods toxic effects must be avoided Potassium phosphate or chloride or papaverine may abolish them (p 1117)

Interpolated Premature Contractions — Premature contractions are interpolated

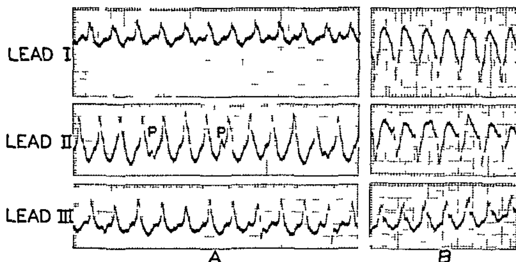

Fig 142 — In A are shown the three leads of ventricular paroxysmal tachycardia from the right ventricle (rate 182 per minute) and B from the left ventricle (rate 200 per minute) The auricles are contracting at their usual slower rate indicated by P in Lead II of A In B the standardization of the string is for 2 cm instead of 1 cm to magnify the waves

when they are a manifestation of congestive failure digitalis is not used because it may increase their number If they are very numerous or multiple digitalis may precipitate ventricular paroxysmal tachycardia or ventricular fibrillation If other measures fail when they occur between two normal heart beats without disturbing the rhythm they are true *extrasystoles* In the electrocardiogram if the premature stimulus occurs near the middle of the R R interval and the ventricles are no longer refractory a premature contraction will occur and recovery will again take place so that when the next normal auricular impulse arrives the conduction tissue is receptive to transmit it

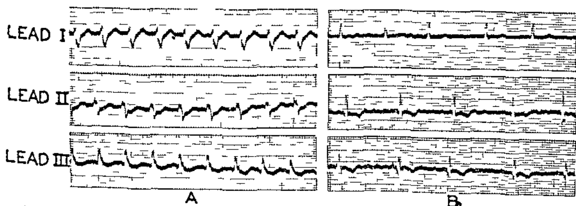

Fig 143 — In A are shown the three standard leads of ventricular paroxysmal tachycardia (rate 125 per minute) from the left ventricle during the paroxysm and in B after reversion to auricular fibrillation (ventricle rate approximately 75 per minute)

quinidine sulfate 0 2 Gm (3 gr) twice or three times a day may abolish them If successful the drug *may frequently* be discontinued without their recurrence If the drug

SYMPTOMS—The symptoms do not differ significantly from those experienced with auricular premature contractions Ventricular ones more commonly give a sense of fulness in the neck due to the auricles and ventricles contracting synchronously When persistent they may be associated with dizziness Dry cough may occur

DIAGNOSIS—Ventricular premature contractions can usually be diagnosed clinically On auscultation the beat is premature the radial pulse may be premature or may show a pulse deficit if the beat occurred so early while the ventricles are in systole Ventricular premature contractions may disappear on exercise The diagnosis is made in the electrocardiogram when the QRS complex which is not preceded by or related to a P wave is wide and split, and the T wave usually opposite in direction to the main QRS deflection Ventricular premature contractions may occur irregularly or after a recurrent pattern Occasionally retrograde conduction occurs and the excitation wave initiates an auricular premature contraction the stimulus of this auricular premature con-

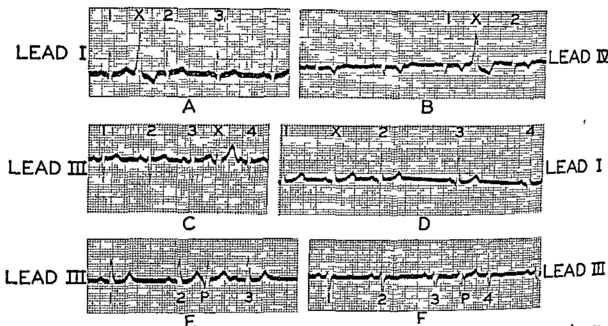

FIG 141—In A and B are Lead I and Lead IV respectively illustrating interpolated right ventricular premature contractions between normal complexes 1 and 2 (X) (see text) In C is shown in Lead I an interpolated auricular premature contraction (X) between normal complexes 3 and 4 and in D in Lead III interpolated auricular premature contraction (X) between normal complexes 1 and 2 QRS complexes of the premature beats are supraventricular in form In E is reproduced Lead III showing an interpolated auriculoventricular premature contraction in which the P wave (P) precedes the QRS between normal beats 2 and 3 and in F Lead III, the P wave (P) of the auriculoventricular premature contraction falls after the QRS between normal beats 3 and 4

that insufficient blood was available to form a radial pulse There is an appreciable pause after the premature beat until the next regular one occurs This *compensatory pause* may be too short however to make differentiation from supraventricular premature contraction certain The interval from the last usual beat to the first one after the premature beat equals two normal cycles (Figs 140A and B) Ventricular premature contractions have a clicking quality There may be a large wave in the jugular vein coinciding with the ventricular premature contractions due to the auricles contracting traction then passes downward through the auriculoventricular tissue and excites the ventricles to contract again this one will be supraventricular in form (short QRS) (Fig 149C)

PROGNOSIS depends upon the circumstances under which the premature contractions occur and upon other evidences of heart disease

TREATMENT—When treatment is required the general principles are the same as for auricular premature contractions elimination of possible factors and use of triple bromide or luminal Triple bromide

with marked decrease in the cardiac output per minute and the stroke volume falls as low as 18 cc There is prolongation of the arm to tongue circulation time without increase in venous pressure unless heart failure supervenes The heart dilates and the blood pressure falls

Symptoms — The patient experiences symptoms similar to those of auricular paroxysmal tachycardia Occurring more commonly as a complication of heart disease however patients appear more ill

Diagnosis — Ventricular paroxysmal tachycardia is to be differentiated especially from auricular and nodal paroxysmal tachycardia The rate is commonly 150–180 slightly slower than the supraventricular forms The rhythm is slightly irregular as compared with auricular tachycardia The heart sounds may change due to the shifting relationship of the ventricular and auricular contractions Frequently a waves can be identified in the jugular vessels and are especially large when the auricles and ventricles contract simultaneously Carotid sinus pressure is ineffectual in most cases Electrocardiograms usually make certain the diagnosis The complexes have the form of ventricular premature contractions and may arise from either ventricle (Fig 142A and B) or may be alternating (Fig 144A) or the QRS complexes may vary If the preceding rhythm was normal the auricles continue to beat slowly and independent P waves appear (Fig 143A and B) The ventricular excitation waves are usually blocked from passing backward Occasionally however *retrograde* conduction to the auricles causes them to contract the sinus node being superseded If auricular paroxysmal tachycardia and bundle branch block occur together the complexes will be similar to ventricular premature contractions The detection of P waves may establish the rhythm as auricular or the occurrence of ventricular premature contractions in other records of the patient may aid in differentiation

Prognosis — Ventricular paroxysmal tachycardia is an alarming hazard when it occurs in the course of myocardial infarction Impairment in the coronary circulation associated with marked decrease in cardiac output and fall in blood pressure is shown in the T wave changes which may persist for days after reversion to normal rhythm Heart failure may be precipitated

Treatment — The patient should be in bed If the paroxysm is brief treatment is not required More commonly it persists unless measures are taken to control it most circumstances under which it occurs require its prompt abolition Quinidine is usually effective 0.2 Gm (3 gr) is given two hours later if there have been no evidences of idiosyncrasy (see auricular fibrillation) and normal rhythm has not been restored 0 4 Gm (6 gr) is given and repeated every four hours 3 0 to 4 0 Gm (45 to 60 gr) may be required in twenty four hours before reversion occurs If it is not urgent 2 0 Gm (30 gr) may be given the first day 3 0 Gm (45 gr) the next but if coronary occlusion is present restoration should be achieved promptly with the larger amounts When possible electrocardiograms should be taken Massive doses of quinidine may occasion ventricular fibrillation After restoration of normal rhythm 0 2 Gm (3 gr) twice or three times a day are given for a few days With therapy the ventricular rate declines followed by reversion to normal rhythm or auricular fibrillation It is only rarely necessary to give quinidine hydrochloride in 0 2 to 0 3 Gm (3 to 5 gr) amounts *intravenously* It does not appear warranted to give quinidine routinely after coronary occlusion to prevent this rhythm For recurrent attacks quinidine sulfate 0 2 Gm (3 gr) twice or three times a day is usually effective and patients should be instructed about its use Digitalis is usually contraindicated because it increases ventricular irritability and may precipitate ventricular fibrillation If the rhythm is not susceptible to quinidine and heart failure ensues it may however be required

Ventricular Fibrillation — In this rhythm the coordinated contraction of the ventricles is replaced by rapid irregular twitches of the ventricular muscle Its persistence is incompatible with life because the twitchings are ineffectual in expelling blood The mechanism may be a circus motion in the ventricles Brief paroxysms are not fatal Ventricular fibrillation is a cause of sudden death especially in patients with coronary artery disease It has been observed in the electrocardiograms of dying patients and of

and the ventricles are capable of responding again. Auscultation reveals three rapid beats, the middle one being the *extrasystole*. Interpolated premature contractions may arise from the auricles (Fig 141C and D), auriculoventricular tissue (Fig 141E and F), or from the ventricles (Fig 141A).

Ventricular paroxysmal tachycardia is a fairly regular rhythm with a rapid rate caused by stimuli originating from an ir

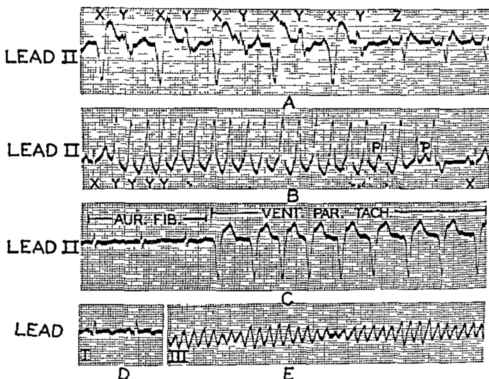

Fig 144—In A is shown in Lead II a run of ventricular paroxysmal tachycardia (134 per minute) with alternation of origin of the beats XXX and YYY followed by reversion to normal sinus rhythm at Z. In B is shown in Lead II one normal complex (X) *followed by a run of ventricular paroxysmal tachycardia* YYY (rate 250 per minute the sequences are slightly irregular) with reversion to normal sinus rhythm at the end of the strip (X). The P waves of auricular contraction can be seen at intervals. In C in Lead II are three ventricular complexes during auricular fibrillation (ventricular rate 80 per minute) with onset of ventricular paroxysmal *tachycardia in which the ventricular sequences are irregular (rate approximately 120 per minute)*. In D is shown Lead I of electrocardiogram of a patient showing normal rhythm which had changed to ventricular fibrillation (E) a few minutes later when Lead III was being taken. The ventricular complexes are somewhat irregular and of bizarre and changing form.

ritable focus in one of the ventricles characterized by sudden onset and sudden offset. It may be considered a succession of premature contractions. If the preceding rhythm was normal the sinus impulses continue and the auricles contract at their usual rate (Fig 142A and B). Auricular fibrillation may however be present (Fig 143A and B). Ventricular paroxysmal tachycardia may result from a circus motion in the ventricles. The ventricular rate is commonly 150–200, *rarely greater than* 220. It may persist for a few beats (Fig 144B and C), several minutes, hours or many days and be resistant to treatment.

Etiology.—Ventricular paroxysmal tachycardia occurs more commonly in organic heart disease than the auricular type but it is found occasionally in normal subjects. Ventricular premature contractions may precede its onset. It is most common in the later decades when arteriosclerotic and hypertensive heart diseases occur. It may follow coronary occlusion and at other times has been thought to lead to myocardial infarction due to the fall in blood pressure or decrease in coronary circulation. It occurs in acute rheumatic fever, in subjects with Wolff Parkinson White syndrome and transiently during pericardiectomy. It may be a manifestation of digitalis toxicity.

Pathologic Physiology.—It is associated

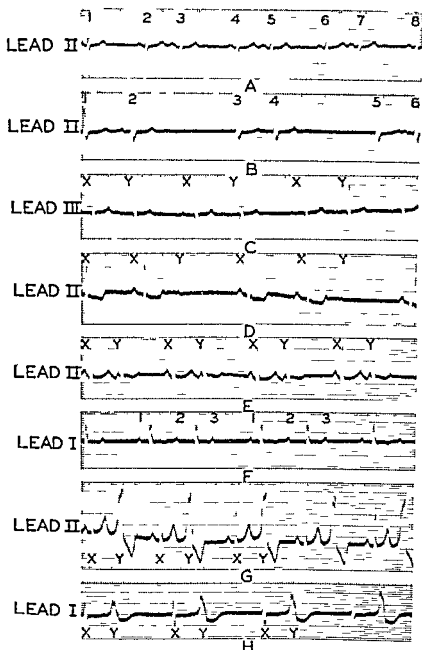

Fig 146—In A is shown in Lead II coupled rhythm due to recurrent sino-auricular block Intervals 1 to 2 3 to 4 5 to 6 and 7 to 8 show sino-auricular block The regular sequence is 2 to 3 4 to 5 and 6 to 7 which was present in Lead I with only an occasional sino-auricular block In B is shown in Lead II coupled rhythm due to normal sinus rhythm with recurrent sino-auricular block and ventricular escape Complexes 2 4 6 are normal rhythm and 1 3 5 are ventricular escape Intervals 2 to 3 4 to 5 are sino-auricular block In C is shown Lead III of coupled rhythm due to recurrent auricular premature contractions X=normal rhythm complex Y=auricular premature contractions In D is shown in Lead II coupled rhythm due to recurrent auricular premature contractions which are blocked X=normal beat Y=auricular premature contractions blocked the form of these P waves is different from the normal P waves In E is shown Lead II of coupled rhythm due to recurrent auriculoventricular premature contractions the P waves in front of the QRS X=normal beats Y=auriculoventricular premature contractions In F is shown in Lead I coupled rhythm due to incomplete heart block in which every third (3) P wave is blocked P waves are indicated as 1 2 3 In G is shown Lead II of basic normal rhythm with coupling due to recurrent ventricular premature contractions X=normal beats Y=ventricular premature contraction In H is shown Lead I of auricular fibrillation with coupled rhythm due to recurrent ventricular premature contractions X=normal beats Y=ventricular premature contractions

subjects during electrocution It may follow ventricular paroxysmal tachycardia and massive doses of quinidine and digitalis Paroxysms which have been diagnosed were accompanied by Stokes Adams like attacks and were characterized by the absence of pulse and of heart sounds Quinidine may prevent attacks even though massive doses may induce them In the electrocardiogram wide *QRS* complexes occur irregularly with bizarre and changing form (Fig 144D and E)

Pulsus Alternans—When the volume of the radial pulse alternates between a large and a small one and the sequence is regular *pulsus alternans* is present It may result because all of the muscle fibers of the heart do not contract with equal force at each systole This may be due to prolongation of the refractory period of some fibers Those beats in which only part of the muscle fibers take part are associated with a small stroke volume and a small pulse Pulsus alternans is found occasionally in luetic heart disease but most commonly in the older age groups in which the arteriosclerotic and hypertensive forms and coronary occlusion predominate It occurs in early and marked heart failure There are no symptoms attributable to pulsus alternans

Diagnosis is made by detection of alternation in volume of the radial pulse on palpitation which is easily observed while taking the blood pressure *Alternation* may also appear in the electrocardiogram tall QRS complexes coinciding with the larger radial pulse and lower ones with the smaller radial pulse (*Fig 145A and B*), *or the* reverse Pulsus alternans should not be confused with coupled rhythm

Treatment is directed to the underlying condition It may disappear when digitalis is given It carries a grave *prognosis* patients surviving only a few years after its discovery It may be transient but if it persists or recurs death may occur in a few months Both pulsus alternans and *electrical alternans* may occur transiently in paroxysmal tachycardia or auricular flutter in which there is not the same grave prognosis

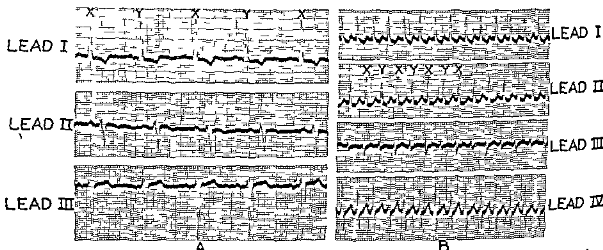

Fig 145—In A are reproduced three leads of an electrocardiogram showing normal rhythm illustrating electrical alternans The QRS complexes marked X are taller than the alternate ones marked Y In B are shown four leads of an electrocardiogram illustrating electrical alternans occurring in auriculoventricular paroxysmal tachycardia (rate 214 per minute) The tall QRS complexes (X) alternate with the lower ones (Y)

Coupled Rhythm—Coupled rhythm refers to recurrent grouping of the heart beats in pairs followed by a pause The radial pulse may also show coupling Coupled rhythm at the apex is most commonly caused by (1) ventricular premature contractions with the long compensatory pause regularly following each normal systole (Fig 146C and H) The radial pulse may be coupled also if the ventricular contractions occur late enough for sufficient ventricular filling if the radial pulse is lacking its rate is half the apical The diagnosis of coupled rhythm due to ventricular premature contractions can usually be made clinically especially if the patient is taking digitalis and auricular fibrillation is present (Fig 146H) Coupled rhythm at the apex and in the radial pulse may also be due to regularly recurring (2) auricular premature con

ing between 2 1 and 3 1 or 4 1 It may also be due to (7) incomplete heart block when every third auricular stimulus is blocked (Fig 146F) One notion of regularly recurring premature contractions is that of the *parasystole* an ectopic pacemaker is constantly and regularly initiating stimuli in much the same fashion as the sinus or auriculoventricular node when the refractory state of the muscle is appropriate and does not interfere the impulse from this new focus gives rise to premature contractions which may be after every normal beat or according to any other fixed pattern (Figs 146C E G 147A B C)

Common causes of *trigeminal* rhythm are (1) premature contractions after every second normal beat the long pause after the premature contraction making the two normal beats and the premature contraction fall together in a group of three (Fig 147A and C) (2) interpolated premature contractions (Fig 141) and (3) regularly recurring incomplete heart block every fourth auricular contraction being blocked

Ventricular Preponderance —From electrocardiograms inference may be drawn about ventricular muscle mass In the most common normal electrocardiogram the major QRS deflections are upright in all three leads and the amplitude of QRS_2 is greater than QRS_1 or QRS_3 (Fig 148A) When the major QRS deflection is upward in Lead I and downward in Lead III *left axis deviation or left ventricular preponderance* is present (Fig 148B), when the major QRS deflection is downward in I and upward in III *right axis deviation* or *right ventricular preponderance* is present (Fig 148C) There are gradations between these three types A calculated electrical axis between +90 and 0 is the normal zone which is designated as the normal axis deviation when the electrical axis is greater than +90 right axis deviation is present and if it is negative left axis deviation is present The position of the heart in the chest alters the axis deviation. Transverse position of the heart as seen in pyknic body types high diaphragm obesity pregnancy ascites increased intra abdominal pressure favor left axis deviation dropped heart as seen in the linear body types favors a tendency to right axis deviation as does displacement of the heart by fluid or air in the chest Left axis deviation may be associated with predominant hypertrophy of the left ventricle such as occurs in hypertension aortic stenosis aortic insufficiency and mitral insufficiency Right axis deviation is associated with preponderant enlargement of the right ventricle It is usual in the first few weeks of life It is associated with mitral stenosis pulmonic valve stenosis (congenital) and pulmonary lesions which place a strain on the right heart namely pulmonary fibrosis sclerosis of the pulmonary arteries diffuse pulmonary thrombosis emphysema and asthma

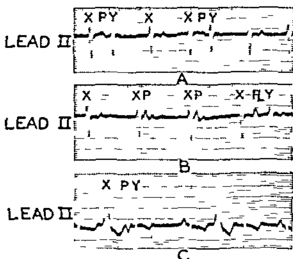

Fig 149—In A is shown auriculoventricular rhythm P waves probably in QRS (X) The excitation wave passes to the auricle by retrograde conduction and initiates an auricular excitation wave (P) which is in turn followed by ventricular contraction (Y) All the complexes have a supraventricular form This pattern is repeated In B is shown another example of nodal rhythm with P waves (P) falling after the QRS At PL the excitation initiates by retrograde conduction an auricular excitation wave (premature contraction) which is followed by QRS (Y) In C is shown Lead II of an electrocardiogram in which the ventricular premature contraction at X gives rise by retrograde conduction to an auricular premature contraction (P) which is in turn followed by ventricular response which is supraventricular in form (Y)

Auricular Hypertrophy —Saw toothed or split P waves which may be tall or low and broad may indicate auricular hypertrophy and may result from mitral stenosis (Fig 148C)

In congenital *dextrocardia* the electrocardiogram has the following characteristics Lead I appears to be upside down and

tractions (Fig 146C) after every normal beat (3) blocked auricular premature contractions after every second beat (Fig 146D) (4) auriculoventricular premature contractions after every normal beat (Fig 146E) (5) sino auricular block every third sinus impulse being blocked (Fig 146A) and (6) block in auricular flutter alternat

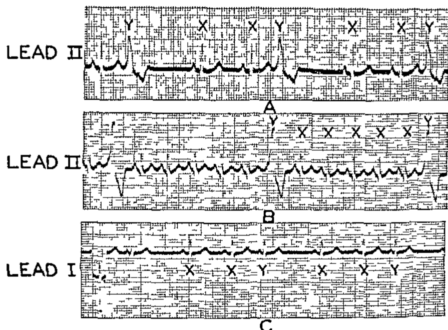

Fig 147—In A is shown Lead II illustrating trigeminy due to ventricular premature contractions (Y) after every two normal beats (X) the compensatory pause after the ventricular premature contractions making the three beats fall in a group In B is shown in Lead II ventricular premature contractions (Y) recurring after every fifth normal beat (X) In C is shown trigeminy due to auriculoventricular premature contractions (Y) occurring after every second normal beat (X) The short P R (0 08 seconds) identifies the auriculoventricular premature contractions

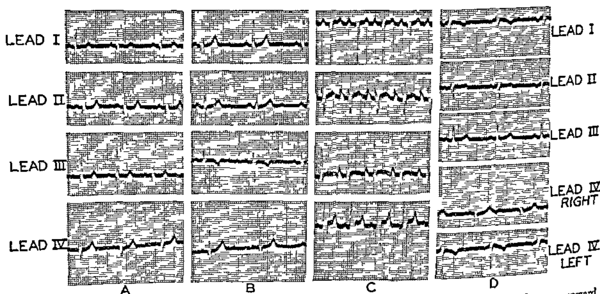

Fig 148—In A are shown four leads of normal or no axis deviation with the major QRS deflections upward in all three leads According to the Einthoven equilateral triangle amplitude of QRS = amplitude of QRS_1 plus amplitude of QRS_3 In B are shown four leads of left axis deviation QRS up in Lead I and down in Lead III In C are shown four leads of right axis deviation with QRS downward in Lead I and up in Lead III In D is shown electrocardiogram derived from congenital dextrocardia Chest Lead IV right, was taken from the right side at the P M I and Lead IV left was taken from the left side where the P M I would have been if the heart had been in the normal location it has the contour of Lead I

Leads II and III are interchanged and compared with the electrocardiogram from a normally placed heart (Fig 148D)

CONGESTIVE HEART FAILURE

(*Myocardial Insufficiency Cardiac Decompensation*)

The association of weakness breathlessness cough abdominal discomfort swelling in the dependent portions of the body and palpitation or precordial distress together with other and less striking or less frequent phenomena makes up the syndrome called 'congestive heart failure' Congestive heart failure is a sequel of preexisting heart disease which may result from acute rheumatic fever chronic rheumatic heart disease hypertension arteriosclerosis coronary occlusion hyperthyroidism and other less important etiologic factors While heart failure may result from a wide variety of organic diseases of the heart it may also follow some of the functional disorders such as prolonged tachycardia and auricular flutter The nature of the organic lesion sometimes influences the frequency of the appearance of one or another of these common manifestations as will be indicated in their further discussion It is important to remember however that whatever may be the underlying organic disease (or functional disorder) this train of symptoms is due to failure of the heart to maintain the normal and adequate flow of blood to the various organs and tissues The pathogenesis of the phenomena of congestive failure is presented in the section on symptomatic Manifestations of Circulatory Failure (p 1019) but it should be emphasized that venous stasis and diminished blood flow resulting in tissue and organ anoxia at present appear to be the factors of paramount significance

Clinical Manifestations —*Shortness of breath* or *dyspnea* of some degree is the

nounced moderate or slight but are usually present Less frequently there may be palpitation, heaviness in the chest, or a sense of dull ache in the precordium

Pleural effusion is common and adds to the respiratory embarrassment by mechanical interference with pulmonary ventilation It is somewhat more frequent on the right side than on the left Not uncommonly it is bilateral The usual physical signs of fluid will be found including diminished expansion of the chest, impaired resonance, dulness, or flatness on percussion present first and always most markedly at the bases and rising often to or above the scapular angle Voice and breath sounds are impaired or absent together with impaired or absent tactile fremitus If the fluid compresses the lung there may be a zone of bronchial voice and breath sounds at its upper level and the transmitted voice may be bleating Withdrawal of fluid by needle establishes the correct diagnosis as does x ray examination by film or fluoroscope

Dependent edema results from venous stasis in the systemic circuit as contrasted to the pulmonary The slowed rate of blood flow, the increased venous pressure and often an augmented blood volume combine to promote the passage of fluid from the blood stream into the surrounding tissues There is a tendency toward retention of sodium in the tissues which contributes to retention of fluid These changes are secondary to the impairment of the circulation but may begin a vicious cycle which must be prevented or broken by therapy This edema at first may be insensible and suspected by otherwise unexplained gain in weight Puffiness of feet or ankles toward the day s end is usually the first evidence noted by the patient Since in its earlier stages cardiac edema is gravitational in distribution such ankle edema usually disappears during sleep As the amount of fluid in the tissues increases cardiac edema is found at all times in dependent tissues merely shifting in extent in response to body position

Anasarca is merely an advanced stage of edema in which the extravascular accumulation of fluid is found over most or all of the body Accompanying anasarca there is usually pleural effusion and *ascites* or free fluid in the peritoneal cavity Both pleural and peritoneal accumulations may appear before any pronounced generalized edema however and the latter may be well marked before pleural effusion or ascites has become manifest There may be some pericardial effusion but this is rarely discoverable and is not important Occasionally when right heart failure develops early, as in cases with rheumatic lesions of the tricuspid valve an asarca may appear earlier and persist for months or even years

Urinary disturbances are frequent especially a reduced daily output called *oliguria* The urine is usually concentrated specific gravity being above 1 020 and frequently contains albumen and casts of various types There is often an increase in the urates present Patients with such changes are sometimes incorrectly called 'cardiorenal cases because the urinary phenomena are generally secondary to renal functional deficiency resulting from the congestion and venous stasis These changes are reversible under therapy with digitalis and diuretics Where congestive failure results from prolonged hypertension and arteriosclerosis the vascular changes may result in nephrosclerosis In both types the blood may show some increase in the nitrogenous metabolites particularly the urea and nonprotein nitrogen (N P N) The amounts retained in uncomplicated congestive failure are usually small while they are often quite large in the presence of organic disease of the kidneys In the presence of nephrosclerosis the urine is likely to be of low and relatively fixed specific gravity as well as of large daily volume until congestive failure supervenes These are irreversible phenomena

The liver is enlarged and congested in both right sided and generalized heart failure There may be a sensation of weight or fulness in the upper abdomen and if the enlargement has developed rapidly also of pain and tenderness When *tricuspid* insufficiency functional or organic is present expansile pulsation is usually to be found Tenderness and pain occur with rapid stretching of the capsule and are absent in chronic hepatic congestion Jaundice is fairly common but usually is only slight to moderate in degree It is generally found only in the later stages and makes the outlook unfavorable

Digestive symptoms may be among the earliest complaints and at first may be the only ones They are usually vague including complaints of dyspepsia bloating fulness belching and the presence of flatus When combined with some of the foregoing such as epigastric or hypochondriac pain and tenderness they may lead to erroneous diagnosis of disease of the digestive tract liver or gallbladder

Complaints of palpitation of aching or fulness in the precordial area or of pounding in the heart chest or neck may be the only symptoms which the patient refers directly to his heart There may be a history of earlier angina pectoris or of acute myocardial infarction but symptoms of these are rarely present once congestive failure has developed The patient with auricular fibrillation may be unaware of the irregularity whereas persons often are conscious of premature systoles

Clinical Course —The course of congestive failure is variable Acute edema of the lungs may cause death in a few hours The symptoms may develop rapidly especially when induced by an intercurrent infection or by multiple pulmonary thromboses which occur relatively often in patients with mitral stenosis and terminate fatally after a few days or weeks Commonly the patient passes through successive attacks of failure often of increasing severity and duration and separated by shortening intervals of freedom from symptoms The later attacks are likely to be less and less readily controlled by treatment until the latter becomes unavailing and the patient succumbs Some patients pass through several attacks without apparent diminution of response to therapy and then begin to manifest signs of exhaustion often with cachexia and rather quickly enter a period of rapid decline to death A lobular pneumonia often terminates the course of the illness Embolism to the brain or lungs or mesenteric thrombosis may be the terminal event Some younger patients with inactive rheumatic heart disease may survive for years during which there may have been several early episodes of failure at long intervals before a progressive downhill course develops Patients with aortic lesions may die suddenly without having suffered congestive failure

Many efforts have been made to devise a satisfactory test of the functional efficiency of the heart but without great success largely because of the several extracardiac factors which may influence the results A few restricted tests deserve brief mention as of value The *vital capacity of the lungs* is reduced by the stasis and congestion resulting from failure of the left ventricle or from stenosis of the mitral valve The test is made easily with the aid of an accurate spirometer The maximal volume of air which the patient can expire in a single exhalation is expressed in relation to the surface area of the patient s body The average normal figures in liters per square meter are for men 2 61 L×M for women 2 07 L×M² The range of normal variation does not exceed 15 per cent

Venous pressure increases in congestive failure and diminishes with its relief Its determination is simple and the results may be helpful in diagnosis and in following the course of the patient s illness. Venous pressure can be estimated fairly accurately by elevation of the patient s head and torso to the level at which the external jugular vein (preferably the right) just collapses Its height above the right auricle is the level of the venous pressure This is normally between 7 and 10 cm An alternative method is the determination of the height above the auricle to which the hand must be raised to cause collapse of its distended veins Both are crude methods but give results which are helpful in routine bedside work Actual measurement may be made by a simple water manometer connected to a pelotte The height of the column required to collapse a distended vein on the back of the hand is measured with the patient s hand supported at the level of the right auricle Finally the most accurate method is that of Moritz and von Tabora This comprises the measurement of the height to which a column of saline or the blood will rise in a manometer connected with a large needle inserted into one of the antecubital veins In severe cases of failure this is often twice normal or 15–20 cm and may even exceed treble the average

The *circulation time or the velocity of blood flow* is conveniently determined by the rapid intravenous injection of some harm

less agent, the arrival of which can be detected at some predetermined point in the body Perhaps the most precise method is that of Blumgart and associates who injected Radium C into an arm vein and measured accurately the time of arrival at each of several points in the body by means of a special detector apparatus While of great value to the research student this technic is too complex for ordinary clinical use Blumgart found that arm to heart time averages 7 seconds, arm to arm time 18 seconds and pulmonary circulation time is 11 seconds in normal humans The use of other substances gives results sufficiently accurate for ordinary purposes and the technic is simple Intravenous injection of 0 6 cc of equal parts of ether and normal saline gives an arm to lung time of 4 to 8 seconds as determined by the patient s detection of ether in the expired air The observer may also detect it on the patient s breath The arm to tongue time may be measured by the development of a bitter taste following injection of 5 cc of 20 per cent solution of decholin or a sweet taste following use of saccharin With either the normal range of times is 10 to 16 seconds In congestive failure these times are prolonged while they return toward normal during recovery Other methods have been devised by Fishberg and others It should be noted that somewhat different values are given by the various methods

The *cardiac output* or *systolic output* of the heart or *minute volume* is best measured by the acetylene method of Grollman Researches with its use have added much to our understanding of the pathologic physiology of congestive failure but it is not applicable to routine clinical use because of its relative complexity The *total circulating blood volume* may be determined approximately in man by the injection and subsequent measurement of a suitable dye While the volume of the blood usually increases in congestive failure and diminishes with its control the method cannot be regarded as clinically useful because of the many factors which enter into the variations in blood volume

Each of the foregoing tests gives information concerning one or another of the circulatory phenomena associated with heart failure None provides complete information for which it is necessary to combine the data of several tests For clinical purposes they are seldom required but the physician should be familiar with the many fundamental facts learned from their use and be prepared to employ any which might be helpful in a given instance

Treatment —This rests on three major requirements lessening the burden upon the heart, increasing the efficiency of the heart and the removal of edema Three classes of drugs are of fundamental value opiates the digitalis bodies, and diuretics especially the mercurial diuretics The treatment of congestive failure is not materially influenced by the type of heart disease which has produced the failure, hence can be discussed most conveniently as an entity special variations being mentioned where necessary

Physical and mental *rest* must be imposed their degree and duration depending upon the severity and acuteness of the failure Most patients require a period of confinement to bed but some may remain ambulant if the failure is mild Because of orthopnea the patient will usually require a semi sitting position for which purpose a Gatch type of bed spring is very satisfactory Very orthopneic patients are at times better off if allowed to sleep in an easy chair with good supporting arms The patient s position should be that in which he is most comfortable The use of oxygen by means of tent face mask or nasal catheter will often relieve the patient of much distress and ease some of the burden on the heart

The *diet* should be simple readily digestible and one which does not cause gaseous distension Salt should be reduced to about 2 Gm daily in the presence of edema and spicy foods and condiments are best omitted Also when there is edema, the total fluid intake per twenty four hours should be limited to between 1 and 1.5 liters In severe edema or in anasarca the Karell diet either in its original form or somewhat modified may prove valuable The strict Karell diet consists of 200 cc of milk four times a day However aside from these possible features the matter of diet is relatively unimportant and all that is usually requisite is that the

diet be well balanced and not too abundant

Simple *laxatives are often required to prevent the patient's having to strain at stool* These include mineral oil cascara milk of magnesia and so on at times in combination *The use of a glycerin suppository or* small enema may be helpful While the bed pan is commonly employed its use by some patients is so difficult and exhausting that a *commode at the bedside is preferable* Generally a bed urinal should be required and this also permits the measuring of fluid elimination The room should be light airy *well ventilated and cheerful Visitors may* readily tire a sick person and therefore must often be restricted both in number and length of stay No visitor who upsets or *fatigues the patient should be allowed Too* often these matters are overlooked by the physician

Sedatives or *hypnotics* may be of really *great help When cough dyspnea or orthopnea* is troublesome an opiate is the most effective Doses of codeine ranging from 15 to 60 mg (gr ¼–1) may suffice but more often morphine will be required The dose lies between 10 and 20 mg (gr ⅙–⅓) and is better given hypodermically Pantopon dilaudid or other substitute may be ordered if preferred. As soon as possible the opiates should be replaced by the simple hypnotics used as required either to produce sleep or to keep the patient calm quiet and free from anxiety Those of particular value include Phenobarbital 0 015–0 1 Gm (gr ¼–1½) giving the small doses several times per day and the larger about half an hour before time for sleep Other barbiturates may be substituted in corresponding doses Chloral hydrate is often useful especially in the hypertensive patient. A dose of about 0 2–0 5 Gm (gr 3–8) usually suffices if repeated from two to four times daily Treble the larger dose may be used at bedtime to promote sleep This may be combined with the same amount of bromide Despite its disagreeable physical properties paraldehyde 4–16 cc (1 drachm–½ ounce) is a splendid hypnotic which acts promptly and does not depress the respiration or circulation It can be *administered* by mouth as the elixir (25 per cent paraldehyde) or in whiskey or on shaved ice The rectal dose is the same as the oral It may be given as an oil enema or suspended in 120–200 cc of *warm tap water and is absorbed rapidly*

Digitalis and Allied Drugs—It is essential for the physician to have accurate knowledge of these all important drugs and make *himself expert in their use All digitalis glu*cosides act directly on the heart muscle to increase the force of its contraction It has also been shown that digitalis, by direct ac*tion on heart muscle increases the efficiency* of its work that is it makes the heart work more economically Thus the digitalized muscle converts a larger amount of its *energy into external work than the undig*italized or can perform a fixed unit of work with less expenditure of energy Except for its action in some types of tachycardia and *its influence on certain abnormal rhythms* the sole indication for the use of digitalis is to control myocardial failure with signs of congestion in the pulmonary circuit (left *ventricular failure) in the systemic circuit* (right ventricular failure) or when both types are present (the common combined form of failure) The clinical phenomena *seen in the therapeutic use of digitalis de*pend upon these primary direct actions Even the slowing of the ventricular rate usually occurring in auricular fibrillation is largely the result of a direct action of the drug upon the heart and cannot be prevented or abolished by large doses of atropine which do abolish the retardation resulting from vagal stimulation The vagal action usually results from smaller doses the extravagal from larger ones bordering closely upon those which are toxic One must be familiar therefore with the common phenomena of *digitalis toxicity* These include colored vision headache nausea vomiting or diarrhea the three last being largely reflex from the heart disorders of heart mechanism such as ectopic beats auriculoventricular block and so on and changes in the electrocardiogram such as depression of the S T segment and lowering or inversion of the T waves

In the presence of congestive failure there are no contraindications to the use of digitalis It may be used safely in the presence of premature beats partial heart block hypertension and even after a recent myocardial infarction

Administration—Digitalis is best given orally in fact other modes of administration are needed only under exceptional circumstances The two preparations among the many available, which are most satisfactory for oral use are the powdered leaf and crystalline digitoxin (Digitaline Nativelle) The currently official *Pharmacopoeia* (U S P XII) requires assay of digitalis on the cat instead of the frog as the latter failed to reveal the true potency of different samples or of different galenical preparations (tinctures) when given to man U S P XI tinctures supposedly of equal potency were actually found to vary 300 per cent in strength The new U S P XII digitalis is also reduced in strength by almost a third as compared with that of U S P XI Several plans of dosage have been found satisfactory based on the average adult requirement of 1 5 to 2 0 Gm (gr 22–30) of the powdered leaf for digitalization The rapidity of digitalization should be guided by the patient s urgency of need but there is little therapeutic justification for requiring more than three to five days In nonurgent cases 0 2 Gm (gr 3) may be given three times a day for two days and then twice daily for two days after which a daily dose of 0 1–0 2 Gm (gr 1½–3) may be continued Adequate digitalization may be secured more rapidly by a descending scale of doses such as two or three doses of 0 4 Gm (gr 6) for one day and one or two on the second day followed by doses of 0 1–0 2 Gm daily Some highly skilled physicians find it wisest to administer a total of 1 5 Gm (gr 22) in divided doses within the first eighteen to twenty four hours following up with 0 1–0 2 Gm daily to maintain digitalization None of these plans is likely to cause toxic effects except rarely in susceptible persons It is wise for the physician to select the product of one manufacturer and become thoroughly expert in its use Larger single initial doses even up to the entire amount of 1.5 Gm have been given safely but they cause gastro intestinal symptoms in nearly half the patients by local irritant action The ventricular rate of patients with auricular fibrillation should be slowed to 70–90 per minute by digitalis If exercise then raises the heart rate markedly the slowing can be assumed to be vagal and additional digitalis will be needed to induce the *extravagal slowing* by which greater protection is given the heart. The use of such extra doses may induce *minor* toxic symptoms for which the physician must be on the watch Often the best therapeutic results are to be had only at this borderline level of high dosage and one must run the attendant small risks of minor intoxication Most patients who have developed congestive failure, and particularly those having auricular fibrillation will require the continued use of digitalis to maintain compensation and prevent recurrence The dose of digitalis leaf for this purpose usually lies between 0 1 Gm and 0 3 Gm per day For digitoxin it is about 0 1 mg to 0 2 mg The dose must be adjusted carefully to the needs of the particular patient but rarely falls outside the range stated Maintenance doses should be given only once daily to relieve the patient of annoyance Both digitalis leaf and digitoxin are eliminated so slowly that a uniform degree of action is well maintained by the daily ration A variety of other preparations is available for oral use but none has proved superior to these two and few are equal to them Fluid preparations are seldom required and are intensely bitter, hence often objectionable to the patient

Only about a third of the active constituents of the leaf is absorbed following its oral use Digitoxin, on the other hand is completely absorbed so that its *dose is the* same by mouth as intravenously The total dose of digitoxin by either route is 1 25 mg (gr 1/50) When there is really urgent need this amount can be given at once for the initial dose but it is wiser to divide it into fractions such as two of 0.5 mg and one of 0 25 mg given at intervals of six hours The maintenance dose is 0 1–0 2 mg (gr 1/650–1/325) During the period when larger single doses are being given the physician should observe the effects frequently enough to avoid the production of toxic symptoms by digitalis modifying or omitting further increments according to need

Rectal administration may be advisable when the drug cannot be retained because of frequent vomiting due to splanchnic congestion or because of unconsciousness The powdered leaf may be incorporated into a

suppository or one of the liquid preparations such as the tincture or injectio digitalis (U.S.P XII) may be given with a small amount of warm water as a retention enema Before either is used a small cleansing enema is desirable The dose for rectal use is the same as for oral When the nausea and vomiting have been due to congestive failure they usually will be controlled by one or two large rectal doses of digitalis so that oral administration becomes possible.

Parenteral administration is required rarely usually only by patients who are in extremis. Intravenous injection is the method of choice especially since many of the water soluble glucosides are poorly absorbed from the subcutaneous tissues and are highly irritant Ouabain appears to be the most satisfactory but others may be used if desired Intravenous digitalization must not be undertaken in a patient who has recently received digitalis in any other manner[7] The total therapeutic dose of ouabain is 1 0 mg (gr 1/60) which is best injected in fractions of 0.25 mg (gr 1/260) at intervals of one or two hours or longer The initial dose may be 0.5 mg (gr 1/130) in extreme need As ouabain is eliminated in about twenty four hours oral administration of digitalis should be started as early as possible to maintain action.

Diuretics —Digitalis causes diuresis by improving general blood flow as well as that through the kidneys This often is inadequate to eliminate edema except when it is of milder degree and diuretics must be used

One of the *xanthines* may be administered by mouth Theophylline is the most effective but is prone to cause nausea and vomiting It may be given three or four times daily in doses of 0 2–0.3 Gm (gr 3–5) for two or three consecutive days to be followed by a similar rest period without the drug Other members of the xanthine group though less effective may be better tolerated such as theobromine calcium salicylate (theocalcin) in doses of 1 0 Gm (gr 15) or theobromine sodium salicylate (diuretin) dose 1 0 Gm or theophylline ethylene diamine (aminophylline) dose 0 1–0 2 Gm All are to be given three to four times daily Urea is often much more effective than the foregoing and is not too difficult for the patient to take One may prescribe a 50 per cent solution of the pure crystalline substance, of which the patient may take from 15–45 cc (½–1½ ounces) four times per day It is best taken ice cold in chilled fruit juice particularly grape juice

The *mercurial diuretics* surpass the xanthines and urea in effectiveness and certainty of action and play a major part in the modern treatment of congestive failure. They are frequently best used from the start of treatment rather than only after other measures have been proved inadequate Employed thus they often hasten materially the recovery of the patient Their efficacy is greatest after intravenous injection The two generally accepted are mercupurin and salyrgan with theophylline The presence of theophylline in each materially reduces the local irritant action of the mercurial component if it should escape into the subcutaneous tissues or when given intramuscularly or in a suppository The dose of either is from 0.5–2 0 cc of the ampoule solution (10 per cent) The initial dose is usually 0.5 cc to test the patient for susceptibility or intolerance both of which are rare Customarily an injection of 1 or 2 cc is given every two to five days but good results may be obtained from two to three doses per day of 0.5 cc. each These smaller and more frequent doses avoid the extreme diuresis and exhaustion sometimes produced by a large single dose Frequent intravenous injections are likely to destroy the usefulness of the veins and are usually possible only in hospitals Injection should be slow The use of a fine gauge hypodermic needle is advisable both to reduce the rate of injection and to preserve the veins Diuresis begins within about two hours and has usually subsided within about eight to twelve hours As it may amount to several liters administration should take place early in the day to avoid disturbing the patient s sleep

These mercurials may be injected intramuscularly usually without too much irritation or they may be administered in the form of rectal suppositories if the patient does not have hemorrhoids They often produce troublesome rectal irritation even when the rectum is normal Their efficiency is less by these routes than by intravenous injection However the mercurial be given,

its diuretic effect often can be increased by the preceding or simultaneous administration of ammonium chloride or other acid forming salt Usually between 6–10 Gm (gr 90–150) are given per day preferably in enteric coated tablets Ammonium chloride may be given during the day preceding and on the day of the injection, or it may be used continuously for the small or moderate diuresis which it produces in many patients Thoracentesis or abdominal paracentesis may be required for removal of pleural effusion or of ascites Rarely the subcutaneous edema may have to be relieved by mechanical drainage of the legs with Southey tubes or by multiple scarification The use of such procedures particularly paracentesis of the abdomen, may be followed by a significant increase in the actions of the diuretic drugs The practice of limiting the ingestion of table salt when combined with the continued use of diuretics may lead to a depletion of the sodium reserves of the body with a resultant failure to obtain satisfactory diuresis It may then be advisable to give 5–10 Gm of sodium chloride daily for several doses to restore satisfactory elimination of edema fluid

Despite their high content of mercury the mercurial diuretics do not appear to cause renal damage even with prolonged use However they are likely to aggravate an existing nephritis It is therefore prerequisite to make certain that the albuminuria and casts are not part of a nephritis but are due solely to the renal stasis of congestive failure One should make certain that there is no albuminuric retinitis that there is no marked retention of nitrogenous metabolites in the blood, that red blood cells are absent from the freshly voided urine, and that the specific gravity of the urine is not fixed at a low level

Attacks of cardiac asthma or of acute edema of the lungs may arise and demand emergency treatment Several measures are helpful and should be employed largely in the order of their immediate availability Morphine is usually required at once (15–30 mg) given by hypodermic Atropine in doses of 1–2 mg may or may not help by reducing bronchial secretion and spasm The slow intravenous injection of 0 25–0.5 Gm of aminophylline often gives dramatic relief Oxygen, by nasal catheter, mask or tent is desirable but it often requires time to make it available According to Barach heart failure of nonrheumatic etiology responds better to oxygen inhalation than that associated with rheumatic heart disease The oxygen tent is the most comfortable method of administering oxygen, the concentration of which should be higher than 50 per cent In severe cases it may be desirable to keep the patient in an oxygen tent for a period of three to four weeks A phlebotomy of 300 to 500 cc may be most effective or a so called bloodless phlebotomy or venous trapping may suffice The intravenous injection of 50–100 cc of a 50 per cent solution of glucose or one of the other sugars such as sucrose helps occasionally Ouabain may be administered by vein or intramuscularly, followed at once by the oral administration of digitalis During the institution of these measures the patient should be kept in the orthopnea position and all possible reassurance given him

Chronic congestive failure requires the meticulous guidance of all of the patient s activities including both physical and mental activity diet, fluid and salt restriction rest and sleep In addition digitalization should be continued and the diuretics be used as required Where effective the diuretics should be given by mouth using those previously discussed Education of the patient and his family in the regulation of his activities combined with encouragement and regular clinical examinations and the foregoing treatment will usually do much to enhance his comfort and prolong his life *One should always remember that it is the patient who is being treated—not his disease*

ANGINAL SYNDROME

(Angina Pectoris Angina of Effort)

Definition.—The anginal syndrome is a physiologic condition characterized by chest pain which is substernal or immediately to the left of the sternum occurring in attacks precipitated chiefly by effort excitement heavy meals or exposure to cold The etiology is varied but anoxemia of the myocardium is probably the most frequent direct cause

Incidence—Although the anginal syndrome is occasionally seen in the third or fourth decade it occurs with greatest frequency after the age of forty the highest incidence being in the sixth decade The condition seems to be on the increase Whether this is apparent due to the marked reduction in infant and childhood mortality *or real is* still debatable It was formerly believed to occur with greater frequency in those whose occupations require considerable mental effort and strain but this has been shown to be untrue Men outnumber women by a ratio of at least 4 to 1 in every series of cases reported The anginal syndrome is said to be common in Jews rare in Negroes

History.—In 1772 William Heberden described a disorder of the breast" which he named angina pectoris At the time he was not aware of the association of this syndrome with cardiovascular disease for he postulated gastric ulcer as a possible cause In 1778 Edward Jenner correlated the clinical picture of angina pectoris with the autopsy findings of coronary artery disease This view was generally accepted until Allbutt, at the close of the nineteenth century put forth the hypothesis that the anginal syndrome was produced by the stretching of a diseased aorta Osler in 1898 not only held to the Jennerian view but frequently demonstrated at postmortem coronary thrombosis in patients who clinically presented the classic picture of angina pectoris Mackenzie believed that angina pectoris was *an expression of myocardial insufficiency Historically* then the anginal syndrome is usually considered as an expression of coronary artery disease The American Heart Association has clarified the situation by designating the anginal syndrome as a physiologic diagnosis

Etiology—The common factor in all cases of anginal syndrome is probably anoxemia of the heart muscle Correlation of clinical and pathologic data in coronary artery disease studies on contracting skeletal muscles in the presence of peripheral vascular disease and numerous animal experiments indicate that muscular ischemia will cause pain Mechanical and chemical irritation of the nerves supplying the heart may also play a part

Factors responsible for myocardial anoxemia may be classified as organic and functional The commonest organic conditions are as follows

1 Damage to the coronary arteries (*a*) narrowing of the lumen such as may occur from arteriosclerosis or an invasion of the wall of the artery by some infectious process for example in rheumatic fever (*b*) blocking of a coronary artery by a thrombus or embolus

2 Interference with the entrance of blood into the coronary arteries such as may occur when a syphilitic process in the aorta involves the mouths of the coronary arteries

3 Aortic insufficiency where in spite of increased demand for oxygen by a hypertropied *left ventricle the coronary blood* flow is decreased because of a low diastolic pressure

Among the functional factors may be cited

1 A very rapid heart rate *e g* in paroxysmal tachycardia where the short diastolic

period causes an inadequate coronary artery circulation

2 Marked anemia

3 General anoxemia *e g* high altitudes inadequate ventilation

The actual attack is precipitated by any cause which will put a sudden additional strain upon the heart which may increase the heart rate or blood pressure such as physical effort, mental strain or excitement systemic infections or a heavy meal

The impulses which reflexly cause the pain are conveyed to the sympathetic trunk by fibers running in the middle and inferior cardiac nerves to the corresponding cervical sympathetic ganglia and by fibers running from the posterior cardiac plexus to the upper fourth or fifth thoracic sympathetic ganglia The impulses then pass through the white rami communicantes into the spinal nerves then through the posterior spinal roots to the posterior root ganglia into the spinal cord There are however no white rami in the cervical region Therefore all pain impulses passing along the cervical cardiac nerves to the cervical ganglia must after reaching the ganglia descend along the sympathetic trunks to the upper thoracic ganglia before reaching the spinal cord A knowledge of these pathways is important for proper surgical treatment of the anginal syndrome

Symptoms—The anginal syndrome is characterized chiefly by recurrent attacks of substernal pain less frequently epigastric or precordial The pain varies in intensity and quality It may run the gamut from a slight sense of heaviness in the chest to a severe viselike crushing pain which is accompanied by a fear of impending death The duration also varies But since precipitating cause is commonly physical exertion such as climbing stairs walking against the wind excitement, or a heavy meal absolute rest usually causes the pain to subside so that the length of the attack is relatively short Occasionally attacks may come on while the patient is at rest or even when asleep There is a tendency for the pain to radiate most frequently to the left shoulder and arm and occasionally to the fingers Less frequently it may radiate to neck and jaw and teeth to the back upper abdomen or to the right shoulder At times the pain will start at one of these points before focusing on the anterior surface of the chest. Following the attack a feeling of soreness in the chest, with hypersensitive skin areas often persists for some time One of the points of radiation may show residual numbness lasting for some time after the chest pain subsides The pain is usually accompanied by shortness of breath which is also relieved by rest If the pain is referred to the epigastrium the patient will often complain of flatulence as well If the attack is not relieved by rest and lasts for an hour or more and is accompanied by symptoms of collapse, coronary thrombosis should be suspected

Physical Signs—Since the anginal syndrome is a physiologic phenomenon and the underlying causes are so diverse there are of course, no uniform objective signs Any physical signs that are present are related to the underlying cause

Diagnosis—The diagnosis is made after a careful evaluation of the history physical examination and laboratory data always bearing in mind that the characteristic anginal symptom complex is due to one of the organic or functional conditions which produce anoxemia of the heart muscle

Concerning the differential diagnosis it may be said that too often one forgets that the anginal syndrome is a purely physiologic cardiac diagnosis produced by many organic and functional factors Usually when the organic disease can be easily determined the disorder is not called the anginal syndrome but rather the name of the disease which produced the symptom complex for example coronary sclerosis or syphilitic aortitis with ostial stenosis The one important feature which is common to all conditions giving rise to this syndrome is an anoxemia of the heart muscle We must therefore differentiate the disorder from conditions which cause chest pain but do not cause myocardial anoxemia *i.e.*, extracardiac diseases such as arthritis of the left shoulder joint pleuritis pericarditis mediastinal tumors intercostal neuritis gall bladder disease and certain psychogenic disorders The psychogenic disorders most commonly confused with the anginal syndrome are neurocirculatory asthenia and anxiety hysteria In neurocirculatory asthenia (also called soldier's heart" effort

syndrome) there are general evidences of vasomotor instability namely, flushing of the face tendency to break out into profuse perspiration low blood pressure No evidence of structural heart disease is found In anxiety hysteria there is also no structural heart disease The chest pain is precordial rather than substernal There are usually pains elsewhere in the body Extreme fatigue is a prominent symptom Frequently personality changes can be detected

Prognosis —The prognosis depends upon the underlying etiologic factor The kind and amount of structural damage determines the subsequent course in those cases where the anginal syndrome is due to organic disease The individuals who have a functional basis for the disorder will probably live the normal life span

Treatment —Here again the basic treatment will depend on the cause Frequently however especially when there is structural damage no cure is possible and treatment is symptomatic in character Activity both physical and mental should be restricted to the point where the anginal syndrome is no longer produced It is a great mistake to make total invalids of patients with this syndrome because of the anxiety which may be induced by so doing Physical effort should be distributed evenly over longer periods of time so that there is never any sudden demand upon the heart

Often patients with this syndrome are *overweight* Adjustment of the diet to bring the weight to normal will help to relieve some of the load on the heart Smoking should be discouraged because of the increase in carbon monoxide in the blood and the consequent decrease of available oxygen for the heart as well as the fact that smoking will increase the heart rate and in general cause an increase in nervousness Coffee because of its action on the central nervous system will increase the heart rate and add to the patient s anxiety These deleterious effects will more than counterbalance any possible coronary vasodilatation which may occur

Drugs used for this condition can be classified under sedatives and vasodilators The sedatives act to decrease the patient s mental activities and help him to obtain restful sleep and in a measure decrease the intensity of the anginal syndrome itself Chloral hydrate or one of the longer acting barbiturates *e g* phenobarbital are usually the most satisfactory Of the vasodilators the most effective are the nitrites For immediate relief in acute attacks a nitroglycerin tablet of 0 0005 Gm placed under the tongue is used For the more severe attacks a pearl of amyl nitrite can be broken in a handkerchief and inhaled The effectiveness of the xanthines particularly aminophylline as coronary artery dilators in the anginal syndrome has not been finally established Experimental work with anoxemia or exercise tolerance tests in man appears to indicate that coronary insufficiency is less easily produced if the patient is receiving aminophylline Several clinical studies in which the results were based on the patient's report of his sensations failed to show a beneficial action In a recent review made at the request of the Council of Pharmacy and Chemistry of the American Medical Association the therapeutic claims for aminophylline and related compounds are critically analyzed The conclusions reached as to the usefulness of the xanthines in the treatment of coronary artery disease are as follows Clinical evaluation of the usefulness of the xanthines in the treatment of coronary artery disease is far from satisfactory It seems wise to place the burden of proof on those who claim therapeutic efficacy and the evidence presented so far does not seem unequivocal Alcohol in the form of whisky or brandy will often relieve the symptoms and increase the general well being of the patient

Surgical measures are used for relief only in intractable cases Several procedures are at present employed Bilateral section of the first five posterior thoracic nerve roots has been done in a relatively small number of cases Its performance requires laminectomy which in patients with advanced coronary sclerosis is not without operative risk When successfully carried through relief of pain is complete and permanent Removal of the stellate together with the second and third thoracic ganglia by the supraclavicular approach has been recommended by J C White He believes that this places less strain upon the patient than laminectomy by eliminating the necessity for the prone position and that it is more effective than excision of the stellate alone

The third procedure is nerve block by alcohol injection into the upper five thoracic sympathetic ganglia or the corresponding rami communicantes Over 50 per cent get marked relief and 12 per cent show no improvement The injection may have to be repeated after its effects wear off and the pain recurs This procedure is becoming more and more widely used as the difficulties in technic are being surmounted It is particularly valuable because there is no mortality Painful, though transient intercostal neuritis occurs in most of the cases even though the injections are skilfully made

The fourth procedure is total ablation of the thyroid gland Theoretically the aim is to lower the metabolism of the body and so relieve the work of the heart The relief of the anginal syndrome which occurs immediately after this operation is supposedly due to trauma or section of sympathetic nerves in close proximity to the thyroid gland The pain will return when the nerves function again The relief of pain which occurs in the fourth or fifth week after operation is thought to result from the lessened demands upon the heart due to the onset of hypothyroidism The postoperative management of these patients is often difficult since they must be kept constantly on a dose of thyroid extract sufficient to prevent myxedema This method is used very little at the present time

The fifth group of procedures is concerned with attempts to increase the blood supply to the heart mainly by encouraging extracardiac and intercoronary anastomoses Various types of operation have been devised In one the pectoral muscle is made adherent to the epicardial surface of the heart, in another a cardio omentopexy is performed and in still another talcum powder is placed in the pericardial sac to produce pericardial adhesions These surgical measures must be regarded as still in the experimental stage further experience will determine their value

NEUROCIRCULATORY ASTHENIA

(Soldier s Heart Effort Syndrome Disordered Action of the Heart)

Definition —Neurocirculatory asthenia is a condition characterized by instability of the nervous and vasomotor systems with clinical manifestations of fatigue dyspnea palpitation and precordial pain

Pathology —No pathologic changes have even been demonstrated which could be ascribed to this condition

History —Because of the fact that neurocirculatory asthenia was first noted as a clinical entity in soldiers it was originally termed soldier s heart DaCosta described it during the Civil War and in World War I many cases were again reported When civilians also were shown to exhibit this syndrome the terms effort *syndrome* and disordered action of the heart were given to it Neither term is quite so descriptive of the condition as the one suggested by Oppenheimer and now in common use namely neurocirculatory asthenia

Etiology —The precise mechanism by which this syndrome is brought about is unknown Basically it is classified with the

neurasthenias that group of borderline psychic disorders wherein fatigue is prominent and the other symptoms present are referred to almost any system or organ The development of neurasthenia appears to be an hereditary characteristic In some members of the family the symptoms may be referable to the gastro intestinal tract in others to the nervous system, and still others may have the syndrome of neurocirculatory asthenia

The disease is rare at the extremes of life the greatest incidence being in young adults In civilian life the age incidence is higher than in the army Craig and White found the average age to be thirty five years There seems to be very little difference in the incidence as related to sex

Symptoms—The chief symptoms are palpitation shortness of breath precordial pain or discomfort and exhaustion The onset is frequently associated with emotional upset, anxiety or social maladjustment but may follow other conditions such as pregnancy or one of the infectious diseases The symptom of palpitation consists of a *consciousness of forceful pounding of* the heart rarely associated with an increase in heart rate Shortness of breath on effort is the symptom which prompted some observers to name this condition the effort syndrome. Again there is more the consciousness of respiratory effort than any true dyspnea Occasionally there may be a marked increase in the rate of respiration White mentions a frequent tendency to sigh as an important point in differentiating neurocirculatory asthenia from organic heart disease The precordial pain usually consists of a dull ache in the region of the left breast The pain often lasts for some time often a matter of hours There is usually no radiation and substernal pain is rare. Occasionally there may also be attacks of stabbing pain which last for only a few seconds The exhaustion *noted in nearly all* cases not only is produced by slight effort but is often unrelieved by rest

Other symptoms are faintness syncope insomnia headache dizziness increased perspiration difficulty in swallowing tremor flushing and pallor These are present in varying degrees They are evidence of instability of the vasomotor system

Physical Signs—In a typical case the patient appears anxious, the face is flushed and there is often profuse sweating at normal room temperature The respirations may be rapid Tremors are noted in pronounced cases An examination of the heart is in the main negative A forcible apex beat and some increase in the heart rate may be noted The blood pressure is usually normal but may be slightly elevated Fluoroscopic examination is negative The electrocardiogram is normal So-called functional tests' of the heart especially those based on standard exercise or vital capacity are subnormal The value of these tests in differentiating this condition from organic heart disease is thereby materially reduced

Diagnosis—The absence of signs of organic heart disease in a patient who has palpitation respiratory distress, precordial pain and fatigue should make one suspicious of neurocirculatory asthenia Further inquiry into the history will usually make the diagnosis certain Hyperthyroidism must be considered but a normal basal metabolism together with the absence of the usual signs *associated with an overactive thyroid gland* would rule it out.

Prognosis—No one ever dies of neurocirculatory asthenia On the other hand the course is usually protracted unless definite measures are taken early to correct the psychogenic factors which form the background for this condition Even then the patient may have a relapse when under some emotional strain Complete recovery can be expected in about 15 per cent improvement in 17 per cent and in the remainder the condition either remains stationary or gets progressively worse

Treatment—The only form of treatment that is in any way effective is psychotherapy The psychogenic background must be carefully explored and maladjustments corrected A plan of life free as nearly as *possible from anxiety should* then be worked out to prevent the occurrence of a relapse

CAROTID SINUS SYNCOPE

(*Vasovagal Syncope*)

Where the common carotid artery bifurcates to form the external and internal carotid arteries there is a slight bulging which is known as the carotid sinus In this region there are in the wall of the artery specialized sensory end plates surrounded by a rich nerve plexus By means of the carotid sinus nerve which joins the glossopharyngeal nerve connection is made with the central nervous system Overactivity of the carotid sinus may cause attacks of dizziness, fainting, and sometimes convulsions The physical signs noted during the attack are a fall in arterial blood pressure and marked slowing of the heart rate Attacks may come on without any apparent cause follow an emotional upset or be induced by pressure over the carotid sinus The overactivity is usually functional without any pathologic change being noted Occasionally some organic disturbance may be responsible such as tumors in the neck pressing on the carotid sinus or a dilatation of aneurysmal proportion of the carotid artery

The *treatment* is surgical Best results are obtained if the carotid sinus nerve can be severed Stripping of the nerve plexus from the carotid artery at the bifurcation may in some cases effect a cure but in others gives only temporary relief

DISEASES OF THE ARTERIES

ARTERIOSCLEROSIS

Arteriosclerosis leads to loss of elasticity thickening and hardening of the arteries While generally considered a process essentially degenerative and hyperplastic (Marchand Aschoff) there is much to indicate that it may be inflammatory Because of his adherence to the latter concept Virchow designated the condition 'endarteritis deformans MacCallum is of the opinion that arteriosclerosis is probably the effect of some injurious or poisonous agent upon arteries with destruction fat accumulation and repair

Pathology—For clinical purposes it is convenient to classify arteriosclerosis as follows (1) Senile arteriosclerosis atherosclerosis nodular sclerosis, (2) Monckeberg s arteriosclerosis and (3) arteriolosclerosis Although the pathologic changes in pure forms of senile arteriosclerosis and Monckeberg s sclerosis are quite distinct, no constant etiologic factor is recognized in either and the two commonly co exist The third form arteriolosclerosis, occurs almost exclusively in association with hypertension

With advancing age arteries lose elasticity This is a result of demonstrable changes in the elastic tissue of the vessel walls Associated with the elastic tissue changes the muscularis tends to atrophy and undergo fibrous tissue replacement These alterations in the vessel walls are ordinarily initiated during the fourth or fifth decade of life and when well marked constitute what is commonly called senile arteriosclerosis' The latter may produce little or no change in the size of the lumina of the vessels and therefore may lead to no significant reduction in the amount of blood supplied by them However vasomotor control in vessels thus affected is probably reduced Moreover the loss of elasticity of the larger vessels reduces their capacity as reservoirs since the ability of the arteries to store the peak work

of cardiac systole and to release it during diastole is reduced As a result, the systolic blood pressure tends to rise Thus in arterio sclerosis more work may be required of the heart for the preservation of normal blood flow and a corresponding reduction in car diac reserve may ensue Demonstrable loss of elasticity of vessels occurs as early as the third decade (Winternitz) This emphasizes the importance of the vital rubber at an early stage in the aging process

In the aorta and larger vessels the earliest macroscopic evidence of arteriosclerosis oc marked intimal lesions are generally asso ciated with less conspicuous changes in the media The atheroma eventually exhibits varying degrees of calcium deposition even bone formation Ulceration of the surface of an atheroma with discharge of its fatty con tents into the blood stream commonly oc curs The presence of such ulcers' in the intima favors thrombosis especially in the smaller vessels This variety of arterioscle rosis in which the intima is the site of maximum involvement has been called *atherosclerosis* or *nodular sclerosis* in con

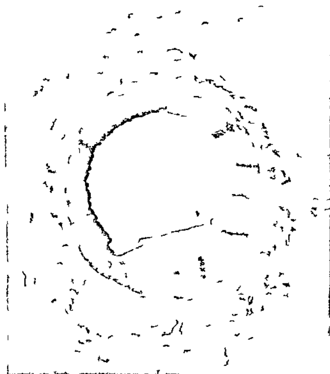

Fig 150—Senile arteriosclerosis Note the atheroma which results in narrowing of the lumen of the vessel (Courtesy of the Department of Pathology Vanderbilt University Hospital)

curs in the form of yellow streaks in the intima These are produced by the presence of newly formed connective tissue and fat ladened wandering cells As these lesions in crease in size they lead to excrescences on the intima which project into the lumen of the vessel Hyaline changes or necrosis occurs Injection specimens (Winternitz *et al*) indicate a rich network of blood vessels vasa vasorum about these lesions Thus is formed the atheroma—so called because of the soft fatty porridge like material con tained in the depth of the lesion Well tradistinction to *senile arteriosclerosis* where as we have seen the media is predominantly altered It is improbable that *any clinical distinction can be drawn be* tween senile arteriosclerosis and atheroscle rosis Indeed many pathologists consider that the two types are simply variants of the same process

It has been emphasized that the usual location of the major arteriosclerotic changes in the aorta is the intima In the arteries of the extremities the media is frequently the site of maximum involvement (Monkeberg s

sclerosis) Degeneration here frequently leads to the development of localized and sometimes encircling calcium plaques which result in palpable beads or rings along the course of the arteries Thus the brachial or femoral artery may feel like the trachea When the process is confined to the media no encroachment upon the lumen occurs and the amount of blood delivered by the vessel is affected but little if at all However in association with these characteristic

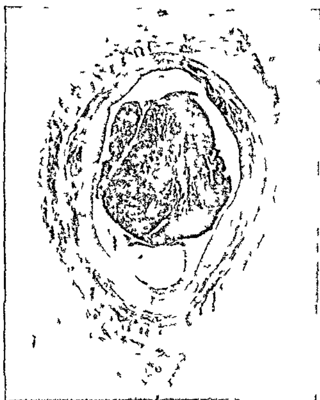

Fig 151—Monckeberg's sclerosis The major changes are in the media where atrophy of the muscularis fibrosis calcification and actual bone formation are present *Although the intima is thickened it does* not in this specimen materially reduce the size of the vessel lumen A postmortem clot is present (Courtesy of the Department of Pathology Vanderbilt University Hospital)

changes in the media in Monckeberg's sclerosis thickening of the intima frequently occurs and results in reduction in or even obliteration of the vessel lumen Arteriosclerosis of this type *is common in the peripheral* vessels of the aged and in diabetes and produces profound disturbances in the circulation of the extremities often terminating in gangrene

Arteriolosclerosis is almost invariably found at necropsy in subjects who have had hypertension Sclerosis of the larger vessels may or may not be encountered The small arteries and arterioles of the kidneys, pancreas spleen, adrenals and voluntary muscles exhibit *varying degrees of* hyaline thickening and narrowing of the lumen with changes in the muscular fibers (See Hypertension)

Clinical Manifestations—The frequency with which arteriosclerosis is associated with hypertension produces confusion and difficulty in *distinguishing between the clinical* manifestations of the two conditions It may prove useful to summarize briefly certain alterations in physiology and structure induced by arteriosclerosis (1) The reduction in elasticity of the walls of the aorta and great vessels diminishes their capacity as reservoirs vasomotor regulation is less effective the systolic blood pressure tends to rise and *additional work is required of the* heart (2) Involvement of the intima (atherosclerosis) narrows the vessel lumen and this narrowing may progress to occlusion Structures supplied by vessels thus affected respond clinically with the development of manifestations of ischemia Thus *reduction in the blood supply* to an area of the myocardium may result in angina *pectoris if the blood supply is completely* destroyed in myocardial infarction Reduction of blood supply to the kidney has been shown to produce hypertension Indeed, it appears that renal artery sclerosis may be a common etiologic factor in so called essential hypertension These are but isolated *examples of the tremendous* importance of arteriosclerosis in the production of structural *and functional changes in* all parts of the body changes due to interference with the normal blood supply (3) *Destruction of* the elastic and muscular coats produces weakness of the vessel wall thus predisposing to rupture and hemorrhage The greater the blood pressure in such vessels the more prone the vessel is to rupture

When the blood supply to various parts *of the body* is reduced sufficiently by arteriosclerosis symptoms and signs appear This *being the case it follows* that manifestations may be absent or confined to one or more areas or systems or generalized as in senility From the clinical point of view the organs which are more *commonly* affected

are heart, brain and kidneys Arteriosclerosis of the vessels of the extremities and the ab domen also produces typical clinical syn dromes

Well marked peripheral and retinal ar teriosclerosis may be demonstrable by phys ical examination, in the absence of any symptoms or signs of impairment of func tion of either these parts or of internal or gans It is a common observation that *gen eralized arteriosclerosis* may exist for long periods of time without giving rise to symp toms In time there may develop evidence that the intellectual processes are slowing etc) are usually emphasized A graceful sane mental and physical adjustment to the aging process is certainly the most desirable and practical measure to be hoped for and the physician can often do much to encour age this The tactful suggestion that the de-mands of the third and fourth decades can not be met easily by the body in its fifth and sixth decades together with the defini tion of a manner of living compatible with the patient s age is often helpful Encour agement is more important than drugs Indeed the latter are effective chiefly through suggestion Bromides and the bar

Fig 152—Arteriosclerosis Changes in the media and intima of a small pancreatic artery (a) and arteriole (b) Intimal thickening has resulted in narrowing the lumina in varying degrees Hyalinization and necrosis of the vessel walls are apparent Malignant hypertension (× 2 5 H & E Courtesy of the Department of Path-ology Vanderbilt University Hospital)

that the special senses are less acute that emotional control is less effective that car diac renal and skeletal muscle function are less efficient In short senility may ensue with its gradual reduction in efficiency of all general and special functions of the body If the aging process progresses more rapidly in one part of the body the symptoms and signs referable to that part dominate the clinical picture

The Treatment of Generalized Arterio sclerosis—There is no specific treatment for arteriosclerosis As prophylactic treat ment good hygiene and the avoidance of excesses of all kinds (food alcohol tobacco

biturates are useful when nervousness and apprehension exist but should be admin istered with care since patients with cerebral arteriosclerosis are especially susceptible to bromide and barbiturate intoxication The time honored iodides provide medicine which is usually administered by drops and taken thrice daily good attributes for a placebo The judicious use of simple analgesics and hypnotics when indicated is in order and constipation should be corrected The prob lem usually resolves itself into symptomatic treatment with due attention to the psyche Resourcefulness and optimism characterize the successful therapeutist

Heart —Arteriosclerotic disease of the heart is one of the commonest causes of death It is responsible for from 25 to 40 per cent of cases of chronic heart disease It has been observed at all ages but is com monest after fifty and increases in frequency with advancing years Men are more fre quently affected than women The symptoms and signs are those of angina pectoris dis orders of the conduction mechanism and diminished cardiac reserve or heart failure These conditions are induced by myocardial degeneration and fibrosis secondary to coro nary sclerosis or by coronary artery throm- bosis or embolism with acute myocardial ischemia Aortic insufficiency secondary to arteriosclerosis of the aorta and dilatation of the aortic ring is rare but does occur espe cially when hypertension is present The reader is referred to the special sections on the Anginal Syndrome Coronary Thrombo sis Cardiac Arrhythmias Diseases of the Myocardium and the Treatment of Cardiac Failure

The Aorta —As stated elsewhere arterio sclerosis of the root of the aorta hyperten- sion and dilatation of the aortic ring may lead to aortic valve incompetency However syphilitic disease of the root of the aorta is common and arteriosclerotic disease rela tively rare a point of importance in the eti ologic diagnosis of aortic valve incom petency Saccular aneurysms of the aorta are almost always syphilitic in origin al though arteriosclerosis may co exist (See section on Aneurysm)

Dissecting Aneurysm —In the presence of hypertension the intima of the aorta may rupture When this occurs blood extravas ates between the coats of the aorta and a dissecting aneurysm is formed Sudden agonizing thoracic or abdominal pain devel oping often during great physical exertion and followed by shock is characteristic The pain may radiate to the head back pelvic region and lower extremities and rarely to the arms In spite of varying degrees of shock even with loss of consciousness the blood pressure tends to remain elevated Evidence of arterial obstruction in branches of the aorta supplying various parts of the body especially the legs or head may de velop Moderate fever and leukocytosis occur Death usually occurs within a few hours or days from rupture of the aneurysm into the mediastinal, pleural, pericardial or peritoneal cavities Clinically, the condition is usually confused with coronary and peripheral artery occlusion The absence of electrocardiographic changes is helpful in dif ferentiating the condition from coronary oc clusion Arteriosclerosis of the aorta with atheromatous degeneration of the intima was formerly considered the cause of dissecting aneurysms However Erdheim in 1930 de scribed a rare form of cystic degeneration of the media which is generally accepted now as the commonest etiologic factor Hyperten sion is almost invariably present Athero matous ulcers may be important factors especially in dissecting aneurysms which originate in the descending aorta

The Brain —The manifestations of cere bral arteriosclerosis may be general or focal Alterations in the blood supply to the brain are brought about by arteriosclerosis through interference with normal vasomotor control of the cerebral vessels or by a gen eral narrowing of the vascular bed as a result of atherosclerosis or by actual thrombosis or hemorrhage of cerebral vessels Hyperten sion greatly favors the occurrence of cerebral hemorrhage in an individual with cerebral arteriosclerosis The reader is referred to the section on Affections of the Blood Ves sels of the Brain

Kidneys —The classic experiments of Goldblatt have focused attention on the significance of renal ischemia in the etiology of hypertension Arteriosclerosis of renal ves sels unquestionably does interfere with renal blood supply and may be found to play an important role in the production of so called essential hypertension Arteriosclerosis of the large renal vessels leads to atrophy of the parenchyma with fibrous tissue replacement (benign nephrosclerosis) Renal function usually is not impaired greatly This is in striking contrast to arteriolosclerosis of the kidney wherein the arterioles become in volved apparently as a result of hyperten sion Here serious impairment of function may occur and lead to uremia although death from cardiac failure is much more common

The Extremities —Atherosclerosis is by far the commonest cause of arterial disease of the extremities It is rare before the age

of fifty five years except in diabetes mellitus when it may appear early in life In the lower extremities obliterative lesions in the terminal branches of the posterior tibial and dorsalis pedis arteries commonly produce the earliest symptoms of the disease numbness tingling and burning sensations in the toes A sense of heaviness and pain nocturnal cramps, and weakness of the legs and feet are common complaints The foot is colder than normal and the skin may appear shiny and atrophic Faint discoloration of the toe tips may be present The pulse is feeble or absent in the posterior tibial and dorsalis pedis arteries If the process is of slow development dry gangrene may ensue, if rapid moist gangrene occurs

Intermittent claudication may develop before the signs of complete arterial occlusion are apparent. This symptom is characterized by the occurrence of severe cramping pain in the calf muscles during walking which subsides with rest The degree of exercise tolerance is determined to a nicety by the patient and continuous walking beyond this critical point is avoided The symptom is due to narrowing of the vascular bed supplying the muscles and loss of capacity to increase vascularity adequately during periods of muscular activity

Although peripheral arteriosclerosis is bilateral clinical manifestations are usually confined to the lower extremities and commonly begin on one side only The lack of pulsation in the posterior tibial and dorsalis pedis arteries is the most important diagnostic sign When the extremity is elevated it blanches promptly when placed in a dependent position color returns slowly and the veins remain collapsed for some time Arteriosclerosis must be differentiated from thrombo angiitis obliterans and from vasomotor disturbances (Raynaud s disease erythromelalgia) Arteriosclerosis rarely occurs before the fifth decade and the clinical manifestations are usually of short duration unilateral and confined to a lower extremity the vessel pulsations are faint or absent gangrene develops early the vessels can be visualized by the x ray Thrombo angiitis obliterans rarely develops after fifty occurs almost exclusively in the male and especially in the Jewish race The clinical manifestations extend over a period of years gangrene is late in development and the vessels are not demonstrable by x ray As in arteriosclerosis the lower extremities are affected symptoms at first are unilateral commonly, and the superficial arteries are usually pulseless Phlebitis and evidence of sluggish circulation may be present in superficial veins Patients with vasomotor disturbances are relatively young predominantly female, the disturbance is characteristically chronic, and gangrene develops quite late The vessels pulsate and are not demonstrable by x ray The upper extremities are predominantly affected The process is usually bilateral and manifests its presence by paroxysmal attacks

The *treatment of peripheral arteriosclerosis* is unsatisfactory The early recognition and proper management of diabetes should delay the development of arteriosclerosis in this condition High carbohydrate low fat diets are employed It should be emphasized that the control of the diabetes rather than the type of diet used appears to be the important factor Actual proof is wanting that cholesterol is an etiologic factor in arteriosclerosis in man Patients with arteriosclerotic disease of the extremities should take every precaution against trauma cold dampness and infections Prophylactic care of the feet is of the greatest importance and lists of instructions should be provided Poorly fitting shoes improper care of corns and calluses and exposure to cold and dampness are especially hazardous and predispose to infection Measures favoring the development of collateral circulation are employed Of these Buerger s postural exercises contrast baths alternate suction and pressure treatment (often called pavaex a contraction of the term passive vascular exercise) and the use of heat cradles and typhoid vaccine intravenously are of established value If definite gangrene develops amputation must be performed

The Abdomen —Although many of the digestive disturbances which occur in the aged doubtless are related directly or indirectly to the effects of arteriosclerosis upon the blood supply of the digestive organs clinical syndromes are few and ill defined The mild diabetes mellitus of the aged and the achlorhydria intestinal atony and obstipation which commonly appear late in life

doubtless are due in part to gradual impairment of the circulation

Mesenteric Thrombosis—The syndrome which develops with occlusive lesions in the mesenteric arteries resulting in infarction of the bowel, is by far the most definite clinical expression of arteriosclerosis of the abdominal vessels This is characterized by the sudden occurrence of agonizing abdominal pain usually accompanied by nausea and vomiting Exquisite tenderness and board-like rigidity of the abdominal wall rapidly develop The blood pressure and frequently the body temperature fall Abdominal distention with constipation becomes marked If bowel movements occur the stools are usually bloody In the absence of melena the clinical picture strongly suggests intestinal perforation Gangrene of the infarcted segment of bowel peritonitis and death rapidly ensue unless the affected portion of gut can be resected

SYPHILITIC AORTITIS AND ANEURYSM

History—In the latter half of the sixteenth century Ambroise Pare remarked upon the frequent occurrence of aortic disease (aneurysm) in those who have often had the unction and sweat for the cure of the French disease The writings of Lancisi of Rome (1654–1720) and Morgagni of Padua (1761) indicate their recognition of syphilis as an etiologic factor in aortic aneurysm. Erichson credits Donald Monro 1760 with the first reference in English to syphilis as a causative factor sometimes a scorbutic or venereal taint has been accused Welch in 1875 presented data proving syphilis to be the cause of aortic aneurysm in 66 per cent of 58 cases of aneurysm found at autopsy Heller and subsequently Dohle (1895) published a description of the gross and microscopic lesions The *Treponema pallidum* was demonstrated in lymph nodes in syphilis by Schaudinn and Hoffmann in 1905 and in the wall of the aorta in syphilitic aortitis by both Reuter and Schmorl in 1907

Incidence—Cohn in a critical review of the literature bearing on the frequency of cardiovascular syphilis that is syphilitic aortitis and its complications, estimates that it constitutes from 8 to 18 per cent of all heart disease The incidence figure is lower in northern clinics serving relatively few Negro patients than in southern clinics with a large Negro clientele Figures from different parts of the United States indicate that in Negroes cardiovascular syphilis constitutes from 20 to 40 per cent of organic heart disease and in the white race from 4 to 10 per cent

While the figures furnished by pathologists indicate that aortitis is a common visceral manifestation of acquired syphilis, indeed the commonest recognized at necropsy, they do not supply the clinician with reliable information concerning the incidence of aortitis in living individuals who have syphilis It should be remembered that even when acute syphilis is untreated, about 25 per cent of patients will eventually attain a state in which no clinical or serologic evidence of the disease is manifest ("spontaneous cure") about 25 per cent will die of causes other than syphilis, about 15 per cent will have serologic (blood serum) evidence of syphilis but will remain otherwise free of sign or symptom, about 12 per cent will experience syphilis of the skin mucous membrane or bone approximately the same percentage will have cardiovascular syphilis and a slightly smaller percentage will have neurosyphilis Thus many subjects with syphilis reach the pathologist without gross changes indicative of the infection and the latter escapes detection at autopsy It is probable that the incidence of aortitis in syphilis does not exceed 10 to 12 per cent

Morbid Anatomy—Syphilitic aortitis constitutes the basic pathologic lesion—the foundation pathology—of syphilitic cardiovascular disease The changes occur most commonly in the root and arch of *the aorta*

The route traversed by the *Treponema pallidum* in its invasion of the aorta is not known The condition has not been reproduced experimentally Invasion probably occurs during the early stages of the infection when spirochetemia is known to exist the organisms penetrating the aortic wall either by direct invasion of the intima or by way of the vasa vasorum or by way of the lymphatics from mediastinal lymph nodes The location and extent of the resulting pathologic changes in the aorta are of the early death whereas more diffuse lesions of the aortic arch involve the heart but little if at all Elongation loss of elasticity and dilatation of the aorta narrowing of the orifices of the great vessels arising from the arch and aneurysm result from aortitis in the latter region

The histologic changes are those of a destructive inflammatory process In early *lesions an obliterative endarteritis of the* vasa vasorum and perivascular round cell accumulation in the adventitia are char

Fig 163.—Cardiovascular syphilis This photograph illustrates the chief manifestations of syphilitic cardiovascular disease all of which are due to syphilitic aortitis (1) Diffuse syphilitic involvement of the aorta, (2) focal aortic weakening with aneurysm formation rupture of aneurysm (3) aortic valvulitis with incompetency and left ventricular hypertrophy and dilatation (4) narrowing of the orifice of coronary arteries

Note. Extensive wrinkling, scarring and dilatation of the ascending aorta (A) a small aneurysm (B) arising from the root of the aorta the wall of the aneurysm (C) has fused with a cusp of the aortic valve (D) and has ruptured through it (at E) into the left ventricle sagging thickened incompetent aortic cusps (F) normal orifice of left coronary artery (G) partially stenosed orifice of right coronary artery (H) Marked hypertrophy and dilatation of the left ventricle is present Note thickness of ventricle wall (I) and papillary muscle (J) (Courtesy of the Department of Pathology Vanderbilt University Hospital)

greatest importance since they determine the clinical manifestations of aortitis in the individual case Thus as commonly happens involvement of the sinuses of Valsalva carries the threat of dilatation of the aortic ring or extension of the inflammatory reaction to the aortic valve with resulting incompetency or of narrowing of the orifices of the coronary arteries with embarrassment of the myocardial blood supply A relatively small area of aortitis in this locality may result in rapidly advancing heart failure and acteristic findings Probably as a result of the diminished blood supply by the vasa vasorum but possibly a direct result of the syphilitic inflammatory process degenerative changes occur in the media and in more advanced cases interruption and fragmentation of the elastic layer is conspicuous (mesaortitis ') Connective tissue replacement eventually ensues Fibrosis converts the media into merely a debris of patches of distorted muscle and elastic tissue separated by scars (MacCallum) The intima is

irregularly thickened and is frequently hyalinized These changes result in characteristic macroscopic alterations of the aorta The intima appears creased and furrowed and exhibits irregular sunken areas beneath which the wall of the aorta is actually thinner than elsewhere If the syphilitic process is fairly evenly distributed, only elongation and dilatation of the arch of the aorta may result Focal weakness of the wall may lead to aneurysm formation If the root of the aorta is involved, dilatation of the aortic ring widening and sagging of the com missures with separation of the leaflets of the aortic valve or syphilitic changes in the leaflets themselves may occur and result in aortic valve incompetency Finally narrow ing of the orifices of the coronary arteries resulting in interference with blood flow to the myocardium, may take place The fre quency with which these manifestations are encountered at necropsy is indicated in the following table

TABLE 1 SYPHILITIC AORTITIS DEPARTMENT OF PATHOLOGY VANDERBILT UNIVERSITY HOSPITAL PROFESSOR E W GOODPASTURE

Syphilitic aortitis	*Number of cases*
1 Uncomplicated	37
2 Aortic aneurysm	8
3 Aortic valve incompetency	17
4 *Aneurysm and aortic valve incompetency*	4
5 Narrowing of coronary artery ostia alone or with 3 or 4	6
Total	72

Because of the nature of the pathologic change in syphilitic aortitis the clinical manifestations of the disease fall naturally into several groups (*A*) *uncomplicated syphilitic aortitis* (*B*) syphilitic aortic insufficiency and congestive heart failure (*C*) syphilitic coronary artery disease and (*D*) *aortic aneurysm Combinations of B C* and *D* are frequent

UNCOMPLICATED SYPHILITIC AORTITIS

Symptoms—Syphilitic aortitis is rarely productive of symptoms during the first decade of acquired syphilis The average time between infections with *Treponema pallidum* and the development of symptoms of aortitis is twenty years Aortitis usu ally becomes manifest in patients who are between thirty and sixty years of age the incidence peak occurring between forty and fifty years This point is of some prac tical importance in diagnosis since rheu matic-heart disease tends to develop in younger and arteriosclerotic heart disease in older age groups Males are three times as frequently affected as females Although it is generally believed that the Negro male is more susceptible than the white male to the development of aortitis this is probably an expression of the great frequency with which syphilis occurs in the former group rather than increased racial susceptibility on the part of the Negro to syphilitic cardiovas cular involvement The frequent association of syphilitic aortitis and syphilitic involve ment of the central nervous system should be emphasized

Approximately one fourth of the cases of aortitis encountered at necropsy are latent or subclinical' That is to say the aortitis produced neither symptoms nor physical signs during life, and the patients died of some other cause The majority of these cases are examples of uncomplicated aortitis In the absence of symptoms uncomplicated syphilitic aortitis is extremely difficult to diagnose with accuracy This indicates the important role of symptomatology in the rec ognition of early cases Indeed with only few exceptions the clinical recognition of aortitis is dependent upon one or more of the fol lowing diagnostic triad (1) symptoms typical of the condition (2) signs of aneur ysm (3) signs of aortic regurgitation Thus in a consideration of uncomplicated aortitis that is aortitis which has not resulted in either aneurysm or aortic valve incom petency the history is a matter of the first importance

Approximately one half of the patients who develop syphilitic aortitis are unable to recall having had a chancre, a rash or any other manifestation of early syphilis The result of a previous Wassermann or floccula tion test may be known to the patient and thus may indicate the presence of syphilis *Substernal pain* and *paroxysmal dyspnea* are commonly referred to as characteristic symptoms in syphilitic aortitis While a sense of substernal oppression or pain is occasion ally complained of it may be and usually is entirely absent in simple aortitis When

present it is more likely due to syphilitic narrowing of a coronary orifice to aneurysm or aortic insufficiency or to unrelated hypertension and coronary disease than to uncomplicated aortitis Similarly paroxysmal dyspnea is exceedingly rare in uncomplicated aortitis (Keefer and Resnik) Its presence is almost invariably indicative of aortic insufficiency, aneurysm coronary orifice narrowing or of co existing arterial hypertension Orthopnea palpitation or other symptoms referable to the circulatory apparatus are usually absent

Physical Signs —In many instances these are entirely lacking in uncomplicated syphilitic aortitis Elongation and dilatation of the aorta may lead to increased pulsations in the suprasternal notch The carotid or radial pulse may be smaller on one side than the other as a result of narrowing of the orifices of the vessels given off by the aortic arch The pulse wave in the carotids may be exaggerated and recede quickly on account of the inelastic aorta The latter may be felt in the suprasternal notch Rarely when dilatation is great a systolic thrust and diastolic shock may be felt over the sternum Substernal dulness is increased especially to the right if the process is extensive and if considerable dilatation has occurred The auscultatory signs are few A systolic *bruit* at the aortic arch may be heard if involvement is at the root and the aortic second sound may be accentuated and characterized by an amphoric or bell like quality In the absence of arteriosclerosis and hypertension these signs over the region of the aortic valve are of considerable diagnostic importance As in senile arteriosclerosis the systolic blood pressure may be slightly elevated because of the diminished elasticity of the aorta However syphilitic aortitis is usually confined to a relatively small area in the aorta and its effect upon blood pressure is insignificant The heart is not enlarged Signs suggesting syphilitic involvement in other parts of the body may be present (Argyll Robertson pupil iritis absent patellar and Achilles tendon reflexes nodular hepatitis enlarged epitrochlear nodes gummatous skin lesions scar on penis among others)

The Wassermann reaction is positive in about 80 per cent of all cases of syphilitic aortitis The figure is somewhat lower for uncomplicated aortitis The flocculation tests yield a higher percentage of positive results Negative reactions do not exclude the diagnosis Syphilis of the central nervous system is a relatively frequent complication (approximately 15 per cent of cases) and an examination of the cerebrospinal fluid should be made in all cases The spinal fluid Wassermann may be positive when the blood Wassermann test is negative

The x ray is of great value in confirming the diagnosis in advanced cases of syphilitic aortitis In simple or uncomplicated aortitis usually it affords the clinician but little help If dilatation of the vessel especially in its ascending arch is demonstrable in a patient with syphilis uncomplicated by arteriosclerosis hypertension severe anemia or hyperthyroidism the observation warrants the diagnosis of aortitis Unfortunately this circumstance rarely obtains It is in the early uncomplicated syphilitic aortitis group that roentgenologic diagnostic aid is most needed and is in practice least reliable

Diagnosis —From the above discussion it is apparent that the diagnosis of syphilitic aortitis at the stage when the disease is uncomplicated by aortic insufficiency aneurysm or coronary artery stenosis is largely an inferential one Substernal discomfort in a man from thirty five to fifty years of age who presents a serologic or physical evidence of syphilis is very suggestive When the signs of aortic dilatation and elongation are present in such a patient in the absence of demonstrable heart disease hypertension or arteriosclerosis they are pathognomonic

Prognosis —Uncomplicated syphilitic aortitis constitutes the only genuinely hopeful aspect of syphilitic cardiovascular disease as regards prognosis The process in the aorta may become arrested spontaneously before serious damage has occurred to the aortic wall valves or orifices of the arteries It is highly probable that adequate antisyphilitic treatment usually though by no means invariably induces complete arrest of the process The co existence of hypertension renders the prognosis much less favorable

Treatment —The prophylactic treatment of syphilitic aortitis is the adequate treatment of early syphilis Moore cannot recall having seen a patient with cardiovascular syphilis who had received as many as 24 in

jections of arsphenamine for early syphilis and states that aortitis may be expected to develop in inverse ratio to the amount of treatment given for early syphilis He adds moreover, that equally satisfactory prophylactic results may be obtained by the proper treatment of latent syphilis Indeed, the rationale of treating latent syphilis rests mainly upon the protection that is thus afforded against the subsequent development of cardiovascular syphilis and neurosyphilis Of these, the former constitutes by far the greater threat

Regardless of whether the presence of uncomplicated syphilitic aortitis is merely suspected—and it should be considered a distinct possibility in any adult with so called latent' syphilis—or definitely proved intensive antisyphilitic treatment is indicated A preliminary course of from 8 to 12 weekly intramuscular injections of bismuth salicylate (0 2 Gm) together with potassium iodide by mouth (15 to 20 drops of the saturated solution thrice daily) is recommended in order to avoid the possibility of suddenly activating the syphilitic lesion with resulting congestion and edema (the Herxheimer reaction) The initiation of treatment with an arsenical is to be avoided because of this possibility Sudden deaths from occlusion of a coronary artery or rupture of a weakened aortic wall have been attributed to this rare treatment reaction On completion of the preliminary course of bismuth and iodides treatment with an arsenical is instituted Mapharsen (arsen oxide) by intravenous injection is the drug of choice The first dose should not exceed 30 mg This is increased 10 mg each treatment for three additional injections which are administered at three or four day intervals Treatment with mapharsen 60 mg twice weekly is continued until a total of twenty intravenous injections have been given (ten weeks) On completion of the first course of marpharsen antisyphilitic treatment is continued as in latent syphilis A six weeks course of weekly injections of bismuth subsalicylate intramuscularly and potassium iodide by mouth is followed by a second course of sixteen to twenty injections of mapharsen (60 mg twice weekly) It is advisable to supplement the last five weeks or the second course of mapharsen with weekly injections of bismuth subsalicylate Systematic follow up examinations with annual or biannual courses of bismuth and mapharsen are in order The Wassermann reaction is commonly irreversible in syphilitic aortitis and especially is this true when neurosyphilis is also present

H J Morgan

SYPHILITIC AORTIC INSUFFICIENCY

Since the root of the aorta at the level of the sinuses of Valsalva is the commonest location for syphilitic aortitis one would predict that involvement of the aortic valves is the commonest complication Such is the case Aortic valve incompetency is present in approximately 30 per cent of all cases of syphilitic aortitis at necropsy (24 per cent of the Vanderbilt University Hospital series) and in about 60 per cent of the cases which are recognized during life Patches of aortitis above the commissures of the valves lead to widening of the commissures with separation of the valve leaflets, extension of the process along the free border of the cusp produces thickening and contraction penetration of the cusp along the attachment to the aorta results in thickening and contraction—all lead eventually to incompetency of the valve Aortic regurgitation results in cardiac enlargement and eventually congestive heart failure, conditions rarely encountered in simple aortitis or aneurysm of the aorta uncomplicated by aortic insufficiency

Symptoms —The clinical manifestations of syphilitic aortic insufficiency and its attending cardiac embarrassment, which help to differentiate it from other forms of aortic valvular disease are (1) the development of symptoms and signs of aortic regurgitation in the third fourth and fifth decades of life later than the usual time for the development of rheumatic heart disease and before arteriosclerotic heart disease occurs commonly (2) its predilection for males and the frequency of its occurrence in Negroes (3) its rapid relentless downhill course with steadily decreasing cardiac reserve increasing cardiac enlargement congestive heart failure and death usually within three or

four years after the onset of symptoms Because left ventricular enlargement and failure develop rapidly and out of proportion to the changes in size and function of the right heart *paroxysmal dyspnea* is an impressive early symptom A sensation of *sternal pressure* is commonly complained of and frank *angina pectoris* occurs not infrequently The presence of a narrow orifice of one or both coronary arteries is always to be suspected in this connection Death often occurs suddenly It results usually from congestive heart failure coronary ostium stenosis ventricular fibrillation or intercurrent bronchopneumonia

Treatment —The nonspecific treatment of syphilitic aortic insufficiency does not differ from that of other forms of aortic insufficiency and congestive heart failure The reader is referred to the sections on chronic valvular disease and diseases of the myocardium

Experience has demonstrated that antisyphilitic treatment affords but little advantage to the majority of patients with syphilitic aortic insufficiency Nevertheless when the valvular incompetency is of recent development and when the patient is seen before cardiac decompensation has occurred specific treatment should be administered cautiously Weekly injections of bismuth together with the oral administration of iodides are recommended for from two to three months If at the end of this period the patient is in a good state of cardiac compensation injections of mapharsen beginning with 20 mg and gradually increasing to 50 or 60 mg at four to six day intervals may be employed for eight to ten weeks Sudden death may occur following an arsenical injection Nevertheless specific treatment is warranted since one occasionally encounters patients in whom the disease has become arrested apparently as the result of specific treatment The writer observed a patient who had syphilitic aortic insufficiency and two aneurysms of the thoracic aorta for a period of eight years[1] Annual courses of antisyphilitic treatment were administered during this period Death resulted from subacute bacterial endocarditis a rare complication of syphilitic valvular disease

The advent of congestive heart failure in syphilitic aortic insufficiency should preclude the use of the arsenicals with very rare exceptions In the syphilis clinic of the Vanderbilt University Hospital no antisyphilitic treatment except potassium iodide is prescribed during periods of congestive failure and only bismuth and iodides when satisfactory compensation has been restored The use of mapharsen (10–20 mg) or neoarsphenamine (0 05–0 1 Gm) in patients who have experienced congestive heart failure is confined to hospital practice and is employed only as a last resort in attempts to relieve intractable precordial pain

H J Morgan

SYPHILITIC CORONARY ARTERY DISEASE

Narrowing of the orifice of one or both coronary arteries is present in syphilitic aortitis in from 10 to 20 per cent of cases at necropsy (approximately 10 per cent of the Vanderbilt University Hospital series) and is due to localization of the syphilitic process in the sinuses of Valsalva or to the abnormally high origin of the arteries at or above the upper level of the sinuses (von Glahn) where syphilitic involvement of the aorta is common Syphilitic endarteritis in the course of the vessels is quite rare though the writer has seen it in association with a gumma of the myocardium The occlusive lesion of the orifice is of slow development and may lead to complete stenosis without producing symptoms of myocardial ischemia Scott has observed two patients in whom the heart maintained an adequate circulation certainly for days and in all probability for weeks without any blood supply through the coronary arteries Presumably collateral circulation was established through the thebesian system of vessels (Wearn) However the occurrence of precordial pain in cases of syphilitic aortitis uncomplicated or in association with aortic insufficiency strongly suggests the presence of either coronary orifice narrowing or aneurysm This is a matter of practical importance regarding treatment since injudicious use of the arsenicals in such cases may induce the Herxheimer reaction with disastrous results The discussion of the contraindications and indications for specific treatment in syphilitic aortic insuf

ficiency is appropriate here (see above) The symptomatic and supportive treatment of coronary disease is considered in the sections of this book dealing with angina pectoris and coronary thrombosis

H J MORGAN

ANEURYSMS OF THE THORACIC AORTA

Definition —An aneurysm is a sac formed as a result of focal weakness and distention of the wall of an artery A *true aneurysm* is one in which the wall of the sac is formed by at least one distended layer of the vessel wall commonly the adventitia A *false aneurysm* is produced when all of the coats of the vessel are ruptured and the blood is retained by the surrounding tissues A *traumatic aneurysm* is produced as the result of injury An *arteriovenous aneurysm* is produced by the simultaneous rupture of an artery and vein usually by bullet or knife the blood passing from artery directly to vein *Dissecting aneurysms* are produced by a linear rupture of the inner coats of the vessel blood being forced into the media or through it to the adventitia and separating the tissues of the vessel wall along its long axis (See section on *Arteriosclerosis*) *Mycotic aneurysms* form as the result of bacterial infection (streptococcic gonococcic pneumococcic etc) of the vessel wall

Aortic Aneurysm —Arteriosclerosis and hypertension in the absence of syphilis commonly produce diffuse dilatation of the aorta but rarely if ever aneurysm Pathologists agree that definite saccular aneurysms of the aorta almost invariably represent complications of syphilitic aortitis When the destructive changes in the elastic and muscle layers of the aorta which are so characteristic of syphilis are more excessive at one area of the vessel than elsewhere the blood pressure tends to balloon out the wall at that point and sacculation occurs This complication is present at necropsy in from 10 to 30 per cent of all cases of syphilitic aortitis (11 per cent of the Vanderbilt University Hospital cases) Multiple sacs may develop though this is rare Because syphilitic aortitis develops in the vast majority of instances in the thoracic rather than the abdominal portions of the vessel thoracic aortic aneurysms are over ten times as frequent as abdominal aortic aneurysms and since the segments which constitute the ascending transverse and descending arch of the aorta are the ones principally affected by syphilis, aneurysms occur here almost ten times as commonly as below the arch (Kampmeier) The condition is most frequently encountered in Negro males and in the second or third decades of syphilitic infection

Pathology —There is little that can be added to the following graphic description by MacCallum " the sac most commonly springs from the convexity of the arch and intense sclerotic alterations of the aorta surround its mouth The orifice is round or irregular in outline, and the edge is rolled over into it somewhat so as almost to overhang its cavity The cavity itself may reach a very great size the sac thus formed pushing aside the surrounding organs or embedding itself in them in the most remarkable way Mechanical effects produced in this way are of great variety depending largely upon the point of origin and size of the sac Pressure on the recurrent laryngeal nerve produces an alteration of the voice from spasm or paralysis of the vocal cord coughing dyspnea etc Pressure on the trachea flattens it and causes dyspnea Later the aneurysm may rupture into it after eroding its wall The lungs yield and collapse before the aneurysm Pressure on a bronchus narrows it and behind the obstruction bronchiectasis arises When the sac reaches the bony structures of the thorax which do not yield it hammers its way through them appearing under the skin through a hole in the ribs or sternum If it extends backward to the spine it destroys the centra of the vertebrae even down to the spinal canal leaving the yielding intervertebral discs standing almost unaltered in the same way it may break through the ribs in the back and appear under the skin there Then it is not long before the skin becomes thinned out and bluish and finally the sac ruptures so that death follows at once Often it ruptures long before reaching the skin into the pleura or pericardium trachea or esophagus or even into the superior or inferior vena cava MacCallum states

further that 'such a sac which can produce a huge and destructive tumor, which destroys itself as soon as it completes its advance is not really composed of the stretched-out walls of the vessels but [of] connective tissue and that essentially new formed the current of blood eddies *about in the cavity and its pulsation gives* the sac its power of breaking down the resistance of the tissues But the endothelial lining is imperfect and thrombosis occurs layer after layer of compact thrombus material may be hammered down on the wall of the sac *Occasionally* the aneurysm may be completely obliterated in this way

Symptoms, Physical Signs —The symptoms of thoracic aneurysm are produced by pressure of the sac upon neighboring structures thus producing interference with their function or upon the bony framework of the thoracic cage Thus a small aneurysm arising from the sinus of Valsalva may remain silent' until rupture occurs in the pericardial sac with resulting hemopericardium and cardiac tamponade or if the sac points anteriorly it may rupture into the pulmonary artery Aneurysms arising from the aorta in the region between the aortic valve and the innominate artery (the ascending arch) may attain great size without producing symptoms Here the sac tends to point up*ward forward* and to the right *Physical* signs may be abundant (the aneurysm of signs) Proximity to the anterior chest wall results in visible pulsations in the suprasternal notch and pulsations of the upper sternum and upper right interspaces with or without an actual expansile bulging in these regions The heart may be displaced downward and to the left and substernal dulness increased to the right over the region of the sac Compression or traction on the innominate artery results in a demonstrable diminution in the size of the pulse in the right carotid subclavian brachial and radial arteries and lowering of the blood pressure in the right arm A systolic thrill and diastolic shock are usually palpable over such aneurysms and on auscultation a rough systolic murmur followed by a snapping sound coincident with closure of the aortic valve (if not incompetent) may be heard Aneurysms rising from this region may point posteriorly or attain enormous *size and* compress *the right bronchus* or lung (resulting in atelectasis) compress and deflect the trachea (dyspnea tracheal tug) compress the superior vena cava (venous stasis, cyanosis) recurrent laryngeal nerve (hoarseness brassy cough) *esophagus (dysphagia) and sympathetic* ganglia (anisocoria unilateral sweating) These manifestations however are much more likely to develop when the sac arises from the transverse portions of the arch (Broadbent s Aneurysm of Symptoms) Aneurysms below the arch in that part of the aorta extending from the level of the sixth to the twelfth dorsal vertebrae are rare frequently nonproductive of either symptoms (unless spinal nerve roots are compressed) or physical signs and are usually discovered only by x ray examination or at necropsy In large aneurysms of the transverse and descending portions of the arch pulsations may be visible in the left interscapular region

Aneurysms rarely develop in patients with syphilitic aortitis already complicated by the presence of syphilitic aortic insufficiency Whether this is due to the short duration of life of patients with the latter complication or to the protection afforded the weakened aortic wall by the low diastolic blood pressure which is associated with aortic re*gurgitation is not clear* The presence of aneurysm however is no protection against the subsequent development of syphilitic aortic insufficiency Narrowing of the orifices of the coronary arteries occurs in about one fifth of the cases and coronary sclerosis unrelated to syphilis may be present Syphilitic aortitis with aneurysm which is uncomplicated by aortic valve or coronary orifice involvement does not produce cardiac enlargement or congestive heart failure Under these circumstances cardiac enlargement if present is almost invariably due to co existing hypertensive arteriosclerotic or rheumatic heart disease

Pain dyspnea and cough are the commonest symptoms of thoracic aneurysm The former occurred in 65 per cent of Kampmeier s series of 596 cases It may consist merely of *a persistent sense of substernal* discomfort The latter may be referred to the neck shoulder or back and sometimes

undergoes periodic intensification of great severity Bone erosion may produce boring agonizing pain which is almost intolerable, or may be painless A striking feature is that certain positions assumed by the patient may cause intensification of pain or afford relief True angina pectoris, occurring either at rest or after exertion and relieved by nitroglycerin occurs with approximately the same frequency that coronary disease is encountered at autopsy *Dyspnea* is complained of almost as commonly as pain When bronchial or tracheal *compression* is present it may be continuous and associated with inspiratory stridor In the absence of pressure on the air passages and aortic insufficiency dyspnea is rarely present When aortic insufficiency complicates the condition paroxysmal dyspnea and frank attacks of acute pulmonary edema are not uncommon *Cough* often of a brassy" character is an important symptom in almost half of the cases It is the result of either recurrent laryngeal nerve tracheal or bronchial pressure or in patients with aortic insufficiency congestive heart failure

X ray —Except in the case of infrequent small sacculations of the aorta which are situated in such positions that they cannot be brought into profile and made a part of the aortic silhouette roentgenology is of inestimable diagnostic value Fluoroscopic examination by an expert with visualization of various profiles of the aortic shadow and confirmatory roentgenograms are usually though not always diagnostic when interpreted in the light of a careful bedside study

Prognosis —The average time which elapsed from onset of symptoms to death in Kampmeier s series was seven to eight months Extremely rare cases are recorded in which the aneurysmal sacs became obliterated by laminated clots which subsequently organized Even calcification may occur Such patients may live many years

Diagnosis — Silent' aneurysms are discovered usually by an x ray examination of the chest or at necropsy When productive of either symptoms or physical signs the condition must be differentiated from other mediastinal or thoracic tumors Neoplasms are not apt to erode bone and may be associated with superficial lymphadenopathy cachexia and anemia The following points may be emphasized in the differentiation of aneurysm from mediastinal neoplasm (1) The *history* of syphilis or serologic or physical evidence of its presence (aortic regurgitation, Argyll Robertson pupils absent knee or ankle jerks superficial gummata or scars gumma of liver etc) (2) the presence of a mediastinal tumor which, regardless of the '*neighborhood*" pressure symptoms and signs is demonstrably expansile by physical examination (pulsations in chest walls systolic thrill and murmur, diastolic shock and accentuated second sound or tracheal tug) (3) expert roentgenologic examination Tuberculosis may be suggested by the pulmonary signs resulting from bronchial or lung compression Fever and tubercle bacilli in the sputum are absent and x ray examination usually dispels all doubt as to the true nature of the condition

Treatment —The treatment of thoracic aneurysms is essentially symptomatic Complete bed rest often affords great relief from pain dyspnea and cough The iodides have a strikingly beneficial effect upon the pain of aneurysms Fifteen to 20 drops of the saturated solution of potassium iodide thrice daily is sufficient Nitroglycerin or amyl nitrite is indicated for angina pectoris Morphine should be used freely for its analgesic and soporific effects The barbiturates are helpful in reducing the amount of morphine required but there is no justification for withholding the latter drug

If aortic insufficiency and congestive heart failure are not present patients with aneurysms should be given the benefit of antisyphilitic treatment Moore s results are so encouraging that one questions the presence of actual sacculation in all of his patients Nevertheless there is but little to lose and possibly much to gain by the institution of cautious antisyphilitic therapy The reader is referred to the discussion of the treatment of syphilitic aortitis complicated by syphilitic aortic insufficiency

HUGH J MORGAN

ABDOMINAL ANEURYSMS

Abdominal aneurysms are rare In asthenic patients with thin abdominal walls the normal aorta can be palpated readily A definitely expansile tumor along the course

of the aorta the upper and lower limits of which are clearly definable by palpation is rarely encountered Excruciating boring abdominal pain is the characteristic manifestation of abdominal aneurysms and this is usually due to erosion of the bodies of the lumbar vertebrae The blood pressure *in the legs may be reduced to a figure* equal to or lower than in the arms In three fourths of the cases radiographic demonstration of eroded bodies of lumbar vertebrae is pos*sible and this is of great* diagnostic assistance Rupture of the aneurysm may occur into the peritoneal cavity or retroperitoneal spaces and, less frequently into the gastro intestinal tract The attending shock and abdominal rigidity may result in a condition suggesting perforation of a hollow viscus

DISSECTING ANEURYSMS

These are discussed in the Chapter on Arteriosclerosis (p 1164)

DISEASES OF THE PERIPHERAL VESSELS

GENERAL CONSIDERATIONS

By usage the term peripheral vascular disease is limited to conditions in which blood flow through the extremities is disturbed by structural or functional abnormality of the peripheral blood vessels In many instances however the primary cause of the disorder is neither peripheral nor vascular as illustrated by some cases of spasmodic cyanosis of the fingers which though closely resembling Raynaud's disease may be caused by such distant lesions as spondylitis or cervical rib Furthermore a great variety of systemic disorders occasionally exert striking effects on peripheral blood flow In this group are such unrelated conditions as the anemias polycythemia vera hyperthyroidism myxedema and of course cardiac disease

In elderly patients pain and indolent ulcers involving the digits may be the initial symptoms of widespread arteriosclerosis of which the peripheral vascular disease is only a part It is true that the extremities are richly supplied with arteriovenous anastomoses but the hands and feet are so frequently exposed to varying temperature and to trauma that the digits are likely to be the first parts to suffer when general vascular disease impairs the efficiency of the circulatory system as a whole For correct diagnosis and efficient therapy one must remember that blood flow to any part depends not only upon the state of the local vessels but also upon the functional adequacy of the general circulation and the influence of the sympathetic nervous system

Vasodilatation, Vasoconstriction and Vasospasm —Normal peripheral blood vessels dilate in response to local heat muscular activity local injury increasing blood volume interruption of sympathetic vaso constrictor impulses warming of the other extremities or of the body vasodilator drugs and injection of pyrogenic substances such as typhoid vaccine Organic arterial disease prevents the affected vessels from dilating fully in response to these agents

Peripheral vasoconstriction results from local cooling chilling of the body decreased blood volume irritation of peripheral nerves and the action of certain drugs Vasoconstriction which is abnormally complete or prolonged is termed *vasospasm* or *angiospasm* This excessive and unphysiologic vasoconstriction sometimes affects structurally normal vessels as in early Raynaud s disease but is frequently secondary to organic arterial disease especially embolism and thrombo angiitis obliterans Severe ar

terial spasm may also accompany acute thrombophlebitis

Excessive dilatation of structurally normal vessels is rare and occurs only in erythromelalgia Prominence of the peripheral veins or capillaries is usually due to structural disease which produces either mechanical distention as in arteriovenous fistula or asphyxial relaxation as in various types of arterial occlusion

The Symptoms and Signs of Peripheral Ischemia—The vast majority of patients with peripheral vascular disease suffer from the effects of ischemia concerning which certain simplifying general principles may be mentioned After routine history and examination have been completed a few additional observations will detect first inadequacy of peripheral blood flow and second its degree and type, whether due to simple vasospasm or to organic arterial disease

Coldness of the extremities signifies decreased blood flow and is normal or abnormal depending on the circumstances under which it occurs Skin temperatures vary widely even in health since body heat is in large part conserved or dissipated by cutaneous vasoconstriction or vasodilatation respectively Temporary coldness of the extremities may be normal but severe and persistent coldness is abnormal Single uncontrolled skin temperature readings are therefore, often misleading whereas differences in the temperatures of corresponding parts of two symmetrical limbs similarly treated and exposed are more significant In the absence of disuse atrophy and diseases of the nervous system unilateral coldness is generally due to structural disease of the corresponding blood vessels Exceptionally however the more grossly diseased limb will be warmer apparently because circulation is largely maintained by superficially placed collateral channels which are relatively insensitive to vasoconstrictor impulses

Intermittent claudication refers to aching or constricting pain which may arise during activity of any group of muscles but most typically affects the calf muscles The pain appears gradually after a relatively constant amount of exercise and is promptly relieved by rest If exercise is continued in spite of pain the affected muscles become spastic and cramps may occur In the absence of general anemia intermittent claudication bespeaks structural arterial disease Advance or quiescence of local vascular disease is reflected by gradual diminution or increase of exercise tolerance which can be measured by controlled pacing or by some type of recording ergometer

Rest pain accompanies (1) sudden arterial occlusion by thrombosis or embolism (2) indolent ulceration, gangrene or other advanced trophic changes and (3) ischemic neuritis In contrast to intermittent claudication it is not relieved by rest and is usually worse at night Patients often discover that they can relieve this agonizing pain somewhat by gently massaging the skin near lesions or by hanging the extremity over the side of the bed

Skin color depends first upon the number and fulness of the capillaries and subpapillary venules second upon the composition of the venous blood with reference to the number of erythrocytes and their oxygen saturation Arterial blood normally enters the skin rapidly enough to prevent conspicuous blanching of the digits even when the extremities of the recumbent patient are raised well above heart level If general anemia be absent *conspicuous pallor* of the elevated extremities suggests but does not prove the existence of organic arterial occlusion *Cyanosis* limited to the extremities indicates that the minute vessels are filled with excessively deoxygenated blood resulting either from venous stasis or from slow arterial inflow

In a cold limb pallor and cyanosis may be due wholly to vasospasm the vessels still being capable of dilating widely under proper conditions Vasospasm can be abolished by warming the limb in a water bath at 35° to 40° C for twenty minutes after which either pallor on elevation or cyanosis in dependency provides strong presumptive evidence that the arteries are organically diseased

Rubor a persistent red or reddish blue discoloration of the cold extremity appears when the cutaneous capillaries and venules are permanently dilated owing to injury from persistent anoxemia cold or low grade inflammation Moderate redness is normal in a naturally warm extremity However peripheral blood flow may be exaggerated

though skin color is still normal since blood flow and skin temperature depend chiefly on arteriolar tone while skin color varies with the tone of the minute vessels

Trophic changes in the skin accompany nearly all slowly developing peripheral vascular conditions and indicate merely that ischemia is severe or has been so at intervals The subcutaneous tissues ordinarily meager may at first be puffy and thickened Later the skin becomes dry atrophic shiny tightly drawn and subject to indolent ulceration The nails become hard brittle ridged and otherwise deformed The severity of trophic manifestations corresponds so closely to fluctuations in the adequacy of peripheral circulation that there is no need to invoke the activity of so-called trophic nerve impulses '

Diminished pulsation of the peripheral arteries is detected with the fingertip or with the oscillometer the latter serving especially to determine the point at which pulsation ceases in the thigh or calf where the vessels are too deep to be palpated The instrument is more reliable in demonstrating relative differences between the deep pulses of two symmetrical limbs than in measuring absolute deviations from normal A pulse not palpable in the cold extremity may appear when vasoconstrictor tone is diminished by heat since vasospasm occasionally obliterates pulsation in arteries still able to dilate Peripheral pulses may be obliterated by aneurysm or coarctation of the aorta while arterial anomalies may be responsible for failure to feel pulsation in the usual situations A normal pulse is sometimes felt at the wrist or ankle while the smaller distal arteries and arterioles are occluded by advanced organic disease

Indolent ulceration and *gangrene* indicate conspicuous or complete local ischemia The vessels in and near the lesion are commonly thrombosed while other vessels in the extremity usually show organic disease but may be structurally normal if the underlying condition is essentially vasospastic The occurrence of local gangrene and ulceration renders it likely that widespread organic arterial occlusion is present but does not justify this diagnosis unless other evidence of widely distributed structural disease is found

Tests for Differentiating Vasospasm and Structural (Organic or Occlusive) Arterial Disease—The degree to which peripheral ischemia is due (1) to pure vasospasm or (2) to organic arterial disease can be determined by *observing the rise of digital skin temperature* which follows temporary abolition of vasoconstrictor tone in the extremities The patient thinly clad lies with the extremities exposed to room air at a temperature between 18° and 21° C When the digits have cooled sufficiently, vasoconstrictor tone in the extremities is abolished by one of the following procedures

1 Injection of procaine around appropriate sympathetic ganglia

2 Anesthetization by procaine of appropriate peripheral mixed nerves

3 Spinal anesthesia (for lower limbs only)

4 General anesthesia

5 Raising body temperature by (*a*) enclosing body (excepting limbs under observation) in an electric heat cabinet (*b*) immersing two uninvolved limbs in water baths at 42° to 44° C for thirty five minutes

As soon as vasoconstrictor impulses are removed from the extremity normal vessels dilate peripheral blood flow increases and digital skin temperature rises rapidly to the normal vasodilatation level between 30.5° and 33° C Such a normal vasodilator response indicates that the peripheral arteries are able to dilate fully and that significant organic arterial disease is absent A partial vasodilator response *i e* rise of digital skin temperature to between 27° and 29 C indicates that moderate organic vascular disease is present in the area studied If skin temperature fails to rise or actually diminishes during the procedure the vasodilator response is absent indicating advanced occlusive disease locally The capacity for vasodilatation has been measured also by observing changes in skin temperature after the intravenous injection of typhoid vaccine (vasomotor index) This procedure should not be used in studying arteriosclerotic patients because of the danger of producing thrombosis The temperature standards of the vasomotor index differ from those of the tests listed above

For studying the upper extremities body warming is the simplest and most reliable method For the lower extremities body warming is generally satisfactory but occasionally fails to release extreme vasospasm, under these conditions anesthetization of the posterior tibial nerves or spinal anesthesia is more reliable

To determine how far upward in the extremity organic occlusion extends other procedures must be used viz (1) the oscillometer (2) histamine puncture (3) reactive hyperemia and possibly (4) arteriography The limitations of the oscillometer have been mentioned Histamine (1 1000) punctured into the skin of the warm horizontally placed extremity normally produces a wheal and hyperemic flares in five minutes or less (Starr) If a wheal fails to appear within five minutes it can be concluded that blood flow is diminished in that skin area Reactive hyperemia (Pickering) is produced by arresting blood flow completely for five minutes after the extremity has been warmed and emptied of blood Sudden release of circulation is followed by a brilliant hyperemic flush which normally reaches the tips of the digits in less than five seconds If organic occlusion is present the flush is delayed and faint Compression of diseased arteries and local arrest of circulation incur some risk of inducing thrombosis

Arteriography involves roentgenography after intra arterial injection of radiopaque solutions This procedure reveals the site and nature of anatomic changes in the peripheral vessels as well as the size and number of collateral channels Arteriography is sometimes painful and is at present contraindicated in active vascular disease owing to the danger of producing thrombosis

Vasodilator Drugs —In treating peripheral vascular disease prolonged vasodilatation is required so that the evanescent effects of amyl nitrite nitroglycerin and acetylcholine are generally of little therapeutic value The efficacy of those drugs which have prolonged vasodilator action depends upon the grade of vasospasm to be overcome and the degree to which structural disease has rendered the peripheral arteries rigid and incapable of dilatation In addition vasodilator drugs often lower systemic blood pressure so that in many cases particularly with structural disease though vasodilatation is obtained peripheral blood flow is increased but little Nevertheless appropriate vasodilator drugs should be tried in all cases because their action though often feeble and capricious is sometimes strikingly effective even under adverse conditions

Ethyl alcohol given in the form of acceptable beverages to provide 0.5 cc alcohol per kilo body weight induces peripheral vasodilatation which lasts on the average for four hours Acetyl β methylcholine should be given orally in doses of 0 1 to 0.5 Gm., and repeated as necessary Undesirably intense side effects can be terminated promptly by injecting atropine Papaverine hydrochloride may be given orally or subcutaneously (0 03–0 06 Gm) and intravenous adminis

DISEASES OF THE PERIPHERAL ARTERIES

Primarily vasomotor (functional) conditions	Vasoconstrictor	1 Acrocyanosis 2 Raynaud s disease (primary) Secondary Raynaud s phenomenon as in scleroderma neurological disorders crutch trauma etc
	Vasodilator	3 Erythromelalgia (primary) *Secondary vasodilator conditions erythralgia*
Primarily organic (structural) conditions	Ischemic (occlusive)	Inflammatory 4 Thrombo angiitis obliterans 5 *Ergotism* 6 Periarteritis nodosa 7 Arteritis in systemic infections Degenerative 8 Arteriosclerosis simple and diabetic Traumatic (with regard to peripheral vessels) 9 Embolism 10 Frost bite Caustics phenol
	Hyperemic	11 Glomangioma 12 Arteriovenous fistula

tration (0 01–0 03 Gm) at intervals of three to four hours has been recommended for relaxing vasospasm in embolism Theophylline ethylene diamine (orally 0 09 Gm three times daily) and theobromine sodio salicylate (orally 0.5–1 Gm three times daily) are said to be helpful in certain vasospastic cases of thrombo angiitis obliterans and arteriosclerosis though useless in Raynaud s disease Thyroid substance in dosage controlled by frequent estimations of basal metabolism is often very useful especially if basal metabolism is low initially

ACROCYANOSIS

Acrocyanosis (Crocq 1896 chronic acro asphyxia Cassirer 1900) is a somewhat indefinite type of mottled peripheral cyanosis which is induced or accentuated by cold and which affects the hands and feet symmetrically with few or no symptoms and no serious consequences

This condition the etiology of which is unknown is primarily vasospastic involving chiefly the smaller arterioles of the skin The cutaneous capillary loops are numerous and tortuous Through large venous limbs they connect with a rich dilated subpapillary venous plexus When vasoconstrictor tone is abolished the peripheral vessels dilate to the normal degree though sometimes rather slowly

Acrocyanosis occurs in men and women especially the latter without special age incidence It may develop suddenly in asthenic individuals at puberty or gradually in later years particularly in those whose work requires prolonged exposure to cold Acrocyanosis may also be associated with the effort syndrome chronic diseases such as arthritis or various neurologic disorders Association with acromegaly and ovarian dysfunction has led to the suggestion that acrocyanosis is merely a symptom of endocrine imbalance

The unevenly mottled blue and red discoloration of the skin extends from a line above the wrists and ankles to the digits increasing in degree distally The cyanosis is intensified by cold or emotion and relieved by warmth The digits are habitually cold and sweat profusely but the soft tissues are normal or at most puffy Hypesthesia of mild grade may be present The course of acrocyanosis is entirely benign since no lesions have developed in patients followed over years The associated hyperhidrosis may however require therapy

Acrocyanosis is easily differentiated from various types of generalized cyanosis because the discoloration is limited to the hands or feet and disappears when the extremities are warmed Acrocyanosis can be distinguished from Raynaud s disease by the type of discoloration and by the absence of even slight pain In acrocyanosis histamine puncture produces a brilliant flare and conspicuous wheal in the cyanotic digits In Raynaud s disease histamine produces neither hyperemic flare nor wheal in the digits *during a paroxysm of cyanosis*

Except for reassurance treatment is usually unnecessary Possible endocrinal abnormalities should be investigated For cosmetic reasons the condition may be made less conspicuous by local protection from cold wearing of warm clothing vasodilator drugs (see p 1178) thyroid substance contrast baths and lotions for hyperhidrosis Carbon dioxide saline baths have been recommended Sympathetic ganglionectomy or preganglionic sympathectomy has been used but the trivial nature of the condition rarely if ever warrants surgical treatment The alcoholic injection of paravertebral sympathetic ganglia has in skilled hands relieved distressing hyperhidrosis

RAYNAUD S DISEASE

Raynaud s disease (Raynaud 1862) is the primary or idiopathic form of paroxysmal, bilateral cyanosis of the digits with or without local gangrene The attacks of cyanosis are produced by cold or emotion and relieved by heat

Etiology and Incidence —The etiology of Raynaud s disease is unknown although constitutional predisposition may be a factor Familial incidence has been described nationality plays no role Women who are underweight asthenic and subject to mental stress are most frequently affected Occurring at any age it is less common before puberty and after forty without relation to menopause or irregular menses Men are affected but so rarely that the essential diagnostic criteria mentioned below should be considered minutely before making the diagnosis in a male Secondary forms of vasospasm are more equally distributed between the sexes True Raynaud s disease occurs on the average once in 3000 general medical cases and once in twenty to twenty five peripheral vascular cases

Pathologic Physiology —The paroxysmal cyanosis of the digits is due to complete interruption of local blood flow by tight constriction of the digital and palmar or plantar arteries Pallor when it occurs spontaneously indicates that the minute cutaneous vessels are sharing in the vasospasm Raynaud in his original descriptions (1862 1874), concluded that excessive vasoconstrictor tone of central origin must be responsible In more advanced cases the involved vessels are also abnormally reactive to cold (Lewis) Typical attacks of digital cyanosis can then be produced simply by immersing the affected extremities for twenty minutes in water at *15° to 18* C

As the attack begins capillary blood flow ceases and capillary pressure falls below normal The digital capillaries, at first small eventually widen and become strikingly saccular or aneurysmal but the intensely cyanotic blood remains stationary and the skin cold As arterial spasm relaxes spontaneously or in response to heat skin color changes from blue to red, blood flow becomes rapid surface temperature rises and capillary blood pressure increases well above normal This reactive hyperemia subsides and circulation remains normal until the next paroxysm of vasospasm is induced

In the early stages of the disease the arteries, large and small are histologically normal Later, in progressive cases the intima is thickened and the muscular coat of the arteries hypertrophied Eventually thrombosis of small arteries in the digits leads to focal gangrene although elsewhere the arteries are still histologically normal or show only slight hypertrophy Pathologic changes in the sympathetic ganglia although described occasionally are not characteristic or uniform

Symptoms and Signs —The onset is usually gradual the first mild attacks appearing in winter or, less commonly during a period of emotional stress Initially attacks may be unilateral but they soon become bilateral and are induced regularly by emotion or by exposure of the body or digits, or both to cold Infections fatigue and nervous exhaustion increase their frequency and severity In a typical well developed attack from one to four digits (thumb often excepted) on each hand become deeply blue or initially white then blue The digits are affected to different levels and the terminal phalanges most severely The fingers are cold more or less numb and may be covered with perspiration Prolonged cyanosis is accompanied by aching pain and awkwardness in fine movements The attacks end spontaneously or can be terminated at any time by immersing the hands in warm water or by going into a warm room During recovery the cyanotic areas are gradually invaded by tongues of reactive *hyperemia* which extend slowly or rapidly until the affected digits are brilliantly red throughout If recovery is slow pallor cyanosis and hyperemia may *co exist in adjacent* patches of skin Tingling throbbing slight swelling and rising skin temperature accompany the rapid return of arterial blood flow Depending on the se

verity of the condition attacks may be rare or they may occur many times per day between attacks the digits appear normal or in severe cases remain mildly cyanotic The attacks may disappear entirely during pregnancy

The hands alone are affected in half the cases hands and feet in the remainder nose cheeks ears and chin are involved much more rarely The course of the disease varies after onset it may persist indefinitely in mild form or improve spontaneously Approximately one third of the cases are progressive the attacks become more numerous persist during summer last longer and disappear less completely until mild cyanosis is more or less constantly present The vasodilator response is usually still normal or *very slightly reduced*

Trophic changes appear in progressive cases usually one to four years after onset The *fingers become thin and tapering* their skin smooth shiny, less mobile and eventually tightly stretched (sclerodactyly) The nails grow slowly and are ridged or curved Recurrent infections and small areas of local cutaneous gangrene appear on the fingertips but gangrene of a whole digit is rare Minute scales of necrotic tissue separate slowly and painfully leaving tiny depressed scars or pits At this stage the abolition of vasoconstrictor tone produces a vasodilator *response which is slow and incomplete* in the more involved digits but usually normal in the others

Prognosis.—Mild grades of Raynaud s disease improve slowly or remain stationary for years and the attacks being few and avoidable are merely an inconvenience The progressive form with recurring infection and local gangrene becomes increasingly painful and disabling though only rarely is more than the distal phalanx lost Generalized scleroderma and atrophic arthritis, which are not infrequently associated with progressive Raynaud s disease may produce extreme deformity and disability

Diagnosis.—The essential diagnostic criteria are (1) digital pallor or cyanosis occurring in intermittent attacks induced by cold or emotion and followed by recovery with the redness of reactive hyperemia (2) symmetric or bilateral involvement of digits, (3) absence of occlusive arterial disease or, at most, in progressive cases mild involvement of the digital arteries (4) gangrene if present usually limited to small areas of skin (5) conspicuously greater incidence in females than in males (10 to 1), (6) absence of any disease or anatomic abnormality to which paroxysmal digital cyanosis might be secondary

Paroxysmal digital cyanosis, or Raynaud s phenomenon of the secondary type occurs with thrombo angiitis obliterans arteriosclerosis (dead finger) crutch trauma pneumatic hammer disease cervical rib and disseminated lupus erythematosus More or less typical Raynaud s phenomenon may occur secondarily in *diseases of the central nervous system* osteoarthritis of the spine traumatic arthritis with painful osteoporosis *spina bifida neuritis causalgia and poisoning* by arsenic or certain heavy metals Spasmodic digital cyanosis hemoglobinuria and *urticaria from cold occasionally occur together* in congenital syphilis

Bilateral gangrene of the digits (Lewis) appears suddenly in children or young adults without previous attacks of discoloration and without exposure to cold The fingers toes nose and ears become permanently cyanotic and within a few days gangrene develops in the distal phalanges of one or more fingers often symmetrically and bilaterally Cyclic color changes of the Raynaud *type first appear during the stage of* healing This syndrome should not be termed fulminant Raynaud s disease since gangrene is extensive and due to sudden thrombotic occlusion of the final end branches of the digital arteries Raynaud s phenomenon has also been observed *after* massive gangrene occurring in malnutrition and during certain *infections e g* typhoid fever typhus pneumonia influenza and streptococcic sore throat

Simple disuse of an *extremity paralysis* and section of mixed nerves eventually produce coldness of the affected parts with vasoconstriction but not the cyclic color changes of Raynaud s disease Some normal subjects at or before puberty observe incomplete cyanosis or pallor of one or two digits (dead finger) after exposure to cold or rarely after emotional disturbance No necrosis or trophic changes are observed and the attacks disappear within a few

years There is no reason to regard this mild form of vasospasm as a prodromal stage of Raynaud's disease

Treatment—Mild cases with infrequent slight attacks limited to the winter months and without trophic changes or gangrene, may be relieved by high caloric diets relax ing mental stress wearing heavier clothing protecting the extremities whenever ex posure to cold cannot be avoided and mov ing to a warm climate Smoking has been *shown to produce vasoconstriction and the* use of tobacco should therefore be avoided Psychotherapy and even simple reassurance concerning the nature of the condition may reduce its severity by allaying excessive fear If the basal metabolic rate is low thyroid substance should be tried Vaso dilator drugs (see p 1178) taken immedi ately before the extremities are exposed to *cold will abort some mild attacks* Repeated reactive hyperemia and contrast baths have been used At best however medical meas ures provide only partial relief

Vasoconstrictor tone is an important fac tor in bringing on and maintaining attacks of vasospasm whether or not the local ar teries are abnormally reactive to cold Re moval of vasoconstrictor impulses by re *gional sympathectomy is the treatment of* choice for the progressive type of Raynaud s disease with increasing distress indolent ulcers local gangrene or early diminution of vasodilator response in the digits If trophic changes or complications are well advanced the usefulness of the operation will depend upon the degree to which the normal capacity for vasodilatation is pre *served as shown by the vasodilator response*

In early Raynaud s disease of the lower extremities lumbar sympathetic ganglion ectomy which is essentially a preganglionic sympathectomy gives complete relief of symptoms For the upper extremity cervico dorsal ganglionectomy being a postgang lionic sympathectomy is much less efficient because of technical difficulties and frequent return of vasospasm through sensitization of the peripheral vessels probably to circulat ing epinephrine The more recently devised preganglionic cervicodorsal sympathectomy apparently avoids sensitization and postop erative vasospasm *and produces greater re* lief of symptoms (Smithwick Telford)

After successful sympathectomy sweating is absent in those areas of skin which have been *deprived of sympathetic impulses* Cer vicodorsal ganglionectomy produces Hor ner's syndrome but preganglionic cervico dorsal sympathectomy does not After opera tion if sensitization of the denervated vessels is avoided the extremities will be warmer to a degree, which can be gauged roughly by preoperative vasodilatation tests In late Raynaud s disease when the digital vessels *are hypersensitive to cold, exposure* may still produce color changes after sympath ectomy of either type but the attacks are less severe and in general, less persistent In patients with complications such as scleroderma or arthritis vasospasm may be relieved with or without improvement of the associated disease

SCLERODERMA

(Scleroderma Sclerema Adultorum Dermatosclerosis)

Scleroderma is a localized or diffuse fibrotic contraction and atrophy of the skin and subcutaneous tissues sometimes asso ciated with paroxysmal digital cyanosis of the Raynaud type

Etiology and Incidence—The specific etiology of generalized scleroderma is un known The symmetrical form which in

volves the digits in Raynaud s disease (*sclerodactyly*) *appears to be secondary to* repeated severe ischemia Vasomotor abnormality fails however to explain the more widespread form of scleroderma which involves the subcutaneous tissues and even the underlying muscle

Scleroderma occurs most frequently in the middle period of life, females are more frequently affected than males

Pathology —Proliferation of preexisting bundles of connective tissue is accompanied by perivascular and periglandular infiltration with lymphoid cells The smaller arteries show changes similar to those observed in Raynaud s disease but in addition the minute vessels are compressed by overgrowth of fibrous tissues and the epidermal structures are atrophied

Symptoms and Signs —The cutaneous changes pass through successive stages of brawny *edema induration or hardening* atrophy and finally deformity with ulceration Atrophy may be restricted to a few punctate areas (morphea) or may involve a whole limb, large areas coalescing until finally the entire body is encased in a rigid shell The disease may appear acutely within a few days or weeks but more usually begins insidiously and requires years for full development Remissions even spontaneous disappearance have been observed Digital pallor or cyanosis of the Raynaud type on exposure to cold may precede the cutaneous atrophy *by years (usual in sclerodactyly)* or may appear only late in the stage of induration Difficulty in making accustomed movements is an early complaint Pain is often absent throughout but paresthesias numbness tingling or burning pain may appear in the prodromal stage The skin is finally either pearly white or pigmented and atrophy is accompanied by anhidrosis coldness of the digits loss of hair and the development of indolent painful ulcers The digits are tapered (acromicria) the nails curved and irregular Cutaneous induration impairs mobility of the peripheral joints and the muscles become flabby and lose their fusiform contour owing to disuse or sclerosis Atrophy of the facial skin produces a typical mask and mastication becomes difficult The bones often show rarefaction especially in the distal parts of the extremities In the early stages of scleroderma the vasodilator *response in the digits remains normal* but later is conspicuously reduced because of slight organic arterial occlusion combined with compression by fibrosis

Fever is usually absent but subacute febrile periods with diffuse pain, digestive disturbances and general malaise occur in some cases The blood reveals nothing distinctive

Diagnosis —For practical purposes scleroderma may be divided into two types The vascular form follows Raynaud s disease and involves especially exposed areas such as the hands forearms face neck and scalp The so called amorphous type bears at first little relation to vasospastic phenomena or exposure to cold If vasospasm occurs it is secondary and appears late in the course of the disease

Prognosis —Sclerodactyly occurring in Raynaud s *disease is progressive unless* vasospasm is abolished or made less severe Scleroderma of the slowly advancing generalized type passes through many periods of activity and remission during which extension to a new area may be accompanied by remission in areas earlier involved Disability may finally be extreme and then difficult respiration and mastication predispose patients to incidental infection which is the usual cause of death

Treatment —Local heat massage hydrotherapy and softening ointments containing *pilocarpine (1 per cent) or salicylic acid* (1–2 per cent) are beneficial The oral administration of salicylates and thyroid substance has been recommended frequently

In the vascular form with conspicuous vasospasm and a normal vasodilator response protection from cold vasodilator drugs and sympathetic ganglionectomy can be recommended according to the principles and limitations described under treatment of Raynaud s disease Acetyl β methylcholine by iontophoresis is said to cause regression of lesions but in many patients relapse follows The administration of ammonium chloride has also been used with occasional success partial parathyroidectomy has been recommended but the results have been uncertain

ERYTHROMELALGIA

Erythromelalgia (Weir Mitchell 1872) is a primary or idiopathic form of paroxysmal bilateral vasodilatation associated with burning pain increased skin temperature and more or less redness of the skin

Etiology and Incidence—The etiology is unknown nor has any uniform pathology been found thus far The characteristic localized and symmetric vasodilatation has been ascribed tentatively to hyperactivity of the vasomotor (dilator) mechanism in the spinal cord Erythromelalgia occurs rarely its incidence at the Mayo Clinic being 1 in 40 000 general patients and 0 5 per cent of patients with peripheral vascular conditions The disease occurs with equal frequency in men and women without special age incidence The lower extremities are more commonly affected

Symptoms and Signs—The onset is gradual and symptoms may remain mild for years or may become so severe and continuous that total disability results Attacks of bilateral burning pain superficial or deep first involve circumscribed areas on the soles or palms but later may spread over the whole extremity The attacks follow stimuli which normally induce only physiologic peripheral vasodilatation or engorgement, *viz* local heat a warm environment exercise standing or simple dependency of the extremity In the affected areas skin temperature rises abruptly to between 33° and 37° C exceeding the temperature observed normally with maximal vasodilatation Local redness of the skin may or may not be striking depending upon the degree to which the minute vessels share in the arteriolar dilatation Arterial pulsation is increased locally and the affected skin often sweats profusely but trophic changes gangrene and ulceration are absent Rest elevation of the extremity and local application of cold relieve the congestion, hyperthermia and pain

Diagnosis—The essential criteria are (1) attacks of bilateral localized burning pain in the extremities, (2) conspicuously elevated skin temperature with more or less redness in the affected area during the attack (3) initiation and aggravation of pain by dependency heat and exercise (4) relief of pain by elevation cold or rest and (5) absence of other conditions which produce peripheral pain and redness secondarily

Polycythemia vera and arteriosclerosis produce localized burning pain which is often unilateral and accompanied by redness but little or no change in skin temperature Many chronic inflammatory states produce in the skin a susceptible state (Lewis) with diminished capillary and arteriolar tone Burning pain (erythralgia, Lewis) is then induced by mild grades of heat cold friction and congestion which leave normal skin unaffected Neuritis infectious ganglionitis and poisoning by thallium lead or arsenic occasionally produce painful peripheral hyperemia

Exposure to cold stimulates vasoconstriction which if unduly prolonged normally gives way to a temporary reactive vasodilatation of the cutaneous vessels in response to a histamine like substance liberated by local tissue damage (Lewis) In susceptible individuals an exaggerated and prolonged reactive vasodilatation after exposure to cold produces chilblains which are local areas of persisting hyperemia redness and low grade edema with tingling and pain In more susceptible patients cold produces pronounced edema of the angioneurotic or urticarial type with increased skin temperature which persists for twelve to twenty four hours A still more exaggerated local vasodilatation after exposure to cold is accompanied by systemic effects similar to those produced by injecting histamine intravenously *viz* flushing of the face tachycardia decreased blood pressure faintness and syncope

Glomus tumor and arteriovenous fistula produce venous engorgement local pulsation and increased skin temperature but not the type of pain observed in erythromelalgia

Treatment —The therapy of true erythromelalgia is in general unsatisfactory Attacks can be avoided or aborted by rest elevation of the extremity and cold applications Contrast baths using heat below the threshold for pain and local irradiation often afford considerable relief at least temporarily Very severe attacks require liberal doses of sedative Acetylsalicylic acid (0.3–0.6 Gm) relieves pain in some cases Occasionally section or alcohol injection of peripheral nerves is required, sympathectomy has been advocated

THROMBO ANGIITIS OBLITERANS

(*Presenile Gangrene Buerger's Disease*)

Thrombo angiitis obliterans is an inflammatory type of obliterative vascular disease affecting chiefly the peripheral arteries and veins especially of males during early adult life Identified first as endarteritis obliterans (von Winiwarter 1879) it was described more fully and given its present name by Buerger (1908)

Etiology —Specific etiology is unknown although infection or the activity of some toxic agent is generally taken to be responsible Bacteria have been isolated from lesions and a type of angiitis has been induced occasionally by transplantation of diseased vessels Systemic reactions characteristic of infection are lacking and infection alone does not explain the sex incidence of the disease Recent work indicates that most patients with thrombo angiitis obliterans also have acute or chronic epidermophytosis and are sensitive to extracts of certain fungi Present evidence does not indicate whether this association is of etiologic importance or merely the result of the general vulnerability of ischemic tissues to infection

Cigarettes are used moderately or excessively by many but not all patients with thrombo angiitis obliterans Smoking produces transient vasoconstriction and probably favors extension of the disease but evidence that tobacco is the primary etiologic factor is lacking Allergic responses to tobacco can be identified in some patients but not in others The disease occurs occasionally *in persons who have never used* tobacco in any form

Constitutional or racial predisposition seems less important than formerly because in recent years authentic cases have been reported in many countries and in practically all races Occurrence in several members of a family and in identical twins has been described Chronic ergotism and abnormalities of calcium or choline metabolism have been mentioned as possible etiologic factors Exposure to cold and repeated trauma favor reactivation and extension of the disease but are not primary causes

Incidence —All races are subject to thrombo angiitis obliterans but approximately half the patients are Jews The average incidence is 1 case in 500 general admissions and approximately 50 per cent of peripheral vascular cases Males are affected far more frequently than females in a ratio of seventy five to one In females the disease is mild and may often escape diagnosis Thrombo angiitis obliterans has been observed at all ages from seventeen to seventy three but occurs most frequently between twenty and forty five

Pathology.—The lesions are segmental in that diseased sections of arteries or veins are separated by areas which are still normal In the acute stage cellular proliferation of the intima is accompanied by the formation of red thrombi Giant cells are found occasionally Polymorphonuclear leukocytes and lymphocytes infiltrate all coats of the artery and extend into the thrombus which is gradually organized Finally the occluded artery

the venae comites and contiguous nerves are bound inseparably into a bundle of hard fibrous cords New segments of artery or vein are involved acutely at intervals varying from days to years, hence a single long artery commonly exhibits many stages of the cycle ranging from earliest intimal proliferation to dense scar formation Many partly organized thrombi are recanalized thus aiding the conspicuously enlarged collateral vessels in restoring peripheral circulation

Symptoms and Signs—Thrombo angiitis obliterans follows a relapsing course in that periods of extending arterial involvement alternate with periods of quiescence during which developing collateral circulation gradually assumes, more or less efficiently the function of the occluded vessels Depending upon the relation between those two concurrent processes of occlusion and compensation the onset varies from insidious to fulminant Ordinarily occlusion gradually outstrips the developing collateral circulation and definite peripheral ischemia brings the patient to the physician within one to four years after the first mild symptoms appear In fulminating or acute cases the whole course is condensed into a few months The disease ordinarily runs an active course of six to twelve years and then advances much less rapidly

The most frequent initial symptom is persistent coldness of one or both lower extremities and less commonly of the upper extremities Aching pain in the digits instep ankle calf (intermittent claudication) wrists or forearm follows exercise of the corresponding muscles Migratory phlebitis may precede or accompany arterial involvement and occasionally the veins alone are affected Tender red elevated areas about 1 cm in diameter appear suddenly in the skin near the valves of the small superficial veins of the foot or lower leg and gradually disappear during two or three weeks to be followed after irregular intervals by new lesions The patient may have observed cutaneous color changes such as cyanosis rubor or even cyclic digital cyanosis and redness of the Raynaud type Trivial trauma ill-advised minor surgery excessive heat or irritant local medication may produce a small ulcer which instead of healing rapidly extends and becomes painful This type of "rest pain" is continuous and is usually worse at night in contrast to the pain of intermittent claudication which is produced by activity and relieved by rest Agonizing pain sleeplessness and excessive smoking frequently form a vicious cycle as the ulcer extends and gangrene develops Rest pain arising from thrombosis and ulceration is generally burning gnawing or aching in type and tends to be constant while the rest pain of ischemic neuritis, which may occur without cutaneous lesions, is paroxysmal and often lancinating Gangrene is usually moist from the beginning but local resistance to extending infection is much higher than in arteriosclerotic or diabetic gangrene

Examination reveals coldness of the involved extremity with reduced or absent arterial pulsation Elevation of the extremity produces pallor and dependency produces cyanosis The grade of rubor trophic changes and wasting of muscles depends upon the duration and severity of peripheral ischemia Vasodilatation tests reveal definite organic vascular occlusion with coexisting vasospasm in one or more extremities When the patient is first seen the disease is usually well advanced in one extremity while the opposite one presents at least vasospasm and frequently mild organic occlusion Although the lower extremities are most frequently involved the disease begins occasionally in the small arteries of the hands Moreover, thrombosis of the mesenteric coronary cerebral or renal arteries is not uncommon

Roentgenograms usually reveal osteoporosis and occasionally osteomyelitis of the phalanges In elderly patients roentgenographic or clinical evidence of arterial calcification does not exclude thrombo angiitis obliterans which may occur in association with arteriosclerosis

Diagnosis—Typical thrombo angiitis obliterans when fully developed in the lower extremities of a young male can hardly be confused with other conditions Paroxysmal cyanosis of the digits sometimes leads to an erroneous diagnosis of Raynaud s disease which in contrast to thrombo angiitis obliterans is rare in males affects the upper extremities more severely and does not obliterate arterial pulsation at the wrist and ankle Thrombophlebitis is accompanied by

normal arterial blood flow and a normal vasodilator response In the elderly with arteriosclerosis the certain diagnosis of thrombo angiitis may require histologic study of an excised vein unless classic migratory phlebitis has been observed

Failure to recognize early stages of thrombo angiitis obliterans is the common error Patients frequently wear a succession of orthopedic appliances for fallen arches before it is recognized that the pain in the ankle or instep is due to organic vascular disease Gangrene may be precipitated by excessive heat (baking) strong antiseptics or ill advised avulsion of a nail for pain or persisting paronychia The rubor of long standing ischemia will not be mistaken for inflammatory reaction if the coldness of the foot and the absence of arterial pulsation are observed

Treatment—Early diagnosis is an important prerequisite for instituting preventive measures to avoid the more serious complications and eventual disability Warm clothing should be worn routinely with fleece-lined gloves or shoes Patients should avoid exposure to cold and if possible obtain sedentary indoor occupation The potential *dangers of trauma minor surgery and dermatophytosis* should be explained The skin should be kept scrupulously clean dry and soft, with frequent inunctions of a bland oil Tobacco should not be used in any form In mild cases without lesions contrast baths postural exercises (Buerger Allen) diathermy and warm sitz baths will increase peripheral blood flow at least temporarily Reflex vasodilatation of those vessels still capable of expanding may be produced by applying electric heating pads to two of the unaffected extremities for a period of forty five minutes several times weekly Foci of infection should be eradicated to avoid possible reactivation of the disease during pe*riods of reduced resistance*

A large fluid intake 3 to 4 liters per day with 5 to 10 Gm of sodium chloride induces hydremia and may relieve distressing nocturnal cramps Intravenous injections of sodium citrate hypertonic sodium chloride solutions or sodium thiosulfate in repeated courses have been recommended Insulin free extracts of pancreas injected intramuscularly diminish the severity of intermittent claudication apparently by aiding metabolism of muscle but do not affect ulcers or rest pain If basal metabolism is low, thyroid substance or thyroxin may be of value The administration of calcium has been recommended

If rest pain is present, with or without lesions absolute rest in bed is essential The affected extremities should be kept horizontal or 20 to 30 degrees below horizontal The latter position aids peripheral blood flow and occasionally is the only one that the patient can tolerate The development of edema and pressure areas should be guarded against External warmth is best applied by means of a thermo regulated cradle kept at the temperature at which the patient is most comfortable usually between 30° and 34° C (Starr) Infected lesions should be kept open moist and clean by means of warm boric acid compresses Antiseptics must be used with caution because of the danger of injuring tissues already partially devitalized Ointments containing sulfonamide drugs are helpful but maceration must be avoided

Typhoid vaccine is given intravenously in ascending doses every four to seven days in spaced courses of eight to sixteen injec*tions The smaller doses do not produce* a chill but may still be followed by vasodilatation relief of pain and healing of ulcers The usefulness of vasodilator drugs (see p 1178) is limited by the degree of organic occlusion but they should be tried because of the conspicuous relief occasionally obtained Suction and pressure therapy intermittent venous occlusion or the oscillating bed may be used cautiously to increase blood flow temporarily in crises of ulceration and rest pain but are useless with massive gangrene or osteomyelitis Spreading infection or recent phlebitis contraindicate their use

Rest pain may also be relieved by anal*gesic ointments applied directly* to lesions and by the oral administration of acetyl salicylic acid acetanilid phenobarbital codeine or morphine with *precautions against* addiction The alcoholic injection or crushing of peripheral nerves produces anesthesia which persists for two to six months when the operation may, if necessary be repeated Chordotomy though occasionally used is rarely if ever indicated

Bilateral sympathetic ganglionectomy has been advocated for the treatment of established gradually advancing thrombo angiitis obliterans with symptoms dating back two years or more, if organic occlusion is not pronounced and if vasospasm is prominent This major operation is not indicated in mild cases responding well to medical treatment nor in advanced cases with massive gangrene and gross organic vascular occlusion The operation is said to have a certain prophylactic value in that the opposite extremity is involved less frequently and less severely Opinion is still divided concerning the general usefulness of sympathetic ganglionectomy in the treatment of thrombo angiitis obliterans The mortality of the operation is extremely low in most conditions but in thrombo angiitis obliterans amounts to 6 per cent primarily on account of lesions in more centrally placed vessels

In skilled hands paravertebral *injection of alcohol* is an effective method of blocking sympathetic impulses and releasing vasospasm Periarterial sympathectomy is at best a temporary expedient Arteriectomy and venous ligation have been abandoned in most clinics

In thrombo angiitis obliterans resistance to systemic infection is fairly high and collateral circulation is usually good so that minor amputations may be performed more safely than is the case in arteriosclerotic gangrene In the presence of ascending infection advancing lymphangitis fever and leukocytosis the oral administration of *sulfonamide* drugs is indicated but delaying amputation is hazardous because the efficacy of the sulfonamides is markedly limited by ischemia of the affected tissues and by local necrosis The oscillometer reactive hyperemia and the histamine test will assist in deciding the safe level for amputation High amputations are required in elderly patients and in those with progressive gangrene rapidly ascending infection or extensive destruction of tissue

ERGOTISM

Ergotism is an acute or chronic intoxication arising from the ingestion of bread made from rye or wheat infested with ergot fungus (*Claviceps purpurae*) Diarrhea colic and vomiting are followed by headache vertigo, paresthesias convulsive seizures and occasionally gangrene of the digits nose or ears It occurred during the past in epidemic form but it is now seen only sporadically, or after the repeated administration of ergot in abortion and of ergotamine in pruritus Peripheral gangrene is due to long continued arteriolar spasm and slow blood flow with secondary intimal hyperplasia and thrombosis In chronic intoxications the convulsive form is said to affect especially women children and the aged while the gangrenous form is more frequent in males during early adult life

PERIARTERITIS NODOSA

Periarteritis nodosa (Kussmaul and Meier 1866) is a form of inflammatory panarteritis affecting any of the medium sized and small arteries and accompanied by systemic symptoms of infection with added regional symptoms depending on the organs involved

Etiology and Incidence—The specific etiologic agent is unknown among the causes suggested are the streptococcus a filtrable virus or bacterial hyperergy The occurrence of this condition in patients who have suffered from asthma serum sickness or sulfonamide reactions argues strongly in favor of an anaphylactic type of hypersensitivity This view is further supported by the experimental production of characteristic lesions in rabbits by the repeated injection of horse serum (Rich) The disease also occurs occasionally in association with rheumatic endocarditis scarlet fever and tonsillitis Periarteritis nodosa is relatively rare approximately 200 cases having been so far described Both sexes are affected at all ages approximately 50 per cent of cases occurring in the third and fourth decades

Pathology—The adventitia the vasa vasorum and the loose perivascular tissues are infiltrated by polymorphonuclear leukocytes lymphocytes and often eosinophils In addition necrosis of the media and the elastic fibers leads to the formation of multiple small arterial aneurysms which may be followed either by fibrosis or eventual rupture with hemorrhage and ecchymosis Intimal proliferation and degeneration lead to thrombosis and arterial obstruction Repair and fibrosis of the adventitial lesions produce characteristic nodules which can be felt along the course of the artery Ischemia mild or severe may occur in any organ through involvement of the corresponding artery Veins are affected more rarely and less conspicuously

Symptoms and Signs—The onset varies from insidious to violent with moderate fever sweating tachycardia malaise fleeting edema and progressive weakness accompanying diffuse joint, muscular or abdominal pain Secondary anemia develops sooner or later with moderate or severe leukocytosis and occasionally conspicuous eosinophilia The liver and spleen may be palpable and the muscles are usually atrophied and tender Blood pressure may be slightly elevated In contrast to thromboangiitis obliterans the visceral arteries are more frequently affected than are the peripheral arteries and local symptomatology is therefore extremely variable Severe internal hemorrhages may occur Renal involvement *is common the urinary signs resembling* those of acute glomerulonephritis The clinical picture may however be that of gastro intestinal hepatic cardiac or organic nervous disease Cutaneous hemorrhages urticaria purpura and tender reddened subcutaneous nodules appear in the extremities Peripheral thrombosis leads to arterial occlusion and digital gangrene The prognosis is poor and although remissions occur recovery has been rare in the cases so far reported

Diagnosis formerly depended almost exclusively upon the discovery of typical pathologic changes in arteries removed at autopsy The examination of biopsy material has led to more frequent diagnosis during life

Treatment is chiefly supportive including repeated blood transfusions and symptomatic therapy for associated conditions Irradiation and neoarsphenamine have been used with occasional success In view of recent work every effort should be made to exclude antigens that might be responsible

SYSTEMIC INFECTIONS PERIPHERAL ARTERITIS AND GANGRENE

Symptoms and signs of peripheral vascular disease mild or severe appear occasionally as complications in typhoid fever typhus pneumonia, influenza cholera bacterial endocarditis septicemia and scarlet fever Mild focal degeneration of the media of the large arteries occurs frequently without producing vascular symptoms Outspoken necrosis of the media and intimal hyperplasia may lead to thrombosis with signs of subacute or acute arrest of peripheral blood flow Peripheral ischemia may be transitory and in large part, vasospastic On the other hand thrombotic vascular occlusion affecting small arteries produces necrosis of the skin while occlusion of large arteries leads to massive gangrene

Tuberculosis of the peripheral arteries is rare but occasionally metastatic infections or embolism produce panarteritis or endarteritis with fully developed tubercles in thrombosed vessels Direct involvement by extension from adjacent tuberculous lesions while common in centrally placed vessels is very rare in the extremities

Syphilis may diminish peripheral circulation by producing periarteritis obliterative intimal hyperplasia or panarteritis but the media is much less affected than is the case in the large elastic arteries True gummata have been found in the vessels of gangrenous limbs Peripheral vascular complications of syphilis are more common in males than in females Peripheral ischemia vasospastic or organic appears insidiously or suddenly but gangrene is rare Active antisyphilitic therapy ordinarily arrests the acute progress of the disease and relieves early vasospasm but organic occlusion remains

PERIPHERAL ARTERIOSCLEROSIS

(Senile Gangrene Diabetic Gangrene Thrombo arteriosclerosis Obliterans Monckeberg s Sclerosis)

The etiology pathology and general symptomatology of arteriosclerosis are discussed on pages 1160–1166 Only peripheral manifestations and their treatment need be considered in this section

Incidence —Peripheral vascular symptoms of arteriosclerotic origin are common in the lower extremities rare in the upper extremities They occur more frequently in men than in women and are more apt to be unilateral than is the case in thrombo angiitis obliterans Symptoms arise with increasing frequency after fifty years of age the average age of hospital patients with fully developed arteriosclerotic peripheral vascular disease being about sixty Diabetes lowers the average age incidence of developed peripheral arteriosclerosis by ten years and if severe and uncontrolled may produce vascular symptoms at any age

Symptoms and Signs.—In most instances peripheral ischemia has begun insidiously long before symptoms appear Coldness of the extremities paresthesias dysesthesia or painful nocturnal cramps may precede intermittent claudication and obvious peripheral cyanosis or rubor Intermittent claudication may be present though digital circulation is good On the other hand mild cardiac failure or angina pectoris may restrict activity so that intermittent claudication is never a prominent feature in spite of advanced occlusion Many elderly persons with marked arterial occlusion and a very narrow margin of safety remain relatively free from symptoms for long periods until trauma or local infection precipitates indolent ulceration and violent rest pain In others without obvious cause sudden thrombosis produces slaty cyanosis of one or more digits with rest pain often of the neuritic type Both pain and cyanosis may gradually disappear as collateral circulation develops but more commonly the affected skin becomes wrinkled and the involved tissues mummify with slow demarcation or become ulcerated as infection occurs

Examination usually reveals obvious vascular sclerosis in the extremities and else-

where The feet are cold pale when elevated and cyanotic when dependent Cyclic color changes of the Raynaud type are occasionally observed in the digits Arterial pulses cannot be felt in the affected extremity and the arteries are sometimes palpable as irregular cords The skin is dry scaly and atrophic the muscles flabby and the nails brittle beaked or ridged Ulcers are indolent with pale, edematous granulations and cyanotic borders The vasodilator response is diminished or absent but vasospasm is not a conspicuous feature Roentgenographic study usually reveals calcification of the peripheral arteries The degree of calcification bears no relation to the grade of peripheral ischemia since calcium deposition is often confined to the media as in Monckeberg s sclerosis

In patients with diabetes arterial obliteration is occasionally limited to segments of small arteries while the larger vessels are still only moderately diseased Local trauma produces superficial cutaneous gangrene although the posterior tibial and dorsalis pedis arteries pulsate normally and the foot in general is warm This type of gangrene due to blockage of arterioles and small arteries responds well to conservative therapy On the other hand diabetic patients with advanced occlusive disease of the large arteries are especially apt to develop lymphangitis and *systemic infection from trifling lesions* because their resistance to infection is extremely low Rest pain is usually less severe in diabetic patients than in those with simple arteriosclerosis

The prognosis of arteriosclerotic peripheral vascular disease simple or diabetic is at best grave because infection is apt to spread rapidly and collateral circulation develops very slowly except in young patients with well controlled diabetes Prognosis must be guarded also because thrombosis is particularly apt to involve the origin of the posterior and anterior tibial arteries a location in which collateral blood supply is especially precarious

Diagnosis—When thrombo angiitis obliterans occurs in the elderly it is usually of the chronic type and resembles arteriosclerotic peripheral vascular disease in its course and therapeutic limitations Ischemia of the spinal cord secondary to sclerosis of the spinal arteries produces intermittent weakness and spasticity of the leg muscles with early fatigue and weakness but not the true pain of intermittent claudication

Treatment—Cardiac insufficiency especially when due to disorders of rhythm may exaggerate peripheral vascular symptoms for this reason appropriate general treatment is indicated when peripheral vascular symptoms are associated with cardiac disease Prompt diagnosis of *early peripheral* arteriosclerosis permits prophylactic care and avoids the more serious complications while careful control of diabetes diminishes the rate at which arteriosclerosis develops Detailed instructions concerning protection against general or local chilling should be provided The potential dangers of trivial trauma or mild infection cannot be overemphasized The skin must be kept scrupulously clean dry and soft a bland oil being used if necessary The use of tobacco though perhaps not so deleterious as in thrombo angiitis obliterans should be prohibited Contrast baths postural exercises diathermy and warm sitz baths may be used cautiously

A generous fluid intake with 5 to 10 Gm of sodium chloride daily will occasionall relieve distressing nocturnal cramps but must be discontinued if edema develops The intravenous injection of hypertonic solution *of sodium chloride has been recommended* Intramuscular injections of insulin free extracts of pancreas apparently aid muscle metabolism and will often decrease the severity of claudication though they do not help rest pain or indolent lesions

For rest pain with or without ulcers absolute rest in bed is essential The affected extremity should be kept in the optimal position usually horizontal or 20 to 30 degrees below horizontal with precautions against the development of edema and pressure areas External heat is best applied by means of the thermo regulated cradle set at 30° to 34° C (Starr) Calcium chloride trays in the cradle are *helpful in preventing moist* gangrene If moist dressings are required bland solutions *e g* boric acid compresses are safer than stronger antiseptics Sulfonamide ointments can be used with benefit if maceration of the skin is guarded against The intravenous administration of typhoid

vaccine is contraindicated because during the chill thrombi are apt to form in sclerotic vessels The usefulness of vasodilator drugs (see p 1178) depends upon the grade of organic occlusion Beverages containing ethyl alcohol in doses up to 0 5 cc per kilo at four- to five hour intervals, have both analgesic and vasodilator action Reflex vasodilatation may be produced by encircling the forearms in electric heating pads for forty five minutes several times weekly Suction and pressure therapy intermittent venous occlusion or the oscillating bed may be useful in conjunction with other procedures, particularly for the pain produced by ischemic neuritis or indolent lesions Suction and pressure therapy is given in one hour periods at first several times daily gradually diminishing to three hours per week as symptoms recede Intermittent venous occlusion and the oscillating bed can be used for much longer periods or even continuously if edema does not develop These physical measures are all contraindicated in the presence of spreading infection or recent phlebitis and must be used with great caution in treating extremities with open lesions

For rest pain due to lesions analgesic ointments may be applied locally Acetylsalicylic acid, acetanilid phenobarbital codeine or morphine are usually required in addition Crushing of peripheral nerves relieves pain effectively but is sometimes followed by sloughing wounds because of widespread organic occlusion

Sympathetic ganglionectomy is generally contraindicated because vasospasm is not prominent and because the age and clinical state of the patient often exclude a major operation Periarterial sympathectomy a minor procedure produces at best temporary results but is occasionally worthy of trial in the elderly Ligation of veins and arteriectomy have been recommended but are not generally accepted as routine procedures

In the presence of ascending infection advancing lymphangitis fever and leukocytosis the oral administration of sulfonamide drugs is indicated but delaying amputation is hazardous because the efficacy of the sulfonamides is markedly limited by ischemia of the affected tissues and by local necrosis In contrast to the safety of minor surgery in thrombo angitis obliterans amputation of digits for local gangrene due to peripheral arteriosclerosis is successful in *only 10 per cent of cases* and if diabetes is present, healing occurs in only 5 per cent. Minor amputations may however be attempted for osteomyelitis of terminal phalanges without gangrene and for sharply localized gangrene at the tip of the digits when pulsations can be felt clearly in the dorsalis pedis and posterior tibial arteries High amputation is required for spreading infection extending gangrene or intractable rest pain with widespread occlusion

EMBOLISM

Dislodged fragments of centrally located thrombi may produce sudden occlusion of the peripheral arteries Emboli usually originate from mural or valvular thrombi in the left side of the heart and less commonly from an atheromatous ulcer in a large artery Predisposing factors include (1) change from auricular fibrillation to normal rhythm (2) bacterial endocarditis and (3) coronary occlusion with mural thrombosis Large emboli lodge most commonly at branchings of the larger arteries *viz* at the origin of the iliac arteries (saddle or rider embolus) at the junction of the femoral artery with the profunda femoris and at the junction of the subscapular and axillary arteries The embolus (1) stops blood flow through the vessel in which it lodges (2) induces widespread secondary vasospasm in

the affected extremity and (3) is followed within a few hours by secondary thrombosis below and sometimes above the point of obstruction

Symptoms and Signs —Onset is usually sudden with severe pain in the region where the embolus lodges, the sensation may resemble that of a blow on the extremity When large arteries are occluded fainting nausea vomiting abdominal pain and local tenderness may precede a shock like state The extremity is pallid and cold while paresthesias such as numbness or tingling develop rapidly Within one or two hours pain in the extremity is often agonizing sensation is absent and muscular weakness or paralysis has developed The initial pallor changes to blotchy cyanosis and if treatment is delayed massive gangrene follows with mummification, bleb formation and spotty vermilion discoloration of the skin Very small emboli produce local cyanosis with or without pain

On examination the extent of coldness and discoloration indicates roughly the size of the vessel affected but it must be remembered that ischemia from secondary vasospasm is added to that from embolic obstruction *per se* Arterial pulsation cannot be detected by finger or oscillometer distal to the embolus Anesthesia paralysis and absence of reflexes are found if large arteries are occluded The oscillometer histamine wheals and skin temperatures will indicate the boundary between normal and abnormal blood flow

Treatment —Early diagnosis is essential since the operation of embolectomy to be successful must be done within eight or ten hours after the embolus has lodged Embolectomy is less often necessary in the upper extremity where collateral circulation is good If the patient is seen early it is best to abolish the widespread reflex vasospasm before deciding definitely whether embolectomy is advisable or not The immediate results of operation are good but new emboli may appear and the mortality after operation is usually due to the underlying condition

In all cases vasoconstrictor tone should be relieved as soon as possible (1) by the paravertebral injection of procaine to block the sympathetic ganglia (2) by administering alcohol by mouth or papaverine hydrochloride intravenously and (3) by warming the body and the uninvolved extremities The affected limb should be placed in a thermo regulated cradle to prevent the burning and trauma which follow the indiscriminate use of uncontrolled heat Heparin is given intravenously to prevent secondary thrombosis The oral administration of dicoumarin for prolonged anticoagulant activity is still in the experimental stage Suction and pressure therapy, applied early and carefully at frequent intervals, is a useful adjuvant measure

The advisability of amputation will depend upon the degree to which collateral circulation fails to compensate for sudden organic occlusion the general condition of the patient and the underlying condition responsible for embolism

FROST BITE

Frost bite results from exposure to cold combined with prolonged physiologic peripheral vasoconstriction Simple exposure of the digits to cold produces local vasoconstriction which if the body is warm gives way periodically to protective reactive hyperemia If body temperature is reduced however physiologic increase in vasoconstrictor tone prevents further loss of body heat and at the same time abolishes this protective local reaction Maintaining body temperature is more vital to the organism than preserving digital tissue

Frost bite appears after prolonged exposure to wind and moist cold usually but not necessarily below 8° F General weakness and peripheral vascular disturbances are predisposing factors The local injury produced by cold ranges from simple erythema transient anesthesia and superficial bullae to persisting ischemia secondary thrombosis livid cyanosis and gangrene

Prophylactic measures include the wearing of warm dry clothing, only brief periods of exposure to cold with avoidance of smoking before and during exposure After local injury has developed the patient should be made warm as quickly as possible The affected parts may be massaged very gently for a few minutes only and then wrapped in sterile dressings and several layers of wool Too vigorous warming and reactive hyperemia may produce severe pain which can be alleviated by immersing the extremity for brief periods in water at 10° to 15° C If on the other hand vasodilatation is slow and incomplete vasodilator drugs (alcohol papaverine or others) and a thermoregulated cradle set at not more than 34° C will be helpful Direct heat especially if uncontrolled, and diathermy are to be avoided because excessive warmth produces pain with marked edema and greater tissue destruction

Suction and pressure therapy in brief repeated periods is helpful for prolonged ischemia Sepsis and gangrene may require amputation at levels depending upon the line of demarcation and the amount of secondary thrombosis

ARTERIOVENOUS FISTULA

Arteriovenous fistula refers to abnormal communications, single or multiple between arteries and veins by which arterial blood enters the vein directly without traversing a capillary network These fistulae are classified as (1) congenital usually multiple and present from birth and (2) acquired usually single and saccular arising after bullet or stab wounds involving an artery and a contiguous vein

Arterial blood following the path of least resistance rushes directly into the vein instead of through the corresponding capillary bed The thin walled veins are distended by the pressure transmitted from the artery through the fistulous opening and eventually become prominent and cirsoid Increased blood flow makes the tissues near the fistula abnormally warm while diminished capillary flow distal to the fistula produces

peripheral coldness and trophic changes Large fistulae impose a burden on the heart the output of which must be increased above normal by an amount proportional to the size of the fistula in order to maintain an efficient general circulation The low peripheral resistance tends to decrease diastolic blood pressure and increase systolic and pulse pressures Males and females are affected equally and any portion of the body may be involved

Symptoms and Signs —Patients complain of aching pain edema disfigurement from dilated veins or hypertrophied extremities and occasionally, cardiac symptoms such as palpitation substernal pain and dyspnea on exertion

On inspection the superficial veins are prominent under spongy subcutaneous tissue and venous pulsation can be felt unless the fistula is small or deeply placed Arterial pulsation is also increased and skin temperature is often elevated Local bruit and thrill occur frequently but not uniformly The tissues near the fistula may be tender more or less edematous and either red or slightly cyanotic The circumference of the extremity is increased by edema or true hypertrophy but bony structures are hypertrophied only if the fistula has been present before epiphyseal ossification occurred Distal to the fistula decreased capillary flow leads to the formation of shallow indolent ulcers rarefaction of bone and occasionally to unilateral arthritic changes Large fistulae elevate systolic blood pressure increase pulse pressure and lead to cardiac hypertrophy and even decompensation The heart rate is abnormally rapid during rest Temporary compression of the artery leading to a large fistula diminishes the heart rate but no effect is observed if the fistula is small

The oxygen saturation of blood removed from distended veins is greater than that of blood removed from corresponding veins in the opposite extremity Deeply placed fistulae require comparisons between blood samples from deeper veins Arteriography reveals the exact location number and size of the communications

Treatment —Single fistulae can be eradicated by ligating the involved artery and vein both above and below the fistula if adequate collateral circulation is available Multiple fistulae are much less amenable to surgical treatment If the arterial supply depends upon one large anomalous artery ligation of this vessel followed by stenosing injections of the dilated veins may be effective Ulcers edema and pain are relieved by applying supporting rubber bandages Amputation is required for large inoperable fistulae producing cardiac decompensation or gross deformity

DISEASES OF THE PERIPHERAL VEINS

The conditions affecting venous blood flow in the extremities may be divided into two categories (1) intrinsic disorders which are produced primarily by disease of the walls of the veins or by abnormality of their contained blood and (2) extrinsic disorders resulting secondarily from invasion or external pressure These various maladies are disabling in proportion to the grade of venous stasis that is produced (1) by anatomic blockage as in thrombosis and external pressure or (2) by hydrostatic forces as in varicose veins

VARICOSE VEINS

Varicose veins are caused (1) by constitutionally defective valves in association with postural strain usually of occupational type or (2) by any condition which obstructs venous blood flow and distends collateral veins over long periods of time especially pregnancy and pelvic or abdominal neoplasm The veins are distended and tortuous while chronic venous stasis produces local edema stabbing or aching pain indolent ulceration overgrowth of connective tissue and occasionally hemorrhage or ecchymosis

Prophylactic measures include the wearing of warm dry clothing only brief periods of exposure to cold with avoidance of smoking before and during exposure After local injury has developed the patient should be made warm as quickly as possible The affected parts may be massaged very gently for a few minutes only and then wrapped in sterile dressings and several layers of wool Too vigorous warming and reactive hyperemia may produce severe pain, which can be alleviated by immersing the extremity for brief periods in water at 10° to 15° C If on the other hand vasodilatation is slow and incomplete vasodilator drugs (alcohol papaverine or others) and a thermo regulated cradle set at not more than 34° C will be helpful Direct heat especially if uncontrolled, and diathermy are to be avoided because excessive warmth produces pain with marked edema and greater tissue destruction

Suction and pressure therapy in brief repeated periods is helpful for prolonged ischemia Sepsis and gangrene may require amputation at levels depending upon the line of demarcation and the amount of secondary thrombosis

ARTERIOVENOUS FISTULA

Arteriovenous fistula refers to abnormal communications, single or multiple between arteries and veins by which arterial blood enters the vein directly without traversing a capillary network These fistulae are classified as (1) congenital usually multiple and present from birth and (2) acquired usually single and saccular arising after bullet or stab wounds involving an artery and a contiguous vein

Arterial blood following the path of least resistance rushes directly into the vein instead of through the corresponding capillary bed The thin walled veins are distended by the pressure transmitted from the artery through the fistulous opening and eventually become prominent and cirsoid Increased blood flow makes the tissues near the fistula abnormally warm while diminished capillary flow distal to the fistula produces

from pneumonia, influenza or typhoid fever It may be produced by direct extension from local suppurative foci e g mastoiditis and osteomyelitis So called "resting phlebitis" in varicose veins may be reactivated periodically by trauma exercise or minor infection elsewhere Polycythemia vera and certain forms of anemia in which the coagulability of the blood is increased are frequently complicated by venous thrombosis without trauma or infection

Symptoms and Signs —Noninflammatory venous thrombosis occurs suddenly or gradually after exertion or slight contusion Edema and cyanosis appear rapidly but pain local tenderness and systemic symptoms are absent

The onset of true thrombophlebitis is usually sudden with mild or severe symptoms depending on the size of the vein involved Pain may be absent mild and localized or severe and throbbing through the whole extremity When the pelvic veins are obstructed abdominal pain faintness nausea or vomiting may appear suddenly and persist for some hours When a peripheral and superficial vein is affected the thrombosed vessel can usually be felt beneath the skin as a tender cord Local tenderness in the calf and pain on forced dorsiflexion of the foot suggest involvement of the deeper branches of the popliteal vein. Edema and mottled cyanosis are present if collateral venous drainage is poor but these signs are absent when small veins are obstructed and the collateral channels are adequate Arterial pulsation is normal and the extremity is not persistently cold Occasionally however in sudden extensive venous thrombosis vasospasm is so conspicuous temporarily that arterial embolism may be suspected but the oscillometer will detect arterial pulsation even when it is too feeble to be palpated Elevation of the extremity does not produce abnormal pallor on the contrary cyanosis may persist during elevation General malaise anorexia fever and leukocytosis appear shortly after onset and barring extension of thrombosis gradually disappear In migrating thrombophlebitis however several widely separated veins may be involved in succession healing in one location being associated with fresh thrombosis in a totally different region

The most serious complication of thrombophlebitis is pulmonary embolism which follows dislodgment of a thrombus shortly after it has formed and before organization has fixed it firmly in the vein of origin In general the greater the local tenderness and pain in the extremity the less is the danger of embolism since thrombi usually loosen before pronounced inflammatory reaction develops Large thrombi dislodged from the femoral iliac or pelvic veins commonly produce fatal pulmonary embolism, a frequent cause of sudden death after operation or deep pelvic irradiation Smaller emboli produce pulmonary infarction pleuritis bronchopneumonia or abscess

Repeated attacks of thrombophlebitis and continued venous stasis, with more or less lymphangitis cause edema fibrosis pigmentation and trophic ulceration and the eventual deformity in untreated cases may be extreme

Treatment —Since sluggish peripheral blood flow is an important predisposing factor bedridden patients can be protected from thrombophlebitis by passive movements and exercises postoperatively by avoiding dehydration and by frequent turning Additional protection has been sought by injecting heparin intravenously or more recently by giving dicoumarin orally but so far neither has been used routinely the latter especially being still in the experimental stage

Once thrombosis has developed the objects of therapy are (a) to prevent pulmonary embolism by loosened thrombus and (b) to relieve the edema before connective tissue overgrowth in the protein rich edema fluid produces permanent brawny organization Pulmonary embolism may occur suddenly before symptoms and signs of peripheral thrombosis appear Phlebotomy and removal of the thrombus (thrombectomy) have been advocated especially for simple noninflammatory thrombosis of large veins Such surgical treatment is contraindicated if diagnosis is late and if there is local inflammatory reaction However when the distal segments of superficial veins e g the long or short saphenous or the deep veins of the calf are thrombosed proximal ligation is a minor procedure which reduces the danger of pulmonary embolism

DISEASES OF THE PERIPHERAL VEINS

Intrinsic conditions	Congenital	Hypoplasia Hemangioma Arteriovenous fistula
	Mixed	Varicose veins (incompetent valves)
	Acquired	Traumatic Arteriovenous fistula Simple thrombosis (phlebothrombosis) Inflammatory Thrombophlebitis Thrombo-angiitis obliterans
	Degenerative	Phlebosclerosis
Extrinsic conditions	Invasion	Neoplasm tuberculosis
	Pressure	Neoplasm trauma anomalies gravid uterus

The extremities are warm and the arterial pulses normal Elevation of the foot produces no blanching but empties the veins rapidly unless obstruction is present when emptying is slow and incomplete Retrograde flow of blood past incompetent valves in the long saphenous vein is demonstrated by the Trendelenburg test The leg of the recumbent patient is elevated to empty the varices and then while firm pressure with the thumb or a tourniquet closes the proximal end of the long saphenous vein, the patient quickly assumes the standing position Sudden release of the saphenous vein will make the varices prominent and turgid within a few seconds if back flow is present If pressure is maintained for a longer time in the standing position dilated communications with incompetent deep veins can be identified In advanced stages the vein responsible for brawny induration and ulceration may be invisible under the deformity it has produced but careful palpation will usually detect the dilated vein Tapping a varix with the finger may produce a transmitted impulse in the long or short saphenous vein Perthes' test is helpful in demonstrating patency of the deep veins Venography has been advocated for doubtful cases Phlebosclerosis is common in chronic cases

Therapeutic measures include bed rest with elevation of the extremity rubber bandages sponge rubber dressings the gelatin boot injection of sclerosing solutions and high ligation or excision Acetyl β methyl choline by iontophoresis excision and skin grafting have been used successfully for treating chronic ulcers resisting other therapy

THROMBOPHLEBITIS

Thrombophlebitis is a form of venous obstruction by thrombosis which is secondary to local or distant infection and is accompanied by inflammatory reaction in the wall of the affected vein It is sometimes difficult to distinguish clinically between simple noninflammatory thrombosis (phlebothrombosis) and true (inflammatory) thrombophlebitis Pylephlebitis is described on pages 760 769

Etiology ordinarily consists of one or more of several predisposing factors viz (1) venous stasis associated with prolonged bed rest or external pressure (2) local injury of the endothelium by stretching contusion chemicals or bacteria, and (3) thrombophilia or changes in the circulating blood which favor coagulation Noninflammatory relapsing thrombosis may follow simple stretching or mild contusion over a vein True thrombophlebitis occurs during prolonged bed rest with associated infection *e g* after operations intravenous therapy, in the puerperium and during convalescence

hypoplasia of the lymphatic vessels and in its secondary form to obstruction by external pressure or repeated low grade inflammation

Primary lymphedema occurs more commonly in females Three forms are described (1) congenital lymphedema present at birth or developing shortly thereafter (2) lymphedema (praecox) appearing at or near puberty, and (3) Milroy s disease (hereditary tropho edema) or lymphedema of familial type The onset is gradual and symptomless except for the increasing size of the limb The edema pits easily at first and disappears when the limb is elevated but later owing to fibrosis pits with difficulty and is not relieved by elevation Low grade lymphangitis and cellulitis absent in the early stages often appear later and add to the original deformity

Secondary lymphedema may be noninflammatory or inflammatory The former is due to compression of main lymphatic trunks by neoplasm or scar surgical removal of lymph nodes fibrosis following irradiation or direct invasion of lymph vessels or nodes by neoplasm

Secondary lymphedema of the inflammatory type follows recurrent low grade lymphangitis In tropic and subtropic regions filariasis must be considered Each attack of lymphangitis produces additional edema which disappears only partially after acute inflammation subsides Recurrences at irregular intervals are due to reinfection from the exterior or to intermittent activity of foci in the extremity itself The edema fluid contains considerable protein and offers an excellent medium not only for recurrent bacterial invasion but also for overgrowth of connective tissue The skin finally becomes thick coarse folded and hard and the extremities are subject to indolent ulceration erysipeloid infection and excoriation so that the eventual deformity may be extreme well deserving the name elephantiasis

Treatment —Painstaking care in keeping the tissues free of edematous fluid will do much to avoid fibrosis and recurrent infection In the early stages frequent elevation of the extremity and assiduous use of elastic bandages or stockings will suffice Focal infection and obvious lesions such as epidermophytosis in the extremity should be eradicated Recurrent lymphangitis is best treated by rest sulfonamide drugs elevation of the extremity and hot moist dressings for comfort with resumed bandaging after the patient is again active Stock or autogenous vaccines and nonspecific protein therapy may be used to increase general resistance to the infective organism In advanced cases with fibrosis and resistant edema the Kondoleon operation and its modifications produce some relief

CIRCULATORY COLLAPSE AND SHOCK

Failure of the circulation results from a variety of causes The terms circulatory collapse and shock' are applied to circulatory failure in which the heart is not primarily at fault The heart cannot act as an efficient pump unless the venous inflow to it is adequate it cannot pump out blood which it does not receive In peripheral circulatory failure it is assumed that the venous return is inadequate because of some disturbance in the peripheral circulation and that if the venous return were made adequate the heart would function normally Thus from the physiologic viewpoint peripheral circulatory failure may be said to be present whenever the blood flow to the tissues becomes inadequate in the presence of a heart capable of sustaining a normal blood flow Homans summarizes the clinical picture of shock as follows (1) An appearance of pallor sometimes associated with slight cyanosis (2) a cold moist or sweaty skin (3) a rapid regular but thready pulse (4) rapid usually shallow respiration (5) restlessness and an appearance of anxiety which may change under unfavorable circumstances to dulness and lessened sensitiv

As soon as thrombophlebitis is suspected the patient should be kept at rest in bed with the affected extremity elevated to diminish edema Blocking the sympathetic ganglia by the paravertebral injection of procaine abolishes reflex vasospasm relieves pain and diminishes edema Anticoagulants as mentioned above can have no effect on existing thrombi but may be used to prevent propagation Local heat should be applied by means of a thermo regulated cradle Proximal venous ligation should be considered if the thrombus is extending into the thigh is suppurating or if a history of previous pulmonary embolism is obtained There is increasing tendency to shorten greatly the period of absolute bed rest because sluggish blood flow predisposes to development of new thrombi or propagation of the original thrombus

After temperature and pulse are normal the patient may sit up in bed unless activity is followed by return of symptoms or a rise in temperature Passive and later active movements of the affected extremity are started gradually to help recovery of muscle tone and to assist the function of collateral venous channels If edema still forms the limbs should be elevated nightly and when normal activity is resumed an elastic stocking should be worn until measurement of the extremity reveals no accumulation of edema fluid while the tissues are unsupported For relapsing phlebitis foci of infection should be eradicated and if latent phlebitis is itself a focus the responsible vessel should be excised For recurring thrombophlebitis autogenous vaccines are occasionally very useful while stock vaccines or nonspecific protein therapy are generally less effective Brawny swelling and induration may be somewhat relieved by vigorous massage and heat if there has been no recent phlebitis Gross deformity ulceration and infection may require amputation

DISEASES OF THE PERIPHERAL LYMPHATIC VESSELS

The lymphatic capillaries form a rich intercellular network and collect excess tissue fluid which as lymph is conducted by valved lymph channels of increasing size to regional lymph nodes and thence through trunk lymphatics to the subclavian veins The flow of lymph depends on muscular contraction respiratory movements and to a certain extent on gravity

LYMPHANGITIS

Lymphangitis refers to acute or chronic inflammation usually streptococcic in origin affecting the lymphatic vessels and the immediately adjacent tissues Advancing lymphangitis indicates that infection is spreading and is therefore a danger signal of special importance The path by which bacteria penetrate the skin cannot be discovered in some cases but usually local trauma trichophytosis or chronic ulcers are obvious portals of entry Slightly indurated red tender streaks appear in the skin of the leg or forearm and the regional lymph nodes in the knee, groin or axilla rapidly become swollen and tender Malaise chills fever increased pulse rate and leukocytosis indicate systemic reaction and possible blood stream infection Lymphangitis, always of grave import is especially dangerous in the ischemic tissues of patients with peripheral vascular disease Under these unfavorable conditions prompt high amputation is often required whereas when circulation is normal drainage of the original focus rest hot wet dressings and sulfonamide therapy will usually produce rapid recovery

E M LANDIS

LYMPHEDEMA

Lymphedema is a form of chronic bilateral or unilateral edema of the extremities due in its primary form probably to congenital

stimuli from the brain the blood drains into the dilated vessels the venous return to the heart becomes inadequate and arterial pressure falls precipitously The resulting cerebral ischemia may produce unconsciousness As noted below respiratory alkalosis is frequently a factor in producing the loss of consciousness

In the circulatory collapse induced by sodium nitrite or by infection the same two factors are operative namely the force of gravity and the relaxation of the venous side of the circulation In these cases the loss of venous tone is probably the result of the action of the drug or of the infection on the veins and venules. Under such circumstances when the patient is in the upright or sitting position more than the normal amount of blood is pooled in the relaxed venous system and circulatory collapse may result Studies of this type of circulatory collapse have shown that the arterioles are constricted to compensate for the decrease in effective blood volume and that further arteriolar constriction by drugs is not helpful

If the blood volume is decreased by hemorrhage vomiting or loss of plasma into the peritoneal cavity circulatory collapse may occur when the patient sits up In these cases the venous tone may not be decreased When the patient is in the erect or sitting position the shifting of a normal amount of blood into the lower portion of the body may decrease the venous return to the heart sufficiently to produce circulatory collapse

In certain patients a similar type of collapse occurs in the recumbent position Subjects who are bled when they are in the recumbent position may develop collapse which lasts for only a short time and from which they may recover without any demonstrable increase in blood volume Palpation of the abdomen in a patient with acute pancreatitis may repeatedly precipitate collapse In these patients the development of collapse may be of more serious import than in patients in whom circulatory failure is precipitated by gravity

Patients frequently develop circulatory collapse after *spinal anesthesia* This is the result of vascular relaxation in the lower extremities and splanchnic areas This relaxation includes the arterial as well as the venous side of the circulation The dilated vascular bed pools blood and decreases the venous return to the heart

Fainting is not always secondary to the cerebral ischemia which results from a *marked decrease in cardiac output* Many of the stimuli which cause circulatory collapse also produce reflex overbreathing This hyperventilation lowers the carbon dioxide content of the arterial blood and alkalosis results This alkalosis causes a disturbance in cerebral metabolism which may lead to unconsciousness In many instances syncope occurs because of the combined effects of circulatory collapse and respiratory alkalosis.

In the *treatment* of circulatory collapse it is important to make use of gravity in aiding the venous return to the heart. The patient is placed in the *recumbent position* and if possible the foot of the bed is elevated In most instances this will produce a rapid increase in the arterial pressure and the pulse will become of good volume In the treatment of collapse which occurs soon after the induction of spinal anesthesia the head down position is contraindicated if the anesthetic used has a specific gravity greater than that of the spinal fluid The *Trendelenburg position* may be used however after sufficient time has elapsed to allow most of the anesthetic drug to be fixed in the tissues

Drug therapy is frequently not needed because recovery may be quite rapid In patients with severe infection or with a considerable decrease in blood volume recovery of the circulation may be much slower If pain is present morphine sulfate in 15 mg (gr ¼) doses is useful Except in collapse occurring during spinal anesthesia the arterioles are usually constricted and drugs which accentuate this constriction without increasing the venous return are usually ineffective in preventing the onset of collapse In laboratory experiments paredrinol sulfate a drug that increases the venous tone when administered in doses of 25 mg (gr ⅜) intramuscularly or 30 to 50 mg (gr ½ to ¾) orally has been effective in preventing the onset of this type of collapse Epinephrine and pitressin were ineffective During spinal anesthesia ephedrine sulfate

ity, (6) thirst, (7) a variable amount of nausea and sometimes vomiting To this picture there are many exceptions Some patients do not show pallor or lividity, in others the blood pressure is well maintained in still others the heart rate is not increased —indeed it may be slower than normal In other patients mental dulness may be absent Thirst is quite commonly *absent* The rectal temperature may be elevated

There is frequently no clear cut distinction made between collapse and shock It has been suggested that the terms 'primary shock or collapse' be applied to sudden short lived insufficiency of the peripheral circulation, and that the terms ' secondary shock" or shock" be used when the circulatory insufficiency is more prolonged This distinction has not been in general use Nevertheless it is a useful one because the *prognosis* and therapy of sudden transitory insufficiency of the circulation is frequently different from that of more prolonged peripheral circulatory failure. The term ' collapse ' is preferred to primary shock because it is more general Primary shock associated with wounds is one type of collapse In this discussion the term peripheral circulatory failure will include all examples of generalized circulatory failure in which the heart is capable of functioning normally Circulatory collapse will include all forms of *sudden*, short lived peripheral circulatory failure, shock" will include the cases of peripheral circulatory failure of longer duration

The Mechanism of Peripheral Circulatory Failure—Investigators agree that the fundamental mechanism of peripheral circulatory failure is a disproportion between the circulating blood volume and the size of the vascular bed This disproportion may occur in two ways because of (1) a decrease in the circulating blood volume so that the vascular bed is not adequately filled and (2) an increase in the size of the vascular bed so that the normal blood volume does not fill the dilated vascular bed This vasodilatation may result from fever infection or drugs or it may be of reflex origin In any case the venous return to the heart becomes inadequate and the cardiac output decreases

Circulatory Collapse—Acute transient peripheral circulatory collapse is very common It may occur in normal subjects at the *sight of blood* during a venepuncture or if the subject is hurt or becomes nauseated It *frequently occurs* in ambulatory patients who have had a cold or infection in the hospital it is seen in patients with pneumonia or other infections who sit up to use the bed pan or in persons who stand up too soon after a bout of fever or after the loss of blood It occurs from time to time when acutely ill patients are moved, or it may be precipitated by palpation of a tender abdomen

Regardless of the *precipitating cause*, the *clinical picture* is the same The patient becomes deathly pale, breaks out in a cold sweat, and complains of epigastric distress and nausea The field of consciousness becomes narrowed, objects become hazy and dark and the subject may lose consciousness At the onset of the attack the heart rate usually becomes rapid but as the arterial pressure falls the heart rate frequently decreases At the height of the collapse the heart rate may be approximately 40 and the radial pulse impalpable If the subject is held in the upright position he may develop clonic movements of the arms and legs

Circulatory collapse in these cases results primarily from *pooling of blood* in a dilated circulatory bed The blood volume is not decreased in the normal subject with circulatory collapse precipitated by *unpleasant* visual stimuli pain or nausea The marked fall in arterial pressure indicates that the peripheral vascular bed has dilated so that the normal blood volume no longer fills the dilated vascular bed and the venous return to the heart becomes inadequate There are two factors operative in this type of collapse The first one is gravity, the second is the stimuli to the central nervous system When the patient is in the upright or sitting position the venous pressure in the parts of the body below the heart is increased by the force of gravity This increased venous pressure makes the cross section area of the venous bed below the heart larger when the patient is in the upright position than when he is in the recumbent position When the tone of these vessels below the level of the heart is suddenly decreased as a result of

stimuli from the brain the blood drains into the dilated vessels the venous return to the heart becomes inadequate and arterial pressure falls precipitously The resulting cerebral ischemia may produce unconsciousness As noted below respiratory alkalosis is frequently *a factor in producing the loss of* consciousness

In the circulatory collapse induced by sodium nitrite or by infection the same two factors are operative namely, the force of *gravity and the relaxation of the venous side* of the circulation In these cases the loss of venous tone is probably the result of the action of the drug or of the infection on the veins and venules. Under such circumstances *when the patient is in the upright* or sitting position more than the normal amount of blood is pooled in the relaxed venous system and circulatory collapse may result Studies of this type of circulatory collapse have shown that the arterioles are constricted to compensate for the decrease in effective blood volume and that further arteriolar constriction by drugs is not helpful

If the blood *volume is decreased* by hemorrhage vomiting, or loss of plasma into the peritoneal cavity circulatory collapse may occur when the patient sits up In these cases the venous tone may not be decreased When the patient is in the erect or sitting position the shifting of a normal amount of blood into the lower portion of the body may decrease the venous return to the heart sufficiently to produce circulatory collapse

In certain patients a similar type of collapse occurs in the recumbent position. Subjects who are bled when they are in the recumbent position may develop collapse which lasts for only a short time and from which they may recover without any demonstrable increase in blood volume Palpation of the abdomen in a patient with acute pancreatitis may repeatedly precipitate collapse In these patients the development of collapse may be of more serious import than in patients in whom circulatory failure is precipitated by gravity

Patients frequently develop circulatory collapse after *spinal anesthesia* This is the result of vascular *relaxation in* the lower extremities and splanchnic areas This relaxation includes the arterial as well as the venous side of the circulation The dilated vascular bed pools blood and decreases the venous return to the heart.

Fainting is not always secondary to the cerebral ischemia which results from a *marked decrease in cardiac output* Many of the stimuli which cause circulatory collapse also produce reflex overbreathing This hyperventilation lowers the carbon dioxide content of the arterial blood and *alkalosis results This alkalosis causes a disturbance* in cerebral metabolism which may lead to unconsciousness In many instances syncope occurs because of the combined effects of circulatory collapse and *respiratory alkalosis.*

In the *treatment* of circulatory collapse. it is important to make use of gravity in aiding the venous return to the heart. The patient is placed in the *recumbent position* and if possible the foot of the bed is elevated In most instances this will produce a rapid increase in the arterial pressure and the pulse will become of good volume In the treatment of collapse which occurs soon after the induction of spinal anesthesia the head down position is contraindicated if the anesthetic used has a specific gravity greater than that of the spinal fluid The *Trendelenburg position* may be used however after sufficient time has elapsed to allow most of the anesthetic drug to be fixed in the tissues

Drug therapy is frequently not needed because recovery may be quite rapid In patients with severe infection or with a considerable decrease in blood volume recovery of the circulation may be much slower If pain is present morphine sulfate in 15 mg (gr ¼) doses is useful Except in collapse occurring during spinal anesthesia the arterioles are usually constricted and drugs which accentuate this constriction without increasing the venous return are usually ineffective in preventing the onset of collapse In laboratory experiments paredrinol sulfate a drug that increases the venous tone when administered in doses of 25 mg. (gr ⅜) intramuscularly or 30 to 50 mg (gr ½ to ¾) orally has been effective in preventing the onset of this type of collapse *Epinephrine and pitressin* were ineffective During spinal anesthesia ephedrine sulfate

given subcutaneously in doses of 25 to 50 mg (gr ⅜ to ¾) is at least partially effective in preventing a drop in blood pressure Altschule and Gilman have reported that paredrine given intramuscularly in doses of 10 to 20 mg is likewise effective in preventing a drop of blood pressure during spinal anesthesia

Shock—More prolonged failure of the peripheral circulation produces the classical clinical picture of shock In collapse the duration of the circulatory insufficiency is short, in shock it is more prolonged It is generally agreed that in shock the circulatory failure is frequently related to a decrease in blood volume as a result of external hemorrhage dehydration or loss of plasma into the peritoneal cavity or into traumatized tissues In addition many observers believe that infection and the breakdown products from injured tissues play an important role not only in causing pooling of blood by vasodilatation but also in producing a decrease in plasma volume by increased capillary permeability Monographs by Blalock Cannon Moon Scudder and Wiggers give reviews of the current opinions on etiology of shock

When the circulatory failure is caused by dehydration the administration of physiologic saline restores the plasma volume to normal and the circulation improves If protein is lost from the plasma either as a result of hemorrhage or of increased capillary permeability at the site of a burn or injury the administration of physiologic saline may not restore the plasma volume to a level adequate to maintain a normal circulation In the case of hemorrhage transfusion of whole blood is indicated In the case of plasma loss into injured tissues plasma is needed The loss of plasma into the tissues may be lessened by external pressure or by cooling the part Elevation of the foot of the bed aids the venous return to the heart Infection should be prevented, or if present it should be combatted by appropriate chemotherapy Pain is controlled by the administration of morphine Usually the administration of sympathomimetic drugs is of little therapeutic value even though a transient rise in blood pressure may be obtained

All observers in World War I emphasized the importance of keeping the patient warm and in the case of broken bones the necessity for splinting and immobilization before moving the patient In certain patients however it may be useful to cool an injured extremity This decreases the metabolism of the cells and lowers the blood flow As the blood flow decreases, less protein leaks through the injured capillaries into the traumatized tissues In civilian practice the importance of treating shock before moving the patient for roentgen ray examination or before undertaking any operative procedure is universally recognized Cannon stresses the importance of restoring the blood volume before using an anesthetic and points out the danger of even slight anoxemia in cases of shock

Terminal Circulatory Failure—If trauma is severe enough or if infection cannot be controlled the circulation eventually fails regardless of treatment In this terminal picture hemoconcentration plays little part because it will occur even if the blood volume is maintained by continuous transfusion The relative importance of the central nervous system of the peripheral vascular system and of the heart in this terminal picture is not clear This problem needs to be elucidated by more clinical observations

DISEASES OF THE DUCTLESS GLANDS

INTRODUCTION

The author won't write the conventional introduction. He won't give the Greek derivation for the word "hormone" coined by Starling; he won't discuss the experiments of Claude Bernard which lead to the conception of an internal secretion; he won't delve into the earliest beginnings of Endocrinology which had as their *raisons d'etre* such ends as the procurement of manpower for the harem, the salvaging of a male soprano voice for the choir, the increased palatability that a rooster attains when he turns into a capon, and so on; he won't trace experimental Endocrinology from 1849 when Berthold studied the effect of the gonads on the secondary sex characteristics of fowl down to the present 1943 when Reichstein synthesized corticosterone from the author knows not what (military "secret"!); no, he won't even list the names of describers of various endocrine syndromes—Addison with Addison's Disease in 1855 down to, shall we say, the almost simultaneous elucidation of hyperparathyroidism in 1928 by Mandl and Du Bois.

Instead, he will discuss what is Endocrinology with special emphasis on what is not Endocrinology and then will comment on certain other aspects of the subject.

What Is Endocrinology?—Endocrinology is an indivisible division of Internal Medicine and has to do with certain glands or tissues which secrete highly specific substances into the blood stream for use by other tissues. The only important thought in the above definition is contained in the word "indivisible." It is impossible to separate Endocrinology from Internal Medicine; by the same token it is impossible to be an endocrinologist without being an internist. The physician who calls himself an endocrinologist and confines his interests to such unfortunate members of society as might appear in the sideshow of a circus never realizes that pneumonia, a broken leg and a bad burn involve important changes in adrenal cortical function (cf. "Alarm Reaction" of Selye); that the disturbance in homeostasis occasioned by chronic renal insufficiency is ameliorated by a secondary hyperparathyroidism; that the somatotropic action of testosterone propionate may be made use of in many conditions other than male hypogonadism, and so on.

The author resents the tendency to limit the scope of Endocrinology to those disorders of the internal secretions which are not clearly understood. Thus once some division of Endocrinology such as diabetes is put on a firm footing, it is removed from the section on Endocrinology to the section on Metabolic Diseases.

What Isn't Endocrinology?—Certain conditions often considered to be endocrinological are probably not so at all.

First in order of frequency comes the fat boy who is slightly late in sexual development and whose genitalia are obscured by excess of fat. This patient, nine times out of ten, is labeled as Fröhlich's Syndrome, whereas in point of fact he is just a fat boy, whatever that is. If left alone, he will develop normally sexually and very frequently will cease to be fat after puberty. True Fröhlich's Syndrome is exceedingly rare and difficult to diagnose before the age of normal onset of puberty.

Then there comes the child that does not do well in school. There is a feeling among would-be progressive educators that such a situation demands a survey by an endocrinologist. In the author's experience there is only one endocrine abnormality which leads to mental retardation, namely cretinism. The diagnosis of this condition is a problem for the obstetrician and the pediatrician, not for the endocrinologist. If it is not made in the first few weeks or at the most, months of life, the damage is already done and one might just as well not make the diagnosis. Parenthetically it might be added that every physician should suspect cretinism in any child with an umbilical hernia at birth which persists after the first few weeks of life. Even juvenile myxedema is not asso-

given subcutaneously in doses of 25 to 50 mg (gr ⅜ to ¾), is at least partially effective in preventing a drop in blood pressure Altschule and Gilman have reported that paredrine given intramuscularly in doses of 10 to 20 mg is likewise effective in preventing a drop of blood pressure during spinal anesthesia

Shock —More prolonged failure of the peripheral circulation produces the classical clinical picture of shock In collapse the duration of the circulatory insufficiency is short, in shock it is more prolonged It is generally agreed that in shock the circulatory failure is frequently related to a decrease in blood volume as a result of external hemorrhage dehydration or loss of plasma into the peritoneal cavity or into traumatized tissues In addition many observers believe that infection and the breakdown products from injured tissues play an important role not only in causing pooling of blood by vasodilatation but also in producing a decrease in plasma volume by increased capillary permeability Monographs by Blalock Cannon Moon Scudder and Wiggers give reviews of the current opinions on etiology of shock

DISEASES OF THE DUCTLESS GLANDS

INTRODUCTION

The author won't write the conventional introduction He won't give the Greek derivation for the word hormone coined by Starling he won't discuss the experiments of Claude Bernard which lead to the conception of an internal secretion he won't delve into the earliest beginnings of Endocrinology which had as their *raisons d'etre* such ends as the procurement of manpower for the harem the salvaging of a male soprano voice for the choir the increased palatability that a rooster attains when he turns into a capon and so on he won't trace experimental Endocrinology from 1849 when Berthold studied the effect of the gonads on the secondary sex characteristics of fowl down to the present 1943 when Reichstein synthesized corticosterone from the author knows not what (military secret !), no he won't even list the names of describers of various endocrine syndromes —Addison with Addison's Disease in 1855 down to shall we say the almost simultaneous elucidation of hyperparathyroidism in 1926 by Mandl and Du Bois

Instead he will discuss what is Endocrinology with special emphasis on what is not Endocrinology and then will comment on certain other aspects of the subject.

What Is Endocrinology?—Endocrinology is an indivisible division of Internal Medicine and has to do with certain glands or tissues which secrete highly specific substances into the blood stream for use by other tissues The only important thought in the above definition is contained in the word indivisible It is impossible to separate Endocrinology from Internal Medicine by the same token it is impossible to be an endocrinologist without being an internist The physician who calls himself an endocrinologist and confines his interests to such unfortunate members of society as might appear in the sideshow of a circus never realizes that pneumonia a broken leg and a bad burn involve important changes in adrenal cortical function (cf Alarm Reaction of Selye) that the disturbance in homeostasis occasioned by chronic renal insufficiency is ameliorated by a secondary hyperparathyroidism that the somatotropic action of testosterone propionate may be made use of in many conditions other than male hypogonadism, and so on

The author resents the tendency to limit the scope of Endocrinology to those disorders of the internal secretions which are not clearly understood Thus once some division of Endocrinology such as diabetes is put on a firm footing it is removed from the section on Endocrinology to the section on Metabolic Diseases

What Isn't Endocrinology?—Certain conditions often considered to be endocrinological are probably not so at all

First in order of frequency comes the fat boy who is slightly late in sexual development and whose genitalia are obscured by excess of fat This patient nine times out of ten is labeled as Frohlich's Syndrome whereas in point of fact he is just a fat boy whatever that is If left alone he will develop normally sexually and very frequently will cease to be fat after puberty True Frohlich's Syndrome is exceedingly rare and difficult to diagnose before the age of normal onset of puberty

Then there comes the child that does not do well in school There is a feeling among would be progressive educators that such a situation demands a survey by an endocrinologist In the author's experience there is only one endocrine abnormality which leads to mental retardation namely cretinism The diagnosis of this condition is a problem for the obstetrician and the pediatrician not for the endocrinologist If it is not made in the first few weeks or at the most months of life the damage is already done and one might just as well not make the diagnosis Parenthetically it might be added that every physician should suspect cretinism in any child with an umbilical hernia at birth which persists after the first few weeks of life Even juvenile myxedema is not asso

ciated with retarded mentality To be sure long standing hypoparathyroidism leads to epileptic seizures and secondary mental retardation The author has seen in consultation a number of children with poor school records and to date has been unable to make an endocrinologic diagnosis on any of them He is impressed by the fact that many of them have been mirror readers'

A third type of case sent to the endocrinologist is the patient with some congenital disorder of the germ plasm such as mongolian idiocy Laurence Moon Biedl syndrome and so on Just why such conditions should be confused with endocrinopathies is not very clear It is probably connected with the belief (v supra) that anything which is not fully understood belongs to Endocrinology

Finally there are the patients with alopecia areata The endocrines have something to do with certain types of hair these patients have too little hair therefore they are sent to the endocrinologist However the fact that this condition starts by being spotty is strong evidence against an endocrinologic etiology It makes no difference that one spot may enlarge to the point where it covers the whole body the disease is still a spotty one Endocrinologic diseases are generalized not localized hormones do not stop in the midline or proceed down one limb and not the other, etc For example Paget s disease of bone is not *endocrinologic since it is not generalized* Though it involves 95 per cent of the skeleton, there will still be a sharp demarcation between the uninvolved part and the Paget s disease Postmenopausal osteoporosis on the other hand may be confined to the spine and pelvis and still be a generalized disease since here there is a rhyme and a reason to the distribution This discussion concerns the *primary* lesion produced by an endocrinopathy Secondary complications can be *spotty* (*e g* gangrene of the toe in diabetes bone cyst with hyperparathyroidism)

Failure of End Organs to Respond to Hormones—Since a hormone acts somewhere it is obvious that one might get very much the same clinical syndrome from failure of the end organ to respond to the hormone as one would get with absence of the hormone itself For example let us take pseudohypoparathyroidism Patients with this condition have the clinical and chemical findings that one associates with hypoparathyroidism but *they fail to respond* to parathyroid hormone and their parathyroid glands not only are not absent but may be hyperplastic (unpublished data) A second example is the failure of the American Indian to develop a beard Recently a patient presented himself his only complaint being failure to develop a beard Elaborate studies were carried out with uniformly normal results Finally some one had the wit to inquire about the patient s ancestry and *found that he was part Indian*

A Caution as to the Use of Pituitary Extracts—Because of the danger of antibody formation the author disapproves of the parenteral use of pituitary extracts He may be overconservative in this respect There is considerable evidence however that these extracts which contain proteins are strongly antigenic this results in the formation of antibodies which inhibit the further action of the injected hormone This in itself would not be so bad if it were not for the fact that the antibodies may also neutralize the patient s own pituitary hormones Dr Kenneth W Thompson at Yale has a dog named Alice which received pituitary extracts and which developed many of the symptoms of panhypopituitarism Other dogs similarly treated developed this same syndrome and showed at autopsy large pituitary glands which *from their histological appearance* (castration and thyroidectomy cells) were in all probability producing an excess of pituitary hormones This word of caution does not apply to chorionic gonadotropin which is strongly antigenic in rabbits but not in man presumably because its origin from the human placenta makes it homologous When a satisfactory preparation of follicle stimulating hormone is obtained from the urine of women after the menopause it too will probably be safe to use

Oophorectomy—The author feels that needless oophorectomy constitutes one of the greatest faults in medical practice A normally functioning ovary *needless to say* is most essential for the future physical and mental well being of a young woman Satisfactory as replacement therapy is it will not produce ova or be a substitute for mother-

hood There are two chief reasons for unnecessary ovarian surgery

The general surgeon does not realize that the normally functioning ovary is a cystic organ he performs an exploratory laparotomy for some sort of abdominal pain and finds nothing but cystic ovaries out they come For some reason the surgeon is never sued for malpractice because of this the story would be very different if under somewhat analogous conditions castration was resorted to in the male *Metropathia hemorrhagica* is the second big cause for unnecessary removal of the ovaries This interesting condition can be treated medically in almost all instances.

Even after the menopause the author disapproves of oöphorectomy He feels that the ovary still functions to a certain extent after the periods have ceased and that one sees more severe osteoporosis following an artificial menopause than after a physiologic one

Fat Distribution —Considerable space has been wasted in textbooks and writings on endocrinology about the distribution of fat. In the writer s opinion there are fat people and thin people but with one exception the distribution of fat is of no diagnostic significance The one exception is in Cushing s Syndrome where there is a tendency for the face to be round (moon faced) this roundness is probably due to a tendency to deposit fat in this region However that a propensity to deposit fat around the hips or on the lower extremities or diffusely throughout the body or where you will has any diagnostic significance is most unlikely it almost certainly has nothing to do with pituitary disease

Practical versus "Theoretical" Knowledge —The subject matter of this paragraph is applicable to all Internal Medicine but especially to Endocrinology The author is frequently asked in giving a talk to make it practical and not too theoretical By practical is usually meant therapeutic by theoretical is usually meant fundamental The author has no patience with such a philosophy One cannot possibly practice good medicine and not understand the fundamentals underlying therapy Very few of any rules for therapy could be more than 90 per cent correct If one does not understand the fundamentals one does more harm in the 10 per cent of instances where the rules do not apply than one does in the 90 per cent where they do apply The same policy carries over to medical education There are those who advocate medical schools which will turn out practical physicians rather than theorists. But they end by turning out a poorer grade of doctors and as in the case of eggs there is no such thing as a poor doctor, they are either good or bad

DISEASES OF THE THYROID GLAND

Clinical classification

Colloid goiter simple goiter struma Large thyroid acini overfilled with colloid

Adenoma Nodular goiter Benign tumor in the thyroid gland

(a) *Without systemic effects*

(b) *With hyperthyroidism* toxic adenoma

Exophthalmic goiter Graves disease Basedow s disease thyrotoxicosis hyperthyroidism

Thyroiditis Acute or chronic inflammation of the gland

Myxedema Diminished activity of the thyroid in adults hypothyroidism

Cretinism Inadequate activity of the thyroid in children with retardation of growth

Malignant disease

The Committee on Classification of the American Association for the Study of

Goiter has recommended the following tentative clinical classification

Type 1 Nontoxic diffuse goiter
Type 2 Toxic diffuse goiter
Type 3 Nontoxic nodular goiter
Type 4 Toxic nodular goiter

This is a simple grouping based on easily recognizable signs and symptoms but it has not yet been generally adopted The chief thing to remember is that simple goiter may be diffuse or nodular and that hyperthyroidism may occur in a gland with or without nodules

The various manifestations of diseases of the thyroid gland are greatly simplified if we consider them in the light of our knowledge of the function of this organ It serves *as a storehouse of iodine and elaborates* iodine containing substances the most important being thyroglobulin and the hormone thyroxin which have a controlling influence on growth and metabolism Recent work has shown that the thyrotropic hormone of the anterior lobe of the pituitary has an influence on thyroid activity There is an interrelationship between all of the ductless glands

As might be expected diseases of this gland are most frequent in districts where the iodine content of food and water is low but this deficiency is not the only factor as many cases appear in regions where iodine is abundant Webster lists the important conditions which increase the need of the body for thyroxin and therefore increase the iodine utilization (1) pregnancy (2) puberty (3) infectious diseases (4) Graves disease (5) pituitary disorders which bring about an increased secretion of the thyrotropic hormone (6) foods which depress tissue oxidation and thus increase the demand for thyroxin as in the simple goiter produced by the injection of cyanide or the feeding of cabbage and other vegetables with a high content of this goitrogenic substance If for any reason the iodine content of the gland falls below the normal minimum (0 1 per cent of dry substance) the organ is stimulated its blood supply is increased and the cells lining the alveoli hypertrophy Hyperplasia of the cells follows with infoldings which fill the spaces left by the decreasing colloid material Usually involution to the normal gland structure takes place with some increase in size If the previous hyperplasia has been marked typical colloid goiter results with large alveoli distended with colloid Occasionally physiologic exhaustion sets in with resulting atrophy If stimulated by thyrotropic hormone or some other substance the gland instead *of involuting* may develop a greatly increased blood supply with many infoldings of hyperplastic cells which replace the diminishing poorly staining *iodine-impoverished* colloid As a result of this glandular stimulation hyperthyroidism develops

Eugene F DuBois

COLLOID GOITER

Definition —Colloid or simple goiter is an enlargement of the thyroid gland generally diffuse and symmetric sometimes nodular which usually starts at the age of puberty The alveoli of the gland are distended by an excessive deposit of colloid The function is normal and the symptoms due merely to enlargement

Occurrence —Goiter is common in certain *mountainous regions* and on the sites of old glacial ice fields The incidence is high in some of the valleys of the Alps Pyrenees and Himalayas also in parts of Austria southern Germany and England In North America it is found chiefly in the northwest in the Great Lakes Basin and in the valley *of the upper Mississippi The examination* of recruits for the first World War showed that twenty one to twenty seven individuals per 1000 were affected in the states of Idaho Oregon Washington and Montana while along the eastern seacoast only two to five per 1000 had simple goiter

Etiology —The disease was *familiar* to the ancients as might be expected from its striking characteristics Its association with the water supply has long been recognized even by savage tribes although definite proof was lacking until the brilliant studies of Marine and his co workers demonstrated that this form of goiter is *due to an absolute* or relative *deficiency of iodine* in the water and food Analyses have proved that goiter *may* sometimes affect as many as half the inhabitants in the parts of our country where the water and local vegetables contain little

iodine. And this has been found to be true in other goitrous regions of the world Such districts are usually rather far inland and it may be supposed that the iodine has been leached out of the soil Near the seacoast iodine is abundant in the water and plants and goiter is therefore relatively uncommon

Certain it is that Marine and his associates have been able to reduce tremendously the incidence of goiter in some of the lake district states by administering to school children small doses of iodine twice a year Even more striking results are being obtained in Switzerland

Preventive treatment should be applied especially to girls since goiter is about five times more common in females than in males The swelling of the neck usually makes its first appearance at the time of puberty and tends to disappear by the age of twenty five or thirty There is a distinct relationship to the *sex glands* and the enlargement may increase with menstruation or pregnancy It is particularly important that pregnant women should have a sufficient supply of iodine in order to prevent cretinism in the offspring

Morbid Anatomy—In colloid goiter the thyroid gland is diffusely enlarged It is firm and on section is of a reddish amber color and contains acini distended with colloid On microscopic examination it is found that the acini vary greatly in size most of them being distended with normally stainable colloid The epithelial cells are of low cuboidal shape and there may be spriglike projections which are the remnants of previous infoldings of epithelium Marine believes that in these glands there has been first a diminished iodine store and second a period of stimulation with hyperplasia The colloid stage is a resting phase in which the function of the gland is practically restored to normal Adenomas are frequently present in colloid goiter causing one or more nodules Other nodules may be formed by large cysts with areas of calcification In some instances the enlarged gland presses on the neighboring organs obstructs the trachea and extends downward into the thoracic cavity The percentage of iodine contained in the goitrous gland during the resting stage may be normal but is usually diminished The functional ability of the gland is also usually normal but some patients give evidence of a slightly diminished thyroid secretion

Symptoms—Enlargement of the neck is the first noticeable sign Later there may be a sense of fulness and if there be pressure on the trachea difficulty in breathing during exertion As a rule the gland is firm and symmetrically enlarged though it may be nodular and asymmetric on account of adenomata Occasionally patients are seen in whom the swelling causes a most unsightly disfigurement Constitutional symptoms are lacking and the basal metabolism is almost always within normal limits Simple goiter rarely develops into Graves disease or myxedema

Diagnosis—Confusion in diagnosis sometimes results from the combination of a diffuse colloid goiter and effort syndrome (neurocirculatory asthenia) or some other nervous manifestations resembling *exophthalmic goiter* The differentiation can be made by a careful analysis of the symptoms with especial attention to the pulse rate during complete rest or sleep A determination of the basal metabolism is of great help The *adenomas* can be distinguished from diffuse goiter by the presence of nodules but it must be remembered that many nodules are chiefly colloid material some true benign adenomas and some malignant

The possibility of *intrathoracic goiter* should always be borne in mind if there are any symptoms suggesting the presence of an abnormal mass beneath the manubrium

Prophylaxis—Preventive treatment should be used in all regions in which endemic goiter is prevalent Iodine may be added to the drinking water or to the table salt in the proportion of 10 mg of potassium iodide per kilogram of table salt There is an objection to the generalized treatment of a community on the ground that it is wasteful and some physicians still believe that if too large an amount is used it may result in the production of hyperthyroidism in predisposed adults A better plan is the individual administration of chocolate tablets* containing 5 to 10 mg of iodine once

* Examples of these are Tablets Iodo-Casein with Chocolate (Mulford) N.N.R and Chocolate Tablets Iodostarine-Roche, N.N.R. Each tablet contains 0 01 Gm iodine

a week or 1 or 2 ounces of syrup of hydriodic acid in divided doses given twice each year Means uses as prophylactic 1 drop of Lugol's solution once a week The most important groups to treat prophylactically are pregnant women particularly those who have had goiter in adolescence, and school children especially the girls

Treatment —In America the simple goiter found in young people usually increases in size for several years and then decreases until by the age of twenty five it has almost disappeared Treatment with iodine sometimes helps regression in the young but the results are disappointing in older subjects This treatment may diminish the colloid portions of a large struma causing the adenomas to become more apparent

The advisability of preliminary treatment with thyroid has been questioned but some believe that with young subjects the best results are obtained by using first the standard U S.P desiccated thyroid* in doses of 1½ to 3 grains (0 1–0 2 Gm) daily for a period of two weeks if there has been no change in pulse or weight or other evidences of hyperthyroidism the same treatment may be repeated Then after an interval of one or two weeks small doses of iodine are started for example 30 to 60 minims (2–4 cc) of syrup of hydriodic acid daily for two or three weeks The treatment should be repeated three times during the year Large amounts of iodine may cause at first such a rapid accumulation of colloid in the gland that it becomes firm and painful

Surgical removal is desirable if there be much deformity or any serious pressure

Eugene F DuBois

* Lugol s Solution Compound Solution of Iodine U.S.P contains iodine 5 per cent and potassium iodide 10 per cent One cc of Lugol s Solution contains 126.5 mg of iodine

Syrup of Hydriodic Acid contains about 1 4 per cent of hydriodic acid One cc contains about 14 mg of iodine

Thyroid U S P Desiccated Thyroid Glands contain about 0 2 per cent of iodine (0 17–0 22 per cent)

Means has found that it makes little difference what form of iodine is given except, of course in the thyroid preparations Comparing these preparations in his experience the following are of equal calorigenic effect in myxedema patients 1½ grains (0 1 Gm) of U S P (Armour Lederle Lilly etc) thyroid 1 grain (0 065 Gm) of Parke Davis thyroid 5 grains (0 3 Gm) of Burroughs Wellcome thyroid or 0.35 mg of pure thyroxin

ADENOMA

Adenomatous enlargement of the thyroid gland usually causes no constitutional symptoms, but in certain cases is associated with hyperthyroidism

Morbid Anatomy —There are in the thyroid tissue rests which probably represent an excess of thyroid not ordinarily needed by the organism Normally these are slowly destroyed but under certain stimuli they react and grow Most of these rests are of the adult type having been fully differentiated others remain fetal in type When the whole gland is stimulated by lack of iodine these fetal rests may develop into adenomas of a type which depends upon the differentiation of the cell rest at the time of stimulus They may pass through the stages of hypertrophy and hyperplasia and then either atrophy or by involution reach the colloid resting stage The anatomic picture, therefore depends upon two factors the developmental stage of the original cell rest and the stage of activity of the adenoma The picture is further complicated by the fact that the term *adenomatous growth* includes a range of conditions extending from a more or less diffuse uniform hyperplasia to a well defined encapsulated mass As a rule adenomas of the adult type (simple adenomas) have poorly developed capsules Fetal adenomas which are benign growths are more frequently multiple resembling large lymphoid foci they contain no visible colloid and the stroma is scanty An intermediate type between the adult and the fetal also occurs All three types of adenomas grow from a subcapsular zone and since their blood supply comes from the periphery the nutrition of the central portions may be impaired There is a tendency toward necrosis and the formation of cysts

Symptoms —A growing lump in the neck may be the first sign noted by the patient but more often the growth takes place in a gland which has previously been enlarged On examination the mass is rounded rather firm perhaps a little tender Often several masses are palpable some of them nodular due to the fusion of adenomas They are not adherent to the skin or deeper structures Sometimes the adenomas become apparent only when the enclosing mass of diffuse goiter has decreased in size as the result of

treatment Often they are first discovered by the pathologist in tissue removed at operation In most cases constitutional symptoms are lacking

Treatment.—Most adenomas produce no symptoms except mild disfigurement and pressure A small number become toxic a very small percentage malignant Surgical removal is desirable but not imperative except for severe pressure or toxicity or suspicion of malignancy Removal of the adenomas is not difficult Some patients improve with the administration of desiccated thyroid

Plummer called attention to a group of *hyperfunctioning adenomatous goiters* (*toxic adenomas*) in which symptoms of hyperthyroidism may occur usually between the ages of thirty five and forty The onset of the constitutional symptoms is often without apparent cause but it may be initiated by the administration of iodine and once started continues even after the iodine has been withdrawn The patient, at the time of examination gives a history of having had a swelling of the neck for many years There has been a gradual onset of the symptoms of hyperthyroidism with a rising *basal metabolic rate* which reaches an average of about 30 per cent above normal *Exophthalmos* seldom occurs possibly because this distressing symptom is infrequent in patients who develop hyperthyroidism after the age of thirty five Rapid recovery follows removal of the adenoma Unless cardiac damage has become too serious operation should be urged as the prognosis is good after removal of the hyperfunctioning adenoma

The opinion of the medical profession regarding the clinical aspects of adenomas and "toxic adenomas has been changing during the past few years This is well exemplified in the 1931 report of the Committee on Classification of the American Association for the Study of Goiter which places the adenomas under the headings nontoxic nodular goiter and toxic nodular goiter At one time it was thought that exophthalmic goiter and toxic adenoma showed distinct differences in etiology symptomatology course and response to treatment Most observers now feel that there is no essential difference between exophthalmic goiter and toxic adenoma but that they are clinical variations of a single disease The writer shares this view

EUGENE F DUBOIS

EXOPHTHALMIC GOITER

(*Graves Disease Basedow s Disease Thyrotoxicosis Hyperthyroidism*)

Exophthalmic goiter is a disease of unknown etiology occurring in constitutionally predisposed individuals It is associated with a diffuse, parenchymatous hypertrophy and hyperplasia of the thyroid gland with an excessive and possibly abnormal thyroid secretion The clinical manifestations result largely from an increased metabolism of the cells of the body and a disturbance of the autonomic nervous system

History —Exophthalmic goiter was first described by Parry but the published account in his posthumous papers attracted little attention and the first well known publication is that of Graves in 1835 A few years later Basedow gave a good account of the condition In English-speaking countries it is usually called Graves disease and on the continent, *morbus basedowi* Moebius suggested that the cause was a pathologic activity of the thyroid gland and contrasted the disease with myxedema which is due to a loss of function of the thyroid Friedrich Muller in 1893 recognizing the increased protein destruction called attention to the probability of an increased total metabolism This was proved two years later by Magnus-Levy who found that the oxygen consumption was above normal in exophthalmic goiter and below normal in myxedema. He later showed that the severity of exophthalmic goiter is roughly proportional to the basal metabolism In severe cases the metabolism is 70 per cent or more above normal and in moderately severe cases 20 to 50 per cent above. The determination of the basal metabolism was used but little as a clinical method until 1916 when a series of studies in America made it applicable to the clinic Since that time there has been a marked improvement in the accuracy of diagnosis and a simplification of the literature of diseases of the thyroid Kendall isolated thyroxin an active principle of the gland in 1915 Harington and Barger synthesized thyroxin in 1927 Aub and his co-workers have shown that the rate of calcium phosphorus metabolism is increased in hyperthyroidism and decreased in myxedema

Etiology —Exophthalmic goiter is apparently a disease of civilization occurring most frequently among young adults in cities where life is strenuous and especially in people of narrow frame light skeletal structure and nervous temperament Women are much more often afflicted than men In a large percentage of cases nervous shock or strain plays an important role and cures are difficult until this strain has been relieved

Most of the symptoms are the direct result of a hypersecretion of the thyroid All of the phenomena, except exophthalmos and certain nervous manifestations have been reproduced in animals by the administration of thyroid substance Overdosage with thyroid in man has given similar results Extirpation of the thyroid in animals and man has caused myxedema which is almost the antithesis of hyperthyroidism There is slight evidence pointing toward an alteration in the nature of the thyroid secretion rather than a mere quantitative increase but some authorities have gone so far as to call the disease dysthyroidism

Fig 154 —Exophthalmos in Graves disease

Pathology —The thyroid gland is diffusely enlarged but sometimes one lobe is bigger than the other It is soft and very vascular and the blood vessels are enlarged The acini show hypertrophy hyperplasia with infoldings of the cells filling up the space left by the greatly diminished and poorly staining colloid Palmer and his associates have shown that the thyroxin thyroglobulin and total iodine content of the untreated gland is below normal but can be increased even above normal by the administration of iodine The extent of the changes in the gland is not always proportional to the severity of the symptoms and in some instances the visible evidences of increased activity are slight

In two thirds of the severe cases there is enlargement of the thymus The heart is usually enlarged In some fatal cases myocardial damage and nutritive change in the cervical sympathetic nerves may exist In one third of the cases adenomas are also present In extreme cases there is great wasting of the body If exophthalmos has existed for some time there may be an increase in the retrobulbar fat Diffuse lymphoid hyperplasia is a constant finding The blood shows an increase in the percentage of lymphocytes and to a lesser extent of the monocytes generally in proportion to the severity of the illness The skeletal muscles especially the muscles of the eye show fatty infiltration Accompanying these muscle changes there is a marked increase in the excretion of creatine The cholesterol content of the blood is low

Symptoms —The patient's complaints are variable Often there is an increasing sense of *fatigue* with nervous excitability and loss of weight In spite of increasing weakness there may be an inward drive urging the patient to purposeless activities An abnormal *appetite* with a sense of warmth and increased perspiration may be noticed *Palpitation* is often the first symptom to attract the patient s attention Sometimes an irritating *cough due to pressure* on the recurrent laryngeal nerve leads to the suspicion of tuberculosis Rarely there are no subjective symptoms until the onset of gastro intestinal crises or cardiac failure

In typical exophthalmic goiter the patient has a peculiar staring expression with brilliant eyes and flushed face and makes many purposeless movements On examination it is found in most cases that the thyroid is enlarged and soft enlargement being as a rule symmetric The gland is sometimes so vascular that the thyroid arteries may be felt and the stethoscope usually reveals a whirring sound called *bruit de diable* The eyes may be so protruding that a rim of white sclera is seen between *the upper* lid and the cornea (*exophthalmos* protrusio bulbi) the lids themselves are usually puffy The patient winks seldom (Stellwag s sign) there is a weakness of convergence (Moebius' sign) and on looking downward the upper lid follows slowly or not at all (von Graefe s sign) The cause of these peculiar ocular manifestations is not known

There is a *fine tremor* of the hands the *skin* is unduly warm and moist and the *heart* beats rapidly with a slapping thrust on the chest and the sounds are of poor muscular quality Sometimes there is distinct cardiac enlargement with relative insufficiency of the valves The pulse pressure *is usually increased due to the rise in systolic* pressure

The *nervous manifestations* may be marked A change in disposition with unwonted irritability and unexpected losses of temper may bewilder the family True psychoses occasionally intervene but as a rule the patients are easily managed once the condition is recognized The cause of the attacks of vomiting and diarrhea which may be alarming is not known Involvement of the autonomic nervous system may be responsible

Most of the symptoms are referable to increased thyroid secretion which stimulates the resting metabolism of all the cells so that the basal metabolic rate is increased roughly in proportion to the severity of the disease Since the oxidations are excessive even while the individual is resting the heart must beat faster in order to supply the tissues with blood Since the body produces more heat than normal each square centimeter of skin must radiate an excessive amount of heat. This accounts for its warmth and perspiration Excessive combustion calls for a greater food intake and if the appetite is not proportionally increased there is a loss of weight The muscles are inefficient they tire rapidly and a given task is accomplished only through the expenditure of an abnormal amount of energy It is easy to see why the continual acceleration of metabolism night and day exhausts the heart and causes great nervous and physical fatigue

In severe cases of exophthalmic goiter the symptoms may develop rapidly causing marked prostration The basal metabolism is increased 75 to 125 per cent or more above normal The heart rate becomes very rapid and auricular fibrillation frequently intervenes Gastro intestinal and nervous manifestations may be prominent these attacks often being precipitated by intercurrent disease or excitement or operation The prognosis then becomes exceedingly grave and death may result from exhaustion In moderately severe cases when the metabolism is 40 to 75 per cent above normal the patient remains an invalid for several years The heart may be seriously damaged and fibrillation may appear The four classic symptoms exophthalmos, goiter tachycardia *and tremor are not necessarily present* but almost invariably some nervous manifestations and the increased metabolism with resulting rapid heart action can be demonstrated In mild cases of the disease when the metabolism is less than 40 per cent above normal there may be few symptoms The characteristic eye signs may be absent or so slight as to attract little attention The thyroid enlargement may be scarcely noticeable Some of the nervous manifestations some weakness tremor and tachycardia will probably be present These cases are often diagnosed as tuberculosis or neurasthenia until the true nature of the malady is discovered They tend to recover early if treated by rest but may progress rapidly in an unfavorable environment In all patients who have suffered from exophthalmic goiter there is danger of recurrence even after operation They may return to active life but seldom to robust health

Complications —The *focal infections* in tonsils or sinuses may demand treatment *Acute infections* are of considerable importance since they increase temporarily the severity of the disease *Glycosuria* occurs in 1 to 2 per cent of the patients, being augmented by carbohydrate food In most of these patients this is merely a spilling of sugar by the kidney and it does not necessarily indicate a diminished power to oxidize True *diabetes* is sometimes a complication and increases the difficulty of treatment There is no specific cardiac lesion but patients whose hearts have been damaged by *rheumatic fever or syphilis or arteriosclerosis* are prone to develop serious cardiac symptoms in hyperthyroidism Fibrillation is a prominent feature often transient often disappearing spontaneously after thyroidectomy

Diagnosis —Errors in diagnosis are frequent *Early pulmonary tuberculosis* may be accompanied by nervousness rapid pulse and loss of weight *Effort syndrome* (neurocirculatory asthenia) may cause the same

symptoms with the addition of vasomotor instability There is another puzzling group of cases with the nervous manifestations of exophthalmic goiter but *without the increased metabolism* a condition that has been called *larval hyperthyroidism* or *forme fruste* Its relationship to exophthalmic goiter is not yet clear Sometimes patients with colloid goiter or adenoma are falsely suspected of hyperthyroidism More and more cases are reported in which an unsuspected thyrotoxicosis has caused cardiac decompensation The diagnosis is suggested by a persistently rapid heart rate that does not respond well to digitalis The recognition of the true etiology is of great importance because in many of these patients relief can be obtained only after thyroidectomy

In guarding against errors nothing is more important than a careful history physical examination and analysis of symptoms The *pulse rate* during sleep or complete rest is as a rule more accelerated in hyperthyroidism than in the other diseases A determination of the *basal metabolism* by one of the comparatively simple machines now used in many clinics is of great value as an aid in diagnosis but only as an aid At the present time many of the metabolism tests are faulty sometimes it is the technic but more often it is the apprehension of the patient that gives results far above the true basal The first test is often unreliable There are a few conditions such as fever leukemia and pernicious anemia which cause a rise in the resting metabolism similar to that of hyperthyroidism but these are readily differentiated Generally the rise in the basal metabolic rate is proportional to the degree of hyperthyroidism but it may be relatively slight in some patients whose cardiac and nervous systems have been badly damaged by a previously severe thyrotoxicosis The majority of patients with Graves disease have increased amounts of creatine in the urine which drop promptly when they are treated with iodine If the patient is given a small dose of creatine hydrate he retains less of this substance in his body than does a normal man This test developed by Richardson and Shorr is of aid in the diagnosis of atypical Graves disease, particularly when the basal metabolic rate is not elevated Salter believes that a determination of the plasma protein bound iodine gives more reliable information than the basal metabolism test in some cases The blood cholesterol level while generally lower in active Graves' disease so overlaps into the normal range that it is of doubtful value in diagnosis

The most reliable diagnostic measure is a therapeutic test with iodine The patient should be kept in bed and the basal metabolism followed for two weeks to observe the natural course of the disease Iodine is then administered and careful observations made on the pulse rate basal metabolism and clinical manifestations Patients with Graves disease almost invariably show a marked improvement Those few caught when the disease was becoming worse show under iodine a retardation in the rate of advance

Treatment—The most important part of all treatment is *physical* and *mental rest* This should if possible be obtained away from home in a place where the patient can be isolated from household cares Sometimes rest combined with small doses of iodine and a liberal diet results in a complete cure If the body weight is to be maintained it is necessary to give about twice as many calories as are needed by a normal individual under similar conditions since there is not only an increase in the resting metabolism but also an increase in the number of calories used for every muscular effort The total protein and calcium in the diet should be liberal and the vitamin allowance generous The room should be cool and quiet, and all sources of excitement must be excluded Fear of operation may raise the metabolism 50 per cent or more Sedatives such as phenobarbital are of service hydrotherapy may be tried Psychotherapy is becoming more and more important Unfortunately there are many patients who cannot afford to stay away long from their homes and *abandon the very responsibilities* that have caused the malady In such cases it is necessary either to find a more rapid method of treatment or to face the prospect of many months of invalidism

The operative treatment of exophthalmic goiter is the method of choice Patients should be observed by the physician for a period of several weeks before they are turned over to the surgeon The best results

are obtained when physicians and surgeons work together as teams Some of the severe cases are obviously unfit for any operative procedure on account of cardiac insufficiency Others are in the stage of rapidly increasing severity and an operation would precipitate a crisis Before the introduction of the use of iodine in large doses it was necessary to wait and hope that the stormy period would pass Some of these inoperable cases did well under x ray treatment Others were able to stand the short operation of the ligation of two or more thyroid arteries

Now, the use of x rays has been more or less abandoned except in special cases where operation is refused by the patient or is inadvisable for some other reason Ligations are now performed but seldom Thyroidectomy in stages may be necessary with patients who are severely ill but most surgeons try to perform subtotal thyroidectomies removing about five sixths of the gland Care must be taken to avoid injuring the recurrent laryngeal nerve and the parathyroids The operation is difficult and the mortality depends on the technic and judgment of the surgeon

The medical preparation of the patient is important H S Plummer of the Mayo Clinic in 1922 reviving an old method of treatment found that if he gave his exophthalmic goiter *patients Lugol's solution in* doses of 1 cc a day for a fortnight it caused in the large majority of cases a temporary diminution of the symptoms of thyroid intoxication and offered the surgeon a subject in comparatively good physical condition Plummer's method of treatment has been universally adopted and has reduced the mortality greatly diminishing the number of serious postoperative crises that were such frequent causes of death

Iodine in almost any form can be used instead of Lugol's solution This solution or a more palatable form such as syrup of hydriodic acid is given in divided doses well diluted with water * Patients with mild thyrotoxicosis usually receive about 15 minims (1 cc) of Lugol's solution a day severe cases three times this amount Thompson believes that much smaller doses 5 drops of Lugol's solution a day give the best results It may be given by rectum if there is vomiting In a few days there is usually a marked improvement in the symptoms and the basal metabolism falls until in a week or two it almost reaches normal The histologic picture of the glands shows a less active state, approximating that of an inactive colloid goiter or even a normal gland The remission does not last many days and it is wise not to delay the operation If the surgeon has observed his patient carefully and has used good judgment in selecting the time for operation the patient stands the subtotal thyroidectomy surprisingly well If he has delayed too long and has started to operate at a period when the basal metabolism has almost regained its previous level and the patient has shown a recurrence of symptoms, the course may be a stormy one with danger to life Therefore if the iodized patient gives evidence of a relapse it is safer to postpone operation and return to a simple treatment of mental and physical rest If the iodine is discontinued for a period of several weeks or a few months it is usually possible to obtain a second remission by giving Lugol's solution Fortunately the dreaded toxic crisis or storm is now relatively rare on account of the careful preparation of patients for operation Occasionally however patients suddenly show an increase in all symptoms and high fever Oxygen tents morphine intravenous injection of glucose hypodermoclysis and cold sponging are of help but the mortality of this complication is very high

In some mild cases of Graves' disease the patients do well on small doses of iodine (0 5–1 cc of syrup of hydriodic acid daily) over a long period of time and recover without operation We must remember always that there is a tendency toward spontaneous recovery in most cases of exophthalmic goiter The clinician in his desire to hasten recovery seldom has the opportunity of following carefully the untreated natural course of the disease One must not promise too much in the way of cure in exophthalmic goiter Patients treated with rest alone may have relapses and these are not infrequent after operation Patients who have been severely ill require a long period of careful supervision before they regain their strength The exophthalmos frequently persists cardiac damage may be permanent Myxedema

* See footnote page 1208

may result if too much thyroid tissue has been removed but this is easily controlled by the use of thyroid extract

There is still some debate as to whether or not Lugol s solution should be employed before operation in cases of adenoma with hyperthyroidism but it helps in almost as large a proportion of nodular goiters as in the diffuse toxic toxic form Patients with cardiac failure should be given digitalis but the effects are often disappointing and of course one cannot expect a slowing of the pulse rate to normal levels The important thing is to relieve the acute thyrotoxicosis by means of complete rest and iodine Operation is indicated as soon as the patient's condition permits After operation quinidine used cautiously may be of help in restoring normal rhythm in cases of fibrillation

EUGENE F DUBOIS

THYROIDITIS

Thyroiditis is a rare condition which ranges from a mild unnoticed inflammation of the thyroid to an active invasion by some pyogenic organism The tubercle bacillus seldom attacks the thyroid as a primary focus but may do so secondarily in a generalized invasion of the body Infection by other organisms may follow operative interference or may spread from some neighboring structure The symptoms are pain tenderness enlargement of the thyroid and sometimes obstruction The disease may subside spontaneously or as a result of local applications of heat or cold Operation is sometimes necessary especially if obstructive symptoms intervene Riedel has described a rare form of ligneous' or iron struma of very firm consistency

EUGENE F DUBOIS

MYXEDEMA

Definition—Myxedema is a constitutional disease occurring in adults and is due to decrease or absence of the secretion of the thyroid gland as a result of its atrophy or removal A marked decrease in the basal metabolic rate is characteristic as well as a myxedematous condition of the tissues a slowed impaired mental condition a typical facial expression and other secondary manifestations (Boothby)

History —The disease as an entity was first recognized by Gull in 18 3 and is sometimes given his name Ten years later Reverdin and also Kocher found a similar condition following total extirpation of the thyroid The latter surgeon gave it the name of *Cachexia strumipriva* Implantation of the thyroid gland was later suggested and gave temporary relief but the first permanent cure followed the administration of thyroid extract (Murray 1891) Magnus Levy discovered the low basal metabolism in 1893

Etiology—Myxedema invariably follows complete removal or destruction of the thyroid tissue either by operation thyroiditis or atrophy of the gland It occurs sporadically and in its more severe forms is rare Mild grades of the disease may be found in patients with colloid goiter and a large goiter is not incompatible with complete loss of thyroid function Myxedema occurs four or five times as often in women as in men When it develops in childhood it is called juvenile myxedema and it results in retardation of growth

Morbid Anatomy—Excluding the cases of large colloid goiter the thyroid gland in myxedema is small and atrophied Microscopically there is a marked decrease in the vesicles and a relative increase in the fibrous connective tisue The walls of the vesicles may show a round celled infiltration

Symptoms—The onset of myxedema occurs as a rule between the ages of thirty and sixty and is very gradual The symptom complex is in many ways the antithesis of that of hyperthyroidism The patients or more often the relatives notice a gradual slowing of the mental and bodily activities with an increased weight a decreased appetite and a curious change in the facial expression In well marked cases the expression is masklike the features coarse the eyelids puffy the hair of the head eyelashes and eyebrows scant The skin is dry scaly and feels thick with a curious nonpitting edema most marked in the hands feet and supraclavicular fossae The speech is thick and slow the result partly of the enlargement of the tongue and partly of the delayed mental processes and the tendency toward drowsiness As a rule the patients are placid a few are nervous and irritable Quite often they are anemic The heart is enlarged and

flabby with greatly diminished output per minute and will not stand sudden strains The joints and muscles are frequently stiff

Fig. 155—Twenty-six year-old woman with myxedema, before treatment. Basal metabolic rate —36

and painful The urine may contain albumin and the phenolsulfonphthalein test gives low results but the renal function is not significantly impaired The blood cholesterol

Fig 156.—Same patient as Fig 155 two months later after treatment with desiccated thyroid gland Basal metabolic rate —5

is high The patients may drift around for several years with a diagnosis of arthritis or obesity or nephritis before the condition is recognized and treated

If the secretion of the thyroid is entirely absent the basal metabolism falls to a level about 40 per cent below normal In milder cases the decrease in oxidation is proportional to the decrease in secretion As a result of the lowered heat production the skin is cool and the patients suffer from cold The food intake is small and there is a tendency toward gain in weight In the milder forms of the disease the patient may show few typical symptoms and in such cases a determination of the basal metabolism which will be only 15 to 25 per cent below normal often gives a clue to the loss of strength and enterprise the constipation the general ill health It must be remembered that there is a large group of persons who are not suffering from thyroid disease whose basal metabolism is also 15 to 20 per cent below the average Some of them are perfectly normal others show a low metabolism on account of chronic illness which diminishes their muscular activity and others form a vague group of neurasthenics

Treatment—The treatment of myxedema with *thyroid* is one of the brilliant achievements of modern medicine In a few weeks the patient may be almost completely restored to normal Thyroid should be given very gradually until the deficit of thyroid secretion in the body has been replaced and then administered in doses just sufficient to counterbalance its rate of destruction The various preparations of desiccated thyroid differ considerably in strength *

Dramatic effects have been obtained by the intravenous administration of thyroxin but it should never be used There is great danger in suddenly increasing the metabolism of a patient who has been living on a relatively low plane especially if the myocardium has been damaged Slower but more satisfactory results can be obtained by the oral administration of desiccated thyroid USP It is best to start with relatively small doses ½ to 1 grain a day increasing gradually until one reaches the full dose of 3 to 4 grains required in severe cases or the smaller dose that is sufficient for the milder types The symptoms disappear in the course of a few weeks and the basal metabolism rises until it is within the normal range Next comes the problem of adjusting

* See footnote page 1208

the dosage for maintenance and this must be regulated chiefly by the patient s symptoms Basal metabolism determinations are helpful It may require careful management to steer the course between hypo and hyper thyroidism Patients with myxedema should not be given morphine as its toxic effect is greatly increased in this disease

Eugene F DuBois

CRETINISM

Cretinism is a disease originating during fetal life or infancy and is due to a more or less complete lack of thyroid secretion and probably involvement of other ductless glands It is characterized by a stunted physical and mental development and a typical appearance It is not incompatible with long life

History —The disease has long been recognized It is very common in the highly goitrous districts and a sporadic type unassociated with goiter occurs rarely throughout the world The relationship to the lack of thyroid secretion was recognized by Curling in 1850 and by Fagge in 1871 In fact it was the discovery of this relationship in children which led to the recognition of myxedema in adults

Etiology —In regions of endemic goiter a lack of iodine in the mother s organism may cause a failure of thyroid development during fetal life or shortly after birth This lack produces a marked arrest in the ossification of the bones which accounts for the roentgenologic picture so highly characteristic of the disease The sporadic form probably has the same etiology as the myxedema of adults but occurring during infancy or childhood causes the characteristic dwarfing of body and mind In goiter districts there is a marked hereditary tendency and the parents may suffer from the milder forms of thyroid disease although adults with the more severe grades are usually sterile In the United States the disease is relatively rare

Pathology —There may be a complete lack of thyroid tissue (athyreosis) or the gland may be small and atrophic as in myxedema Sometimes a large colloid goiter is found

Symptoms —Talbot says that an experienced clinician may detect in the early weeks of life some thickening of the subcutaneous tissues a hoarseness of the voice and a suggestion of the facies characteristic of cretinism By the second or third month the tongue may be large and the eyes far apart with a piglike expression Usually the parents do not suspect anything wrong until the child is a year old They then begin to notice that the infant is gaining very slowly in stature intelligence, and bodily activities At this time the syndrome becomes characteristic The child is late in sitting up walking and talking Growth particularly of the extremities is stunted The skin is rough and scaly the face bloated the nostrils wide and flaring with a sunken bridge of the nose thick tongue and drooping jaw Dentition is delayed and imperfect and the teeth decay early On stripping the child one notices a pot belly and puffy pads on the buttocks and back of the shoulders Growth is very slow and the intelligence much below the normal Many cretins are unable to say more than a few words and remain uncleanly in their habits They sit quietly for hours responding to questions by a characteristic grin which wrinkles the whole face Some cretins develop a clownlike intelligence and are good humored preserving a perpetual childhood

Treatment —Prophylactic treatment is all important In goiter districts iodine must be given to pregnant women Recognition early in childhood is essential if we hope to attain a complete relief of symptoms If the arrest of development has continued for a long time it may be impossible to obtain satisfactory results Talbot recommends for infants of four to eight months ½ grain desiccated thyroid a day from twelve to twenty four months 1 to 2 grains from four to twelve years 3 to 6 grains daily When brought to normal the dose can be reduced Control of dosage by measurements of the basal metabolism is usually impossible and the treatment must be guided by clinical symptoms Thyroid preparations vary greatly in strength and in some patients they are poorly absorbed Some cretins do well on large doses but others become distinctly ill even on repeated attempts with smaller and smaller amounts With or without successful thyroid medication cretins may live to old age before they succumb to an intercurrent infection

Eugene F DuBois

MALIGNANT DISEASE OF THE THYROID

Malignant disease of the thyroid is fortunately rare in the United States, being found once in every 928 postmortem examinations It is said that a correct early diagnosis is made less frequently than in malignant tumor in any other organ The growth usually starts in a goiter or adenoma when the patient is between forty and sixty years of age About two thirds of such growths are in women

The most common form is *carcinoma simplex* The growth is firm encapsulated and on microscopic examination there is no colloid and the alveoli form closely packed columns of cells This is a most malignant form which causes metastases even though it does not penetrate its capsule *Adenocarcinomas* contain colloid and show a tendency to infiltrate *Papillary cystic carcinomas* grow slowly and are not always malignant The *scirrhous* and *squamous types* are rare *Sarcomas* may occur during the fifth and sixth decades of life

In the early stages it is difficult to distinguish between malignant growths and benign adenomas but malignancy should be suspected in any firm steadily growing tumor of the thyroid In the later stages of malignancy there may be a stony hard mass attached to the skin and deeper structures with a secondary involvement of the cervical lymph nodes or metastases into lungs skull or liver There may be pressure on the trachea or esophagus Cachexia is not striking

The occasional development of malignancy in adenomas is an argument for operation even if there are no suspicious symptoms If malignancy is suspected operation should be performed early Even then the hope of cure is small X ray and radium treatment may help inoperable cases

DISEASES OF THE HYPOPHYSIS (PITUITARY BODY)

THE pituitary gland and its adjacent structures in the region of the circle of Willis inspired the curiosity of Galen Andre Vesale and other early anatomists who gave it uncertain humoral properties But it aroused little interest beyond this and when comparative anatomy later made clear that structures having function in lower forms remain as functionless ones in the higher forms the pituitary (newly named the hypophysis in 1778) was relegated to the category of vestigial relics

Attention was recentered on this gland by a clinician (Pierre Marie) who in 1886 described a curious malady of hypertrophic skeletal changes in the adult which he called acromegaly It was observed some time later that there was an accompanying hypophysial tumor and assumed that this accounted for the clinical picture Moreover it was soon realized that gigantism was a related condition and differed from acromegaly merely in that it appeared earlier in life This conception of the hypophysial

relation to growth had later to be proved by further clinical observation and laborious experimentation In the process, still other functions have been ascribed to this gland until today it is recognized that growth, nutrition and reproduction, the basic functions of life have their center here

Development and Structure—The development of the hypophysis has been fairly well studied and the few remaining discrepancies are mainly those of terminology The buccal mucosa *anterior to the oral plate* develops an outpouching (Rathke's pouch) which extends upward and backward to invest a downward outpouching from the floor of the diencephalon The tubular structure of the latter is usually obliterated, leaving a *simple stalk*, the *epithelial cavity* of the buccal portion is also obliterated but occasionally remnants remain to form cysts in later life Finally the sphenoid bone unites to separate the buccal from the intracranial portions of Rathke's pouch and partly invest the gland in a bony shell known as the sella turcica A dural diaphragm penetrated by the pituitary stalk roofs the sella turcica and further serves to isolate the gland

Genetically it may be said that the development of the human hypophysis follows that common to all mammals and bears the imprint of a design which goes back to the earliest reptiles It has been surmised that such antiquity in structure must be significant of equally great constancy in function On this basis the results of experimental studies of the mammalian hypophysis may be directly applied to man

As a result of the dual origin of the gland there are two structurally and functionally distinct lobes The anterior lobe (pars glandularis) represents the derivation from the buccal mucosa and is made up of three cellular elements more properly speaking they represent a single element in two different stages of activity The chief element or mother cell possesses a nonstaining cytoplasm (chromophobe cell) which in the process of maturing acquires coarse secretory granules that stain deeply (chromophile cell) these exist in about equal proportion But the chromophile cells can be further divided into those whose granules take the acid or eosin dye (acidophile or eosinophile) and those *whose granules* take the basic dyes (basophile), they exist in a proportion of 4 1 The arrangement of these cells in cords separated by vascular and connective tissue structures conforms to glandular tissue Since there is no duct the inference is that *secretion occurs directly* into the vascular channels

The posterior lobe (pars neuralis) represents the derivation from the diencephalon and is made up of cells of glial origin plus fine myelinated nerve fibers which descend *from the diencephalon by way of the* pituitary stalk to end in a plexiform arrangement There is no glandular arrangement of cells here and scanty blood supply which is evidence enough for some that this lobe has no secretory product But others have found scattered through *the lobe* certain hyaline bodies (Herring bodies) believed to represent a secretory principle which eventually migrates into the lumen of the third ventricle The hyaline bodies may be artifacts and evidence for the existence of hormones from the posterior *lobe* is *scanty so* that this lobe biologically is still puzzling

The intermediate lobe (pars intermedia) is a structure so rudimentary in man that it appears to have no special function of its own The function and morphologic significance of the pars tuberalis are *unknown*

The blood supply to the hypophysis has a history dating back to the ancient conception of a network of vessels through which the pituitary secretion was filtered (the rete mirabile) This vascular net *following* Willis' description came to be *known* as the circle of Willis" branches from which supply a large part of the brain as well as part of the hypophysis But the intricate vascular supply to the gland both arterial and venous has more recently been formulated following comparative studies on mammals The interesting facts brought to light by this study which may have significant bearing on hypophysial function are the posterior and anterior lobes have individual arterial supplies independent of that of the *vegetative centers* in the hypothalamus the anterior lobe is drained by veins leaving its lateral border to enter *the* adjacent cavernous sinuses and no veins have been found draining either lobe via the stalk to ultimately reach the hypo*thalamic* vegetative centers

Physiology —The exact function of the hypophysis is an absorbing question to an army of both clinical and laboratory investigators and is still not entirely understood The literature on the subject to say the least is extensive and bewildering The interdependence of all the glands of internal secretion in which the hypophysis admittedly holds the dominating position plus the now well established connection between it and certain hypothalamic nerve centers has served to complicate the solution of this complex riddle The early experiments in which dwarfing obesity and sexual dystrophy resulted from hypophysectomizing puppies were later shown to be inconclusive because of the coincidental damage to structures adjacent to the pituitary body The rat, however was found to be ideally suited to hypophysectomy because the body of the gland as in the human is overlaid by a dural diaphragm and can readily be removed without damage to adjacent structures Thus in the rat an exact state of apituitarism can be produced thereby furnishing a means to test the effects of replacement therapy

If the hypophysis be removed from a young rat there results a retardation in the rat s growth and a failure to mature sexually the animal has the appearance of a delicate dwarf and is kept alive only by careful attention to diet and environment If the hypophysis be removed from a sexually mature rat there results a progressive loss of weight a degeneration of the genital system characterized by atrophy of the gonads and immediate cessation of estrus in the female as well as atrophy of other endocrine tissues including thyroid parathyroid and suprarenal cortex the animal becomes sluggish and possesses a lowered basal metabolism If the deficiency be replaced in these animals by the simple expedient of repeated intramuscular transplants of fresh hypophysial tissue from normal rats the dwarf grows and matures sexually while the adult resumes normal weight estrus returns genital atrophy disappears and the associated endocrine glands recover their former structures the general economy of both animals is greatly improved The inference then is that the changes following removal of the hypophysis are due to a lack of the secretory products of this gland Furthermore since it has been shown that these changes do not occur if the posterior lobe alone is removed it appears that the anterior lobe is entirely responsible for growth and sexual maturity

It has been possible to separate the two anterior lobe substances and to demonstrate the specific effect of each The growth hormone has been utilized experimentally to produce symmetric overgrowth of all tissues in some animals and skeletal overgrowth with hyperostosis and splanchnomegaly in others These are the counterparts of gigantism and acromegaly seen in man The sex hormone (gonadotropic hormone) introduced into young animals produces sexual precocity is undifferentiated for the two sexes and apparently acts through an intermediary effect on the gonads It has been sufficiently demonstrated that the growth promoting principle is derived from the acidophile cells of the anterior lobe and there is indirect evidence which suggests that the sex maturing principle may be associated with the basophilic elements

It would be simple enough were there but two hormones produced by the two specific types of secretory cells of the anterior lobe but it is very probable that there are several other hormones elaborated by this lobe If this is eventually found to be true it means that there are more types of secretory cells than we now know or what is more likely the product of the known types has a variable action perhaps under variable circumstances Some of the other hormones alleged to emanate from this lobe are found to influence the activity of the thyroid the adrenal cortex the parathyroid the secretion of milk and the metabolism of carbohydrates fats and probably protein The postulation of these additional hormonal properties of the hypophysis was of course foreshadowed in the first hypophysectomized animals which showed unmistakable structural changes in other endocrine glands and in distorted metabolism

Because the structure of the posterior lobe is a relatively avascular mass of glial tissue not glandular in type and its experimental extirpation fails to give convincing changes it is widely believed *to be a relatively un*important structure Pituitrin which is an

extract of the posterior lobe is not a chemically pure product, nevertheless, its effects on blood pressure, smooth muscle and urine output have been strikingly suggestive of a true hormonal property of this lobe Two fractions have been isolated from pituitrin one known as vasopressin (pitressin) increases blood pressure influences diuresis stimulates the intestine and expands the cutaneous melanophores the other known as oxytocin' (pitocin) acts solely on uterine muscles The hyaline bodies (of Herring) seen in the posterior lobe are considered by many as secretory products from the adjacent pars intermedia (derived from the buccal mucosa) and are thought to make their way into the third ventricle by way of the stalk *where they stimulate hypothalamic* nuclei of the vegetative system It has been demonstrated that cerebrospinal fluid in the third ventricle seems to have an oxytoxic and melanophore stimulating property not found in the fluid elsewhere *Furthermore when pituitrin has been in*jected into the human ventricle immediate flushing, sweating and other changes occur of striking nature and when this reaction is compared to the reverse physiologic effect of intramuscular injection it appears evi*dent that the responses result from direct* nuclear stimulation A substance resembling posterior lobe extract is claimed to have been found in the blood of patients with eclampsia and perhaps in certain patients with so called essential hypertension Also sections of the posterior lobe from a fatal case of essential hypertension show striking increase in the elements assumed by some to form hyaline bodies However these findings are to be interpreted they at least indicate that the possibility of an active posterior lobe principle *cannot safely* be ignored

Many of the functions ascribed in the past to the hypophysis alone are now found to be at least partly dependent on vegetative centers in the diencephalon Indeed it is suggested that action of the two may be reversible *impulses from the nerve centers* may influence secretion by the hypophysis and as has been suggested these secretory products may in turn stimulate the nerve centers This is not to be wondered at perhaps when it is remembered that the diencephalon is an *ancient* portion of the brain and that similar to the hypophysis it has remained essentially unaltered through phylogenetic development The anatomic juxtaposition of the two and the direct neural connection imply that they are inseparable and important to perpetuation of the species Obviously disease involving one may likely involve the other Water balance fat metabolism and carbohydrate metabolism are the principal processes concerned in this implied mechanism while heat regulation and *pathologic sleep are additional features* of any disease that involves the diencephalon as well as the hypophysis

The interrelationship of the different hormonal glands must also be given due consideration Much of what was originally *thought to be the result of direct influence* of hypophysial secretion is now known to result from secretions of other glands activated by the hypophysis The gonad stimulating hormone has been found to have a dual effect on the ovary namely stimulation *of normal follicular growth and ovulation* (folliculizing hormone) and the formation of premature corpora lutea (luteinizing hormone) These changes in the ovary are responsible for the menstrual cycle and this cycle ceases if either the ovaries or the *hypophysis are removed A comparable* relation exists with the thyroid in which it has been shown that ablation of the hypophysis produces states of hypothyroidism Similar relationship prevails with the suprarenal cortex the parathyroids and possibly the *pancreas—thus* the terms gonadotropic thyrotropic' corticotropic parathyrotropic and pancreatropic' hormones There are also instances of reciprocal action as for example the marked alterations in the hypophysis caused by *ovarian secretion* during pregnancy In addition whereas some hormonal interchange is blood borne there appear to be instances in which we may assume that the hypophyseal secretion exerts its influence on other glands of the body through its action on the vegetative centers innervating that gland

One more variable recently come to light is the antihormone theory prompted by the observation that in prolonged treatment with certain pituitary extracts there is a progressive diminution in effects This is

ascribed to the formation of antihormones and suggests that such a process may be responsible in certain cases for hypoglandular states The hypothesis is attractive yet not well justified on the basis of present information

An appreciation of these complicated functions of the hypophysis is necessary before attempting to understand the various clinical manifestations resulting from pathology in and about the gland

GEORGE J HEUER

CLINICAL CORRELATION—THE COMMON TYPES OF PITUITARY DYSFUNCTION

To attempt to transfer what knowledge the laboratory provides to clinical experience is a difficult and perplexing task Processes in the human body are not in all respects exactly comparable to those that can be produced in the experimental animal This is partly due to the ability of the human body to adapt itself to pathologic processes even to the degree of masking such effects as might otherwise be expected In addition experimental work has been largely limited to removing the activity of the hypophysis no activation of the gland itself has yet been produced comparable to nature s experiment in man

Conflicting observations of clinical cases must await explanation until the eventual marshalling of incontrovertible facts and no doubt much of what we now believe will be greatly modified in the course of time

However for practical purposes from the admittedly incomplete evidence at hand the clinical manifestations of hypophysial disease are divided into hypo and hyper pituitarism For those syndromes in which it seems impossible to decide which of the pituitary states exists some have resorted to a third division heteropituitarism or dys pituitarism

The hypopituitary state results either from idiopathic undersecretion or from destruction or compression of the hypophysis Complete or partial destruction may follow trauma such as skull fracture in the region of the sella turcica or degeneration may follow inflammatory or vascular disease of the hypophysis The acute infections of childhood upper respiratory infections, typhoid fever and syphilis are possibly causative factors in some instances Compression of the gland results from expanding adenomas gumma metastatic carcinoma and from other tumors that arise outside the gland but in its immediate neighborhood

Dwarfism.—The lack of hypophysial secretion in infancy or childhood results in varying degrees of underdevelopment Individuals thus affected range from just under the lower limits of normal to frank dwarfing Such dwarfs may be normal at birth and thereafter until delay or complete cessation of growth occurs or they may be already too small when born (primordial dwarfs) and develop at a delayed rate But the term dwarfism requires qualification for in a broad sense it includes all conditions characterized by stunted growth Thus the etiologic possibilities are numerous and varied and often there is lack of agreement concerning the category into which a given case should be placed The term infantilism commonly used synonymously with dwarfism strictly applies to individuals in whom there is impairment of growth sex and intellect while the term nanism is used to imply conditions in which there is impairment of growth only In the type of arrested development due to secretory deficiency of the hypophysis the mentality is rarely retarded though in the majority of instances there is lack of sexual development and regarding the things that are influenced by sex it perhaps may be said they do not become mentally mature

Hypophysial dwarfs are usually children of normal parents though it has been reported that occasionally there have been ancestors with various forms of hypophysial disease In hypophysial dwarfism there is good symmetry of the body and the physical make up is essentially that of early childhood in which the lower measurements are relatively short Obesity is not a feature of the pure form of this condition and most individuals are thin During the age of childhood these individuals simply appear to be small for their age but later they develop a mature appearance and as time passes a frankly oldish and even wizened look develops which is incongruous with their infantile stature (progeria) The genitalia re-

main in an underdeveloped state also but in proportion to the general physical development are not small The secondary sex characteristics are absent or retarded and usually there is amenorrhea in the females and aspermia in the males There are records nevertheless of hypophysial dwarfs producing normal offspring There is no gross evidence of dystrophy of bones or joints but the skeletal framework is smaller and more fragile than normal and epiphyses remain open much longer The appetite is small and an attempt to increase the caloric intake is usually futile There is sometimes an increased tolerance for glucose otherwise the blood chemistry is normal The basal metabolism is usually low but within the range of normal unless there is an associated hypothyroidism of some degree There is no change in the water balance and no characteristic change in the urine

Occasionally roentgenograms of the skull have shown a proportionately small or a completely bridged sella turcica but this is not a common finding in hypophysial dwarfism and the size of the sella cannot be used as an index of function of the gland A craniopharyngioma or even an hypophysial adenoma may be the cause of dwarfing and the sella in these cases may be considerably enlarged In the final analysis however the exact diagnosis depends largely on the operative or postmortem demonstration of an abnormal hypophysis and in instances in which the elements of the anterior lobe are found simply to be deficient the etiologic factors can only be speculated upon

In the differential diagnosis of hypophysial dwarfism every other cause of arrested development must be eliminated Considering all the possibilities of abnormal germ plasm the effects of systemic diseases and of abnormal diet and the interrelationship of all the endocrine glands it is doubtful whether any type of dwarfism can be said to have an uncomplicated etiology Dwarfing which is not directly the result of hypopituitarism may be disproportionate or proportionate The former appears in certain diseases of the bone in which limbs or trunk are misshaped or are out of proportion with each other as occurs for example in achondroplasia rickets Pott's disease of the spine and osteopsathyrosis The latter is seen as a result of chronic infections intoxications or nutritional deficiencies that exist during the growth period among these diseases may be mentioned tuberculosis syphilis cardiovascular disorders, and digestive disorders such as pancreatic insufficiencies and celiac disease The dwarfing of cretinism is an example of underdevelopment resulting from disease primarily involving the thyroid but it is likely that in this disease associated hypophysial dysfunction is partly responsible for growth and other deficiencies The same may be said for dwarfing seen in diseases of other endocrine glands The condition sometimes referred to as ateliosis is so akin to what has just been described as hypophysial dwarfism that the two may be considered one and the same

Dystrophia Adiposogenitalis of Frohlich—The most common cases of hypopituitarism by far are the adolescent boys and girls who become obese and show delayed puberty the stature may be small but this is inconstant The boys have a slightly feminine type of body with degrees of obesity about the thighs buttocks breasts and face The fat has a hard firm feel The genitalia are small and often the testicles descend imperfectly or not at all The axillary and pubic hair is scant and of fine texture the beard thin or absent The girls have similarly distributed obesity and the breasts which enlarge moderately with fatty tissue contain no glandular substance The pubic hair is sparse and the external genitalia small The uterus is similarly infantile menses begin late and are variously abnormal These youths may be mentally bright, even precocious but often are listless and sluggish failing to concentrate long on any protracted task The muscular system has an abnormally low tonus frequently associated with hyperextensibility of the joints Basal metabolism is normal or lowered and the sugar tolerance tends to be increased

The classic cases of this description are associated with craniopharyngiomas which compress the hypophysis But obviously all the children that appear with this condition do not have such tumors what pathologic changes are present in the hypophysis is not always known

A typical state of hypopituitarism seen in the adult is that accompanying chromo

phobe adenomas of the hypophysis, and described under that heading Cessation of menstruation is the usual occurrence in the women but hypopituitarism is not always expressed as amenorrhea It appears that the condition of hypertrophic endometritis excessive bleeding and dysmenorrhea may be the result of a deficiency in the gonadotropic hormone more particularly the luteinizing fraction

Simmonds Disease —An extreme example of hypopituitarism is an insidious condition that occurs usually during maturity It is the result of extensive degeneration of the hypophysis from one cause or another and characterized by cachexia of remarkable degree wasting is so marked that the patient is literally ' skin and bones There is precocious senescence manifest by loss of hair falling out of teeth and dry wrinkled toneless skin Pulse blood pressure and temperature are all subnormal basal metabolism is reduced and there may be hypoglycemic crises There is no sensation of hunger or thirst and the excretion of water is reduced perhaps impaired These patients become depressed, finally comatose and death follows Although there are authentic cases of this condition with atrophy of the hypophysis a word of caution is in order for cases with the same or similar clinical picture appear without pituitary atrophy and may recover on merely being forced to eat and drink

Diabetes insipidus a state of polyuria and polydipsia hardly needs be mentioned as a manifestation of hypopituitary function in the light of present knowledge for it now appears to be the result of hypothalamic lesions However it frequently accompanies hypopituitary states and the effect of pituitrin on the condition is well known

Hyperpituitarism at least one type of it produces individuals of inordinate height Gigantism and acromegaly are both manifestations of eosinophile adenomas of the hypophysis though presumably there are periods of overgrowth at various times of life resulting from hypereosinophilism not associated with adenoma formation Basophilism is possibly another form of hyperpituitarism both are discussed with the adenomas

The adenomas of the hypophysis as a whole together with the craniopharyngiomas represent the largest group of cases about which we have a fairly definite knowledge concerning the clinical and pathologic changes that go with hypophysial disease These will be discussed as a group

BRONSON S RAY
GEORGE J HEUER

HYPOPHYSIAL ADENOMAS

Adenomas are prone to occur rather commonly in the hypophysis though actually they exist in a small percentage of the cases usually thought to demonstrate clinical evidence of hypophysial disease They produce in every instance a striking group of symptoms which have been considered as manifestations of hypo or hyperpituitarism or occasionally a mixture of both The extensive clinical study of these cases has played almost as great a part as has laboratory experimentation in establishing the function of the hypophysis The tumors always arise in the anterior lobe none are known to exist in the posterior lobe They occur primarily in young adults about equally in the two sexes and vary in size from a few millimeters to 5 to 6 cm in diameter

Corresponding to the three types of cells in the anterior lobe there are three different types of adenoma chromophobe eosinophile and basophile The chromophobe and chromophile adenomas occur in a ratio of about 3 1 the basophile are extremely rare and never attain an appreciable size The chromophobe adenomas are usually larger than the eosinophile but otherwise both have as a rule a soft friable and vascular gross appearance

Histologically the chromophobe adenoma is composed of cells arranged in strands or groups separated by a stroma of connective tissue and blood sinuses The delicately granular cytoplasm stains faintly and the nuclei are large in rare instances there may be mitotic figures In the eosinophile adenoma the cells form loose clusters without stroma and with fewer blood vessels The granules of the cytoplasm stain with eosin and the nuclei also large show no mitotic figures Between these two transitional

types occur which are known as mixed adenomas but they are predominantly chromophobe adenomas with eosinophile elements The cells of the small basophile adenomas possess granules staining with the basic dyes and many of them are multinuclear It might be expected that these tumors being epithelial in origin might become carcinomatous but rarely does one find more than occasional mitosis and in general the tumors are comparatively slow growing

As the adenoma grows it displaces and compresses the rest of the hypophysis until the gland may be hardly recognizable The dural envelope of the hypophysis and the bony confines of the sella turcica are more resistant but they too finally yield The sella turcica gradually increases in size (normal dimensions—10–14 mm anteroposterior by 14–15 mm in width by 8 mm deep) usually symmetrically giving it a characteristic ballooned appearance clearly discernible in the x ray plate Eventually the dural diaphragm covering the sella turcica or the thin floor separating it from the sphenoid sinus will give way Usually the floor does not completely disintegrate but when it does the tumor invades the underlying sinus and may even appear as a projection in the nasopharynx If the dural diaphragm above ruptures as it frequently does the enlarging tumor pushes the optic chiasm upward and backward at the same time flattening and stretching the optic nerves

As a result of encroachment on the chiasm the decussating optic fibers are physiologically interrupted or become degenerated thus producing atrophic changes in the nerve head and changes in the visual fields which at first are characteristically bitemporal upper quadrantal defects With progression of the growth the bitemporal defect becomes complete and implication of the macular fibers impairs the capacity for reading ordinary print Eventually the optic nerves degenerate resulting in total blindness Infrequently the tumor may project posterior to the chiasm and though the dominant changes in the visual fields are still bitemporal the early defects are less likely to be manifest in the upper quadrants Should such a posterior projecting tumor grow laterally, the optic tract on that side might be compressed producing a contralateral homonymous hemianopia

Once the tumor has broken through the dural diaphragm it takes on the aspects of any other intracranial tumor Though these growths rarely attain massive size, encroachment on the floor of the third ventricle producing hypothalamic symptoms, does occur and occasionally further extension in this direction blocks the ventricular system producing internal hydrocephalus with its accompanying symptoms The form of the growth is usually globular and tends to lie in the midline but occasionally it may spread irregularly to encircle the carotid arteries it may compress the oculomotor nerves producing extra ocular palsies it may invade the temporal lobe producing uncinate seizures and other temporal lobe symptoms, cases have been reported even of extension through the tentorial incisura into the posterior fossa

Degeneration or hemorrhage in these tumors is not uncommon and results in cystic formations These degenerative processes account no doubt for the unexpected remissions of symptoms observed in some cases

Each of the three varieties of hypophysial adenoma has been found to have distinctive constitutional manifestations wholly apart from the local pressure effects on the intracranial structures (producing so-called neighborhood signs) The chromophobe adenoma whose cells are thought to have no hormonal function produces a train of symptoms which have been considered to represent a state of hypopituitarism resulting from compression of the hypophysis The eosinophile adenoma whose cells are believed to have a growth producing function are always associated with signs of overgrowth—gigantism or acromegaly—and the intensity of the overgrowth varies with the degree of eosinophilia The basophile adenoma whose cells by deductive reasoning are thought to have gonadotropic function are now believed to produce an equally striking clinical syndrome The proportion in a series (by Cushing) of 385 verified cases of hypophysial adenoma was 277 chromophobe 107 acidophile and mixed and 1 basophile Each of these will be taken up separately

Chromophobe Adenoma (*Hypopituitarism*) —By far the most common tumor of

the hypophysis is the chromophobe adenoma In view of the fact that to other adenomas of the hypophysis and indeed, to those of most ductless glands a hypersecretory function is ascribed one would expect the chromophobe adenoma to possess similar properties On the contrary it is an exception to the rule for chromophobe cells are known to be functionless Yet by the mechanical compression of the remainder of the hypophysis the adenoma produces a the face and neck The hands appear pudgy and the fingers delicate and tapering the nails showing no crescents The hair is scant and of fine texture, in males the beard requires infrequent shaving and the pubic hair takes on a female distribution A moderate adiposity develops of feminine distribution or more nearly like the indifferent infantile contour Menstruation ceases in the female and impotence and loss of libido occur in the male The temperature is frequently sub

Fig 157.—Roentgenogram showing destruction of posterior clinoids and floor of sella turcica caused by chromophobe adenoma of pituitary

state of hypopituitarism with symptoms less dramatic but just as recognizable as those resulting from hyperpituitarism

The sexes are equally affected and the incidence of the disease is about evenly distributed in the three decades between twenty and fifty In isolated cases the disease has appeared after fifty and in a few before twenty Should the child or adolescent be afflicted he becomes dwarfed and fails to mature sexually This clinical picture is more frequently encountered in other conditions of hypopituitarism the most usual being the craniopharyngioma

Hypopituitarism in the adult produces symptoms of sluggishness lassitude fatigue and an unusual sensitivity to cold The complexion becomes pallid and the skin dry thin and delicately wrinkled especially over normal the pulse slow and the basal metabolism materially lowered

Although the chromophobe adenoma has a tendency to grow to a larger size than the eosinophile adenoma the resulting symptoms and signs never take on the aspect of profound hypopituitarism manifest by the advanced cachexia and senility of Simmonds disease in which the last vestige of the hypophysis is destroyed

Headache of frontal and temporal distribution commonly accompanies an expanding hypophysial adenoma though the exact mechanism by which the headache is produced is not established The sella turcica balloons as the adenoma enlarges and when the growth finally breaks out of its confines as it does in a very large percentage in this type of adenoma the neighborhood signs

types occur which are known as mixed adenomas, but they are predominantly chromophobe adenomas with eosinophile elements The cells of the small basophile adenomas possess granules staining with the basic dyes and many of them are multinuclear It might be expected that these tumors being epithelial in origin might become carcinomatous but rarely does one find more than occasional mitosis and in general the tumors are comparatively slow growing

As the adenoma grows it displaces and compresses the rest of the hypophysis until the gland may be hardly recognizable The dural envelope of the hypophysis and the bony confines of the sella turcica are more resistant, but they too finally yield The sella turcica gradually increases in size (normal dimensions—10–14 mm anteroposterior by 14–15 mm in width by 8 mm deep) usually symmetrically giving it a characteristic ballooned appearance clearly discernible in the x ray plate Eventually the dural diaphragm covering the sella turcica or the thin floor separating it from the sphenoid sinus will give way Usually the floor does not completely disintegrate but when it does the tumor invades the underlying sinus and may even appear as a projection in the nasopharynx If the dural diaphragm above ruptures as it frequently does the enlarging tumor pushes the optic chiasm upward and backward at the same time flattening and stretching the optic nerves

As a result of encroachment on the chiasm the decussating optic fibers are physiologically interrupted or become degenerated thus producing atrophic changes in the nerve head and changes in the visual fields which at first are characteristically bitemporal upper quadrantal defects With progression of the growth the bitemporal defect becomes complete, and implication of the macular fibers impairs the capacity for reading ordinary print Eventually, the optic nerves degenerate resulting in total blindness Infrequently the tumor may project posterior to the chiasm and though the dominant changes in the visual fields are still bitemporal the early defects are less likely to be manifest in the upper quadrants Should such a posterior projecting tumor grow laterally the optic tract on that side might be compressed producing a contralateral homonymous hemianopia

Once the tumor has broken through the dural diaphragm it takes on the aspects of any other intracranial tumor Though these growths rarely attain massive size encroachment on the floor of the third ventricle producing hypothalamic symptoms, does occur and occasionally further extension in this direction blocks the ventricular system producing internal hydrocephalus with its accompanying symptoms The form of the growth is usually globular and tends to lie in the midline but occasionally it may spread irregularly to encircle the carotid arteries it may compress the oculomotor nerves producing extra ocular palsies it may invade the temporal lobe producing uncinate seizures and other temporal lobe symptoms cases have been reported even of extension through the tentorial incisura into the posterior fossa

Degeneration or hemorrhage in these tumors is not uncommon and results in cystic formations These degenerative processes account no doubt, for the unexpected remissions of symptoms observed in some cases

Each of the three varieties of hypophysial adenoma has been found to have distinctive constitutional manifestations wholly apart from the local pressure effects on the intracranial structures (producing so-called neighborhood signs) The chromophobe adenoma whose cells are thought to have no hormonal function produces a train of symptoms which have been considered to represent a state of hypopituitarism, resulting from compression of the hypophysis The eosinophile adenoma whose cells are believed to have a growth producing function are always associated with signs of overgrowth—gigantism or acromegaly—and the intensity of the overgrowth varies with the degree of eosinophilia The basophile adenoma whose cells by deductive reasoning are thought to have gonadotropic function are now believed to produce an equally striking clinical syndrome The proportion in a series (by Cushing) of 385 verified cases of hypophysial adenoma was 277 chromophobe 107 acidophile and mixed and 1 basophile Each of these will be taken up separately

Chromophobe Adenoma (*Hypopituitarism*) —*By* far the most common tumor of

notices an increase in dimensions and shape of his hands and feet X rays show a proliferation at the tips of the distal phalanges spoken of as tufting The palms and fingers become broadened producing a square spadelike appearance of the hand The entire hand looks puffy though creased, and feels stiff to the patient He is made aware of these changes further by the necessity for increasing both his glove and shoe size At the same time the facial features coarsen the lips thicken the nose takes on an overgrown bulbous appearance and the nostrils widen The head becomes large and supraorbital ridges prominent from thickening of the skull bones Similar overgrowth of the mandible produces a square protruding jaw (prognathism) and widely spaced teeth The jaws frequently match so badly that mastication is impaired The tongue becomes so large and awkward as to impede lingual speech The skin everywhere hypertrophies and wrinkles and the scalp particularly is loose and ridged like a bulldog s Perspiration is profuse and possesses a peculiar acrid odor noticeable to the patient as well as to others Hypertrichosis is usual and when superimposed on the prominent supraorbital ridges gives a striking beetle-browed appearance There is a stoop to the shoulders and the general appearance takes on the aspect of a ferocious caricature almost frightening until one hears the lisping (though deep voiced) speech and sees these weakened miserable creatures break into tears as they so frequently do

Later on the patient experiences dull headaches in the frontal or bitemporal regions from distention of the dural envelope of the hypophysis He feels extreme weakness and lassitude and becomes easily dyspneic on exertion He is uncomfortable with backache with neuralgic pains and paresthesias in the extremities He is constantly hungry and may have increased thirst and polyuria The basal metabolism at this time will show an increase and a glycosuria is present which is notably resistant to insulin therapy Menses in the female and sexual libido and potentia in the male are sometimes increased in the early stages but eventually diminish or disappear entirely

With the enlargement of the adenoma the sella turcica balloons giving the characteristic picture on the x ray plate in about 90 per cent of the cases A third of these never reach sufficient size to break out of the natural confines The others extend into the intracranial cavity and present the usual signs of chiasmal hypothalamic or temporal lobe compression

The progress of the disease is usually self limiting Occasionally it appears to have remissions and exacerbations and there are cases which show only slight acromegalic features (fugitive acromegaly) In the course of most acromegalics a phase of hypopituitarism appears The skin softens, hair falls out the disagreeable perspiration ceases polyphagia polydipsia and polyuria subside feebleness increases basal metabolic rate becomes normal or subnormal, and diabetes mellitus if present may disappear

Fig 159 —Roentgenogram of skull of an acromegalic with verified eosinophile adenoma of the hypophysis Note the ballooned sella turcica, thick skull large frontal sinus and large mandible

If there is progression death may result from intracranial extension or from cardiovascular complications associated with the hypertrophic changes that affect the heart and blood vessels But even progressive cases may go on for many years one is recorded as having a fifty year duration and a patient who lived to be eighty three had symptoms for thirty eight years the tumor having become cystic

resulting from compression of the optic chiasm, hypothalamus, temporal lobe and others appear

The differential diagnosis is usually not difficult The enlarged sella turcica points to an adenoma (except in those rare instances of gumma or metastatic carcinoma of the hypophysis) and certainly there should be no difficulty in distinguishing the appearance of hypopituitarism of the chromophobe adenoma from the acromegaly or gigantism of the eosinophile adenoma The lesions about the sella turcica producing hypopituitary symptoms do not characteristically balloon the sella though the hypophysis is compressed and the clinoid processes may show destruction A disconcerting occurrence, as far as early and accurate diagnosis is concerned is the occasional rupture of the chromophobe adenoma through the diaphragma sellae without previous erosion of the sella turcica But the gravest danger is in not diagnosing a tumor at all until the patient s vision has undergone perhaps irreparable damage

Eosinophile Adenoma (*Hyperpituitarism —Gigantism and Acromegaly*) —The classic description of two cases of this remarkable disease by Marie in 1886 laid a foundation for all subsequent clinical studies The acral enlargements, on which the clinical recognition of the disease rests served to name the disorder The final proof of the part played by the eosinophile adenoma of the hypophysis came a number of years later

The disease occurs in adults and appears most commonly between the ages of twenty and thirty though rare cases have been thought to begin as late as fifty If it begins before twenty that is, before the epiphyseal lines have closed the clinical picture is that of gigantism, almost all circus giants are examples of this Acromegalic features may never appear if the hypophysial adenoma becomes inactive before maturity but if it continues to be active acromegalic features superimpose those of gigantism and all transitions between the two may result It is far from being a disorder which affects all its victims in the same way or in equal degree The disease is not hereditary but occasionally is familial It occurs about equally in male and female and in the latter may follow soon after pregnancy

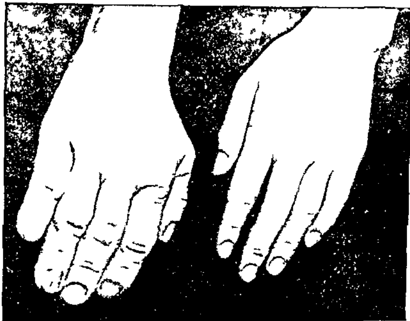

Fig 158 —Hand of a woman with acromegaly compared with normal woman s hand

Whereas in gigantism there is a general ized symmetric increase in size particularly in the length of bony structures in acromegaly there is a localized increase in the size of various structures producing a curious bodily configuration which cannot be mistaken for any other malady The changes occur slowly but eventually the patient

symptoms is in proportion to the amount of tumor removed But the pituitary insufficiency which may result from too radical removal may be much more disagreeable than the acromegaly and it is to be remembered that operation is performed only for the purpose of saving vision and relieving the symptoms of extrasellar extension

Following successful operation there are all degrees of improvement Reestablishment of normal menstrual cycle is frequent and pregnancy is possible potentia and sexual libido may return in the male There is usually great improvement in the appearance and well being of the patient Though there is little hope for the restoration of vision once blindness has supervened many of those patients with partial loss get complete return of visual function and others regain a part of it

Basophile Adenoma (*Pituitary Basophilism—Cushing Syndrome*) —A curious clinical syndrome was pointed out by Cushing (*in 1932*) which he termed pituitary basophilism" and ascribed to the presence of an hypophysial adenoma made up of basophile cells

It will be recalled that there appear to be at least two established functions of anterior lobe secretion—growth provoking and sex maturing And there are three kinds of cells in the anterior lobe chromophobe eosinophile and basophile, each known to develop adenoma forms The cells of the chromophobe adenoma are functionless whereas the cells of the eosinophile adenoma have been shown both clinically and experimentally to promote growth By inference therefore the basophile cells and the sex maturing hormone represent a combination of cause and effect it merely remained to be found which one of the many clinical dyspituitary states was the resulting syndrome of the basophile adenoma This in

A B

Fig 161.—*Girl fifteen years of age, with basophilism (one of Dr Cushing's original cases) A Note the plethoric appearance of the face with abnormal growth of hair on brows and face B Note the obesity of the trunk and round shoulderedness also the abdominal striae (Courtesy of the Archives of Surgery)*

Besides the overgrowth of subcutaneous tissue and bone manifested by the external appearance of the acromegalic patient post mortem examination reveals widespread splanchnomegaly of unusual degree involving all organs of the thorax and abdomen There is an evident tendency for the other ductless glands to develop hypertrophic and adenomatous changes sometimes with associated alterations in their function

Treatment of the Chromophobe and Eosinophile Adenoma—So far there is no outstanding therapy with which to supplement hypopituitarism and there is none to counteract hyperpituitarism except x ray radiation and surgery The use of x ray therapy to reduce the growth of the chromophobe adenoma has on the whole been disappointing although the beneficial results in the occasional case make a therapeutic trial worthwhile Unlike the chromophobe adenoma the eosinophile adenoma is relatively sensitive to x ray therapy and unless the tumor has extended outside the sella turcica producing neighborhood signs operation is to be avoided If there is no immediate danger to vision therefore x ray therapy should always be tried for it may retard or even stop the growth This is not entirely without danger however, for edema or hemorrhage may result in a degree sufficient to produce blindness or more serious symptoms if the tumor has a tendency to invade the cranial cavity It is now common practice in the majority of cases in which part of the adenoma has been surgically removed to follow with a complete series of x ray treatments

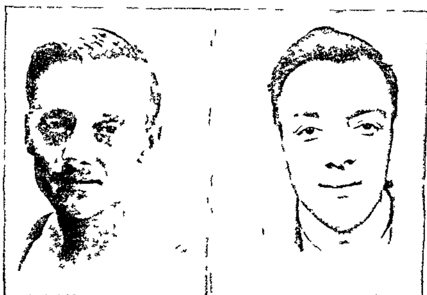

Fig 160—Photographs of the same patient taken ten years apart The one on the right shows the development of acromegaly during the interval

Surgery on these patients offers numerous hazards but must not be delayed when indicated that is when the tumor has extended beyond the sella turcica These patients are notoriously bad surgical risks and experience shows that the reserves upon which one depends in grave surgical procedures are unaccountably lacking The choice of operative approach to the tumor hardly offers a problem except to the surgeon Formerly a transsphenoidal approach to the sella turcica was used but obviously extrasellar extensions of the tumor are impossible to reach with this approach and meningitis is a hazard The various intracranial approaches allow better exposure although with the necessary retraction of the brain the hypothalamus may be damaged and postoperative extradural blood clots and cerebral edema are prone to form

It is also difficult to decide how much of the tumor to remove There is always a tendency to do a more radical extirpation than is safe in an attempt to prevent a recurrence In the acromegalic especially the improvement in the hyperpituitary signs and

symptoms is in proportion to the amount of t mor removed But the pituitary insuf ficiency which may result from too radical removal, may be much more disagreeable than the acromegaly and it is to be remem bered that operation is performed only for the purpose of saving vision and relieving the symptoms of extrasellar extension

Following successful operation there are all degrees of improvement Reestablishment of normal menstrual cycle is frequent and preg

clinical syndrome was pointed out by Cush ing (in 1932) which he termed pituitary basophilism' and ascribed to the presence of an hypophysial adenoma, made up of basophile cells

It will be recalled that there appear to be at least two established functions of an terior lobe secretion—growth provoking and sex maturing And there are three kinds of cells in the anterior lobe chromophobe eosinophile and basophile each known to

nancy is possible, potentia and sexual libido may return in the male There is usually great improvement in the appearance and well being of the patient Though there is little hope for the restoration of vision once blindness has supervened many of those pa tients with partial loss get complete return of visual function and others regain a part of it

Basophile Adenoma (*Pituitary Basoph ilism—Cushing Syndrome*) —A curious

develop adenoma forms The cells of the chromophobe adenoma are functionless whereas the cells of the eosinophile adenoma have been shown both clinically and experi mentally to promote growth By inference therefore the basophile cells and the sex maturing hormone represent a combination of cause and effect it merely remained to be found which one of the many *clinical* dyspituitary states was the *resulting syn* drome of the basophile adenoma This in

brief, was the reasoning behind the prediction of a basophile adenoma in an obese and hirsute young woman of twenty who began at nine to have profuse menstrual flow At fourteen she had attained adolescence and menses became most irregular At fifteen she had grown exceedingly obese eventually reaching 206 pounds She died of an intercurrent infection and, on postmortem examination was found to have a small hypophysial adenoma made up of basophile cells

In his original paper dealing with this subject Cushing collected a group of twelve patients all young adults from which the following features were characteristic of all cases (1) a rapidly acquired and usually painful adiposity confined to face neck and trunk (2) a tendency to kyphosis from a peculiar softening of the bones of the spine, (3) sexual dystrophy shown by early amenorrhea in the females and ultimate impotence in the males (4) an alteration in normal hirsuties shown by hypertrichosis of face and trunk in all females as well as preadolescent males and possibly the reverse in the adult males (5) a dusky or plethoric appearance of the skin with purplish striae (6) vascular hypertension (blood pressure varying from 230/170 to 178/100) (7) a tendency to polycythemia (8) variable backaches abdominal pains fatigability and ultimate extreme weakness A list of other less constant features includes acrocyanosis ecchymoses aching pains in the eyes slight exophthalmos dryness of skin polyphagia polydipsia, polyuria edema of the lower extremities and an unusual susceptibility to infection

While Cushing s syndrome is more often found to be associated with basophilic adenoma with or without adenomas of the adrenals there are a number of authentic cases in which the syndrome is accompanied not by an hypophysial adenoma but by a malignant tumor of the adrenal In a few cases autopsy has failed to reveal tumors of either the hypophysis or adrenal But in all cases it is believed that there exists in the basophilic cells of the hypophysis certain degenerative changes described by Crooke

In any case the evidence such as it is suggests that the syndrome is in the nature of an hyperadrenocorticism whether the state is initiated in the hypophysis or the adrenal and the clinical features are sufficiently constant to establish the syndrome as a disease entity

Treatment —None of the basophile adenomas reach sufficient size to produce pressure changes and therefore do not require surgery It would be expected however that these adenomas like the eosinophile, would react favorably to x ray radiation and this to a degree has been found true In cases where there is sufficient reason to suspect the presence of an adrenal cortex tumor operation on this gland should not be withheld

Albright and his associates have stressed that in this syndrome there predominates an overproduction of sugar with decreased glucose tolerance and a decreased availability of amino acids with which to build protein The administration of testosterone proprionate has had some beneficial effects

CRANIOPHARYNGIOMA

After Marie s description of acromegaly and later after its probable association with tumor of the hypophysis had become known reports began to appear of instances of hypophysial tumor without acromegaly Most of these cases presented a picture of hypopituitarism and Frohlich (in 1901) described in detail a case of an obese boy with underdevelopment of the genitalia Since then it has been found that the clinical picture is often the result of a cystic tumor arising from epithelial rests due to an imperfect closure of the craniopharyngeal duct This duct it will be remembered is a part of the outpouching from the buccal mucosa which unites with an outpouching from the diencephalon to form the hypophysis

Craniopharyngioma is the usual name given this tumor though it is variously called suprasellar cyst hypophysial duct tumor craniopharyngeal duct tumor Rathke s pouch tumor and on a histopathologic basis 'adamantinoma epithelioma etc The size may vary from a few millimeters giving no symptoms to one

of unusual proportions, giving many symptoms Occasionally these tumors are solid but usually they are cystic with a comparatively tough though thin wall in which is found the cauliflower-like epithelial tumor mass in various stages of degeneration and calcification The cyst also contains varying amounts of viscid, yellow brown fluid which when held up to the light has the iridescent appearance of machine oil and on closer inspection, is seen to contain shimmering crystals of cholesterin which testify to its epithelial origin

Since these are congenital tumors symptoms may arise from them at any time in life What influences the growth of these embryonal rests is unknown of course but with surprising frequency there is a history of preceding and possibly associated trauma About half of the cases develop symptoms during childhood and adolescence, the rate of frequency steadily diminishes after twenty and only rarely will a case appear with symptoms beginning after sixty The sexes are affected equally These tumors are not rarities but (in Cushing s series) comprise 4 per cent of all verified intracranial tumors and are about half as frequent as the chromophobe adenomas from which they must be differentiated clinically

The tumors may arise above or below the diaphragma sellae Those arising below it may do nothing more than compress the hypophysis or they may grow upward and involve structures about the sella just as the hypophysial adenomas Those arising above the diaphragm involve the optic chiasm and other parasellar structures early but they too usually compress the hypophysis In doing so they cause erosion of the clinoid processes and dorsum sellae and produce changes different from the symmetrically ballooned sella caused by the hypophysial adenoma On the whole these tumors tend to grow larger than the adenomas and a not infallible rule is that the earlier in life they make their appearance the larger they are likely to become Though they tend to grow upward in the midline some project in other directions and it is not unheard of for one of them to grow through the tentorial incisura into the posterior fossa giving as first symptoms those of a cerebellopontine angle tumor

The symptoms show a wide variation, as would be expected on considering the gross features of the tumor Compression of the hypophysis produces a state of hypopituitarism damage to the optic chiasm impairs vision invasion of the hypothalamus disturbs the center of the vegetative nervous system and blocking of the third ventricle results in internal hydrocephalus In addition the manifestations of these states and

Fig 162—Two children of the same age The one on the right is normal The one on the left developed a craniopharyngioma at the age of five Note the complete cessation of growth

the complaints differ greatly depending on the time of life in which they appear Children complain most of headache and vomiting adolescents and young adults of sexual changes and personal appearance and older adults of failing vision

The children afflicted with this tumor present a striking appearance of underdevelopment This may take the form of general dwarfing with normal proportions or there may be a tendency to obesity or still another

group may show emaciation—known as the Loraın type ' The tardy growth or delicate appearance is frequently disregarded by parents as is the usual enuresis of these children But eventually the increasing headache and vomiting bring them to the physician who finds evidences of hydrocephalus in the enlarged head, separation of cranial sutures choked disks and sixth nerve palsy In the early stages, the children are notably bright and even precocious but sluggishness and somnolence supervene with advance of the disease In the very late stages there may be fits of violent thrashing about, retraction of the head and extensor spasms of the extremities Lowered metabolism and subnormal temperature are expected but a hyperthermia is likely to accompany the final events

Children who pass into adolescence with pituitary insufficiency undergo no sexual development, the girls do not menstruate and the boys are apt to have underdeveloped genitalia If the disease begins during adolescence or young adulthood menstruation stops in the female and sexual libido disappears in the male The body becomes moderately obese and in both sexes takes on the asexual contour of a child Growth stops or is slowed up giving the appearance of being younger than the actual age This is frequently spoken of as infantilism though the term should not imply mental retardation for these individuals are often mentally bright—even brilliant and are characteristically pleasant and likable The skin is delicate and pallid in some there is fine wrinkling of the skin about the face and neck which together with the small size suggests early senescence—a condition known as progeria There is scanty fine hair over the body and in the male female distribution at the pubis and lack of beard Frontal and bitemporal headaches develop and vision begins to fail

Older patients are less apt to show changes in bodily configuration but the hair becomes scanty and the skin wrinkled Menses and libido disappear indeed their disappearance may long precede the later symptoms of headache and failing vision Lassitude and somnolence are common Basal metabolism and blood pressure tend to be lowered

The *failing vision* in any of these patients is usually due to pressure on the optic chiasm the optic nerves in front of it, or the optic tracts behind and just as in the hypophysial adenomas the tumor may displace the chiasm forward or backward The characteristic visual defects are at first in the temporal fields but the configuration of the blind areas tends to be bizarre and less regular than is seen in cases of hypophysial adenoma The flat pallor of primary atrophy is seen in the nerve heads and complete blindness may finally result In some cases the chiasm may be largely spared but, if hydrocephalus develops, papilledema and secondary optic atrophy follow also producing failing vision One may expect sometimes, to find a combination of both of these processes Diplopia may be present as a result of direct compression of the third fourth or sixth nerve or a sixth nerve palsy may accompany the increased intracranial pressure of hydrocephalus

The mechanism of the internal hydrocephalus can be clearly understood by picturing the tumor obliterating the third ventricle and blocking the foramina of Monro The lateral ventricles dilate and headache vomiting and papilledema follow This headache is more severe and generalized than the frontal and temporal headaches that often accompany less extensive tumors in the region of the sella

There remains (for brief consideration) a group of interesting phenomena often and particularly associated with craniopharyngioma which are the result of damage to the hypothalamus This region contains the central nuclei for the entire vegetative nervous system its complicated blood supply from the circle of Willis and its connection with the hypophysis through the hypophysial stalk are frequently destroyed or injured by the tumor Lesions of the hypothalamus produce most notably states of pathologic sleep cardiac irregularities hyperthermia maniacal attacks inequality of pupils adiposity and diabetes insipidus The last two adiposity and diabetes insipidus are particularly interesting because of the dispute over the part the hypophysis plays in their production Without answering the question raised it may be said that both states may result from emboli or infectious processes

involving only the hypothalamic centers Also it may be said that the classic state of dystrophia adiposogenitalis Frohlich s syndrome does not result from hypopituitarism alone but from a combination with injury to the hypothalamus

The ataxic phenomena spastic states with retraction of the head and extension of the extremities seen in advanced cases, are due to compression of the *descending motor* tracts

The differential diagnosis for the most part is made from hypophysial adenomas and rarely from a few parasellar tumors The clinical pictures of the states of hyperpituitarism resulting from the chromophile adenomas offer no difficulty The hypopituitary syndrome of the chromophobe adenoma *is the one most likely to be confusing* There are several distinguishing features however *i.e.* the age limits are of some aid since adenomas never appear before fifteen but most of the craniopharyngiomas appear before that the sella turcica in the case of the craniopharyngioma shows on the x ray plate *irregular erosion mostly involving the* clinoid processes and the dorsum sellae unlike the ballooning of the sella from adenoma 80 per cent of the craniopharyngiomas show calcified areas in the tumor on the x ray plate the visual field defects of the adenoma are more regular

If there is any question with regard to the cause of hydrocephalus ventriculography is invaluable

Other lesions which may exist in the region of the sella turcica and optic chiasm are gliomas of the chiasm meningiomas arising from the tuberculum sellae tumors arising *from the floor of the third ventricle* rare tumors such as chordomas and cholesteatomas and chronic circumscribed arachnoiditis which may simulate tumor There are features in each of these that facilitate differential diagnosis but even though diagnosis is uncertain whenever vision is impaired operation is indicated

Treatment of Craniopharyngioma — Surgery is the only logical treatment for craniopharyngioma But to remove the entire growth without destroying or damaging the *surrounding structures is difficult* and usually the surgeon must be content with something less radical Merely tapping the *cyst will frequently serve to give long pe*riods of remission and some few may have no recurrence but at least a partial removal of the cyst wall is desirable If the cyst refills a succession of taps may serve to carry the patient along quite well but there is an unfortunate tendency for this type of refilling cyst to become progressively solid In such cases the outlook is not good

In recent years the impression is gaining that x ray treatment may provide unexpected benefit in the prevention of refilling *of the cyst once it has been drained surg*ically

PITUITARY ORGANOTHERAPY

Endocrinology has great possibilities for explaining the vagaries of growth sex and metabolism yet lends itself to two dangers one the popularization of the subject and *the other* the tendency *of* clinicians to draw on their fancy both as regards symptoms and treatment Our knowledge concerning the therapy of hypophysial disease has by no means kept pace with the advance in knowledge of pituitary dysfunction and too little is known of biochemical products on *which we pin our chief hope*

Posterior lobe extract—pituitrin—has marked transitory effects on cardiovascular respiratory and renal systems as well as on metabolism smooth muscle and certain glandular structures Separation of the product into pitocin (oxytocin) and pitressin *has not been entirely satisfactory* and their physiologic effects overlap Clinically these preparations are variously used by obstetricians to cause uterine contraction and aid in the expulsion of the fetus or placenta also to control hemorrhage and overcome atony No particular clinical advantage has been shown from the use of pitocin Pituitrin and pitressin have a limited use in stimulating bowel action and allaying abdominal distention

Pituitrin because of its antagonistic action on insulin has found use in helping to overcome the effect of hyperinsulinism Its antidiuretic properties are employed *to ad*

vantage in treating diabetes insipidus but the action is transitory and continued usage is necessary Convenient preparations for nasal spray and snuffing are obtainable

But aside from these uses of posterior lobe preparations one cannot definitely assign to them any physiologic role in the treatment of disease of the hypophysis

In the preparation and use of anterior lobe and whole gland extracts there has been only limited success Various growth hormones are on the market but in an uncertain state of purification and not yet officially recognized Beneficial results are reported from their usage during the growth period but growth is not stimulated at a rate sufficiently above normal to rehabilitate the dwarf and even the most enthusiastic admit that a more potent extract is to be desired if it is to find wide use in clinical medicine It is one thing to transplant gland tissue daily to a laboratory animal and another to put the principle to clinical use

The sex maturing hormones prepared from the gland itself so far have had no value However following the discovery of anterior pituitary like hormone in the urine of pregnancy—prolan—preparations from this urine have appeared on the market and attained wide vogue in the treatment of conditions supposedly the result of deficiency in gonadotropic hormone The beneficial results obtained from these preparations in some cases of functional uterine bleeding warrant their trial but their employment in endocrinopathic amenorrhea alone has no value Beneficial and sometimes striking results have followed their use in some cases of undescended testicle not the result of a mechanical defect

The value of any of the pituitary preparations in the treatment of other pituitary deficiencies besides those mentioned is questionable The fact that in no instance has the more or less blind usage of these extracts led to definitely harmful results testifies to their lack of potency The oral administration of pituitary preparations is looked upon by most investigators as useless and the cost of repeated injections of the comparatively expensive extracts over months and years is prohibitive to most patients Much of the overenthusiasm on the question of pituitary extracts is to be deplored yet no doubt some day, aided and abetted by their intelligent employment meanwhile, perfection of these preparations will be attained

In contrast to the unsatisfactory results in the use of whole pituitary substance are the brilliant successes in the use of purified and synthetic substances employed in the treatment of disturbances in the peripheral endocrine glands Thus the secondary deficiencies of the other glands in dyspituitary states often can be dealt with by substitution therapy The most useful of the substitution products at present are thyroid, parathyroid, insulin adrenalin adrenocortical hormones testicular and ovarian steroids diethylstilbestrol, methyltestosterone and dihydrotachysterol Thyroid and testosterone in small amounts are thought to stimulate the pituitary gland while large doses of gonadal hormones probably inhibit it The ramifications of the use of substitution therapy in pituitary disease are too complex to discuss here but the indications and methods of administration are rapidly being established and the reader will find ample accounts in current writing

DISEASES OF THE SUPRARENAL GLANDS

The suprarenal glands were first described by Eustachius in 1563 Despite much speculation and considerable investigation no true inkling of their function was apparent until the memorable studies of Thomas Addison culminating in 1855 in his classic description of the disease which now bears his name morbus addisonii This probably represents the beginning of endocrinology since his discoveries directed medical thought and effort into new and fruitful channels In the following year Brown Sequard showed that these glands were essential to life and Vulpian the discoverer of the chromaffin system, demonstrated in them the presence of a substance probably adrenalin which turned greenish on contact with ferric chloride Physiologic studies by Oliver and Schaefer in 1894 demonstrated the vasoconstrictor and pressor properties of the medullary extracts the chemical nature of which was studied in turn by von Furth and by Abel the latter in 1897 preparing a physiologically active monobenzoyl derivative of epinephrine from the suprarenal medulla This was followed by the isolation crystallization and purification of the adrenalin base by Takamine and Aldrich the structural formula being determined by Jowett in 1904 and its synthesis effected in the same year by Stokes The cortical hormone the substance essential to life has eluded the chemist until quite recently when a mildly active aqueous extract was prepared by Rogoff and Stewart (interrenin) and by Hartman (cortin) However the most potent extract was isolated in 1930 by Swingle and Pfiffner who used lipoid in place of aqueous solvents Their extract is capable (1) of prolonging the lives of adrenalectomized animals indefinitely (2) of restoring morbund adrenalectomized animals to the normal state and (3) of overcoming the clinical manifestations of hormonal deficiency in patients with Addison s disease The essential cortical hormone is concerned with water distribution in the body sodium metabolism with blood volume and circulatory efficiency with appetite nutrition digestion the assimilation of food and with energy transformation The active hormone is still unknown though desoxycorticosterone (Reichstein) probably approaches it in chemical structure and physiologic activity In all probability there are several hormones

The cortex of the adrenal gland is concerned in some way with the development and function of the gonads as evidenced by sex changes occurring in patients suffering from cortical tumors These sex anomalies will probably find their explanation in the bisexual anlage and in the chemistry of the hormones concerned *i.e* adrenosterone androgens and estrogens Some interrelation exists also between the function of the adrenal and the pituitary glands

ADRENAL HEMORRHAGE IN THE NEWBORN

Hemorrhage into the adrenal in the newborn usually results in death It is rarely diagnosed except at autopsy Eighty-one cases appear in the literature 11 of which were diagnosed during life Endocrine dysfunction is evidenced by rapid respiration high temperature rash (purpura or petechiae) convulsions cyanosis and gastrointestinal disturbances such as vomiting diarrhea and abdominal pain The concomitant hemorrhagic symptoms are evidenced by (*a*) shock and collapse weak small and irregular pulse air hunger, increased pallor (*b*) distended abdomen with a boggy sensation to touch and a palpable tumor in one or both renal areas The treatment consists of intravenous injection of cortical extract of saline and of 10 per cent glucose solution

LEONARD G ROWNTREE

TUMORS OF THE SUPRARENAL GLAND

In order to understand the tumors of the suprarenal glands it is essential to know something of the anatomy and histology of the glands and more particularly the cytology and origin of the cells concerned since the type of cell present may determine the nature of the clinical manifestations encountered in the individual case The gland consists of two portions the cortex and the medulla which are of different embryonic

origin The medulla is made up of chromophile cells from the embryonic sympathetic nervous system and the cortex of epithelial cells arising from the wolffian body

Cortical Tumors —Tumors of the cortex of the suprarenal lead to the 'syndrome genitosurrenale in the fetus to congenital pseudohermaphroditism, in the infant, to pubertas praecox and in the adult to virilism and hirsutism The age at which the tumor develops is crucial in determining the extent of the changes induced Prenatal overactivity brought to bear on an underdeveloped organism brings about such extreme changes as pseudohermaphroditism while the same influence operating in adult life causes moderate hypertrophy of the clitoris hirsutism and virilism

Pseudohermaphroditism more frequent in the female consists in marked overgrowth of the clitoris which comes to resemble the penis with concomitant suppression of growth of the uterus and ovaries

Infantile pubertas praecox is more frequent in the male It is characterized by premature and excessive development of the sex organs and early appearance of secondary sex characters Thus a male infant of thirty months may exhibit genitalia of adult proportions voice changes and profuse coarse pubic hair In addition to genital changes a tumor may be felt in either flank Metastases are common especially in the joints and when present bespeak a bad prognosis Such tumors developing in young girls usually lead to hypertrophy of the clitoris and to increased growth and male distribution of hair

Virilism and Hirsutism —The incidence of cortical tumors in adults is higher in women Clinically the patients tend almost invariably to become more masculine The skin becomes coarse greasy and often presents an acneform rash The growth of hair is stimulated particularly of the beard and mustache The pubic hair partakes of male distribution The clitoris tends to enlarge the uterus ovaries and breasts to atrophy In the course of a few months an erstwhile beautiful woman may assume the appearance of a coarse, hairy and rather loathsome male the voice becoming masculine Such tumors occurring in men usually lead to increased masculinity but in one of Holl s cases feminism developed in a man past forty years of age, marked hypertrophy of the mammary glands atrophy of the testes and penis loss of libido and potentia and reversal of sex interest

The *treatment* of these cortical tumors is surgical removal of the tumor, which if undertaken prior to the development of metastases may result in absolute and permanent cure and a complete disappearance of all abnormal clinical manifestations Probably the most interesting case of this type in the literature is that described by Gordon Holmes This patient observed for two years prior to operation presented the typical picture of hirsutism and virilism and within a few months after operation was completely restored to normal and still remained so nine years later One of our own patients similarly recovered within a year after operation

Formerly surgical treatment of these tumors was associated with great risk collapse and death frequently resulting from hormonal deficiency within a few hours or days after operation This is probably best explained on the hypothesis that owing to the assumption of adrenal function by the tumor cells themselves the function of the contralateral or normal gland is suppressed The removal of the tumor deprives the body of its supply of cortical hormone The temporary administration of cortical extract (Swingle) or desoxycorticosterone acetate by way of substitution therapy and of sodium chloride is desired until the remaining adrenal resumes its function

Radiation of the gland through deep x ray therapy or by radium may prove helpful temporarily where operation is contraindicated because of metastasis or for other reasons

In connection with these tumors the displacement of the contiguous kidney best appreciated through pyelography is of diagnostic importance Certain clinical phenomena are of unusual interest and deserve further investigation (1) the tremendous increase in appetite and in body weight which may accompany the metastasizing tumor (2) the concomitant development of hypertension which may disappear as a result of removal of the tumor (3) the coexistence of cortical tumor and the clinical

manifestations suggestive of Addison s dis ease—brownish pigmentation of the skin, extreme exhaustion, and in certain cases emaciation

Medullary **Tumors**—The immediate anlage of the suprarenal medulla lies in the sympathetic ganglia which are themselves derived from the neural crest Medullary tumors are of three varieties depending on the type of cell from which they arise All are rare

Neuroblastomas—These are of three types that described (1) by Pepper char acterized by metastases to the liver and lungs or to the abdominal lymph nodes (2) by Hutchinson characterized by metastatic involvement of the orbit skull and long bones, recognized therefore most frequently by orthopedic surgeons or roentgenologists and (3) by Goldzieher characterized by marked anemia suggesting the pernicious type Hutchinson s variety is relatively the most frequent It runs a rapid and fatal course and metastasizes freely particularly to the scalp skull and vertebrae

Ganglioneuromas are benign and occur usually prior to the twentieth year

Paragangliomas consist of chromaffin type of cells and may occur where chromaffin cells exist These tumors were first described by Rabin in 1892 since then about thirty cases have appeared in the literature They are accompanied not infrequently by intermit tent paroxysmal hypertension

One of my patients is of unusual interest in this connection as the surgical removal of the tumor was followed by immediate complete and permanent recovery The pa tient a young woman thirty years of age was admitted complaining of peculiar spells The paroxysmal attacks had com menced one and one half years previously and were increasing in frequency and se verity occurring once or twice daily and lasting from one half hour to three or four hours The spells were preceded by discom fort in the epigastrium followed by dyspnea occipital headache tachycardia palpitation vomiting and peculiar blanching of the skin particularly of the face Observation in an attack revealed hypertension a systolic pres sure of over 300 mm of mercury with nor mal blood pressure between The tumor on removal proved to be a paraganglioma This constitutes the first complete clinical record with cure Since this report, similar cases with successful removal of the tumor have been reported by Shipley and Pincoffs and by Porter and Porter The presence of epi nephrine in the tumor removed by Shipley was demonstrated by Professor Schultz

Although the hypertension accompanying paragangliomas is usually intermittent in type it may become continuous The clinical picture observed during these spells so closely resembles malignant hypertension that it would seem desirable to reconsider the whole question of the relation of the adrenals to hypertension

Intermittent hypertension has also been observed in association with cortical tumors accompanied by clinical manifestations of hirsutism and virilism (Oppenheimer and Fishberg) In one of these cases autopsy revealed a tumor involving both the adrenal cortex and the medulla The removal of such a tumor by Murray and Simpson resulted in complete relief both from virilism and from hypertension the systolic blood pres sure dropping from 200 to 130 mm of mer cury although it continued to rise abnor mally under stress and strain

The *treatment* of these tumors is surgical The use of cortical extract or hormone and of sodium chloride decreases the surgical risk and greatly enhances not only the prospects of the individual patient but also an effec tive understanding of the various types of cells and their function in the organism The correlation of clinical pathologic and histologic findings is urgently needed in all tumors of the adrenal glands Similarly such correlations are essential in all tumors ac companied by virilism and hirsutism among which should be included pituitary bas ophilism tumor of the kidney (hyper nephroma) tumor of the ovary (arrheno blastoma) and the oat cell tumor of the thymus gland

LEONARD G ROWNTREE

HYPOFUNCTION OF THE ADRENAL GLAND —HYPO ADRENALISM OR HYPO ADRENIA

The clinical syndrome involving exhaus tion chronic fatigue emaciation low basal metabolism low blood pressure and loss of libido and potentia is often diagnosed hypo

adrenalism or hypo adrenia The justification of such a diagnosis is questionable Two such cases so diagnosed by prominent internists were subjected to treatment with cortical hormone in amounts sufficient to control Addison s disease Both failed to show improvement Since epinephrine is likewise ineffective further evidence implicating the adrenal is needed

LEONARD G ROWNTREE

ADDISON S DISEASE

(*Morbus Addisonii*)

Definition — The leading and characteristic features of the morbid state to which I would direct attention are anemia a general languor and debility a remarkable feebleness of the heart s action irritability of the stomach and a peculiar change of color of the skin occurring in connection with the diseased condition of the suprarenal capsule (Thomas Addison 1855)

Etiology —The remote cause of the disease from the practical point of view is tuberculosis of the gland in 80 to 90 per cent of the cases and atrophy of unexplained origin in 10 to 20 per cent The immediate cause of the clinical manifestations is deficiency of the cortical hormone which appears when approximately four fifths of the gland substance is destroyed by pathologic processes Syphilis coexists in a not inconsiderable proportion of cases Its etiologic relationship to Addison s disease is still a matter of controversy Amyloidosis is occasionally concerned Other causes frequently assigned are of almost negligible consideration namely carcinoma mycosis fungoides and lesions involving the semilunar ganglion, the solar plexus and the abdominal sympathetic chain Hemorrhage and infarction play a role in the newborn

The disease is rare about sixteen cases per 100 000 admissions in the Mayo Clinic It is twice as common in the male as in the female and is most frequent between the ages of thirty and fifty According to the mortality statistics of the Bureau of the Census its incidence has decreased approximately 33 per cent since the beginning of the century It is now 0 3 per 100 000

Morbid Anatomy —Bilateral fibrocaseous tuberculosis was found in fourteen of fifteen cases by Hedinger, in twenty two of twenty nine cases by Conybeare and Mills and in twenty six of thirty one of our cases studied by Nelson W Barker The bacillus of tuberculosis was demonstrated in eleven of our fourteen cases studied within five years of death As a rule the glands are found to be definitely enlarged sometimes weighing from 20 to 30 Gm (normal 4–10 Gm) Complete calcification is not frequent, although marked increase in calcium may be easily shown roentgenologically during life and by chemical analyses at necropsy

One case of atrophy was observed by Addison Bittorf reviewed thirty such cases described in the literature Conybeare and Mills described six cases in 1884 Brenner five in 1923 and we have studied six The cause has been ascribed to simple atrophy secondary to necrosis from some toxin with specific affinity for the suprarenal cortex (Brenner) Congenital hyperplasia and lesions of atypical tuberculosis and syphilis have also been suggested by others In one of our cases the possibility of injury from x ray was considered Complete absence of the adrenal glands has been described at times In one of our cases no glands could be located except on serial section of the tissues concerned

Tuberculosis, healed or active lesions, existed elsewhere in all our cases of adrenal tuberculosis as pulmonary tuberculosis nodules in the lungs or lymph nodes of the hilum pleural adhesions genito urinary tuberculosis or osseous tuberculosis particularly of the spinal column Active tuberculosis was absent in all of our cases of atrophy but in two healed lesions were found Tuberculous involvement of the chromaffin system contiguous to the medulla is not frequent

The heart is disproportionately small in a large majority of the patients with Addison s disease This is commonly ascribed to brown atrophy It may in our opinion represent a primary result of hormonal deficiency rather than the atrophy of disuse to which it is commonly ascribed The thymus and lymph nodes are occasionally enlarged especially in the presence of adrenal atrophy Pigmentation is seen at times in the serous membranes

Physiopathology.—Recent investigation concerning the function of adrenal cortex has been immeasurably helped by advances in our knowledge of the chemistry of the cortex *In all some twenty four different* sterone compounds have been isolated Desoxycorticosterone has been synthesized by Reichstein An extract of the adrenal cortex such as Swingle s probably contains a large number of closely related steroid derivatives which have specific effects differing from one another quantitatively and qualitatively Desoxycorticosterone has been chiefly utilized in the investigation of the adrenal cortex It exercises marked control on the metabolism of sodium chloride and potassium but does not affect the carbohydrate mechanism to any great degree

While much yet remains to be learned, it is probably safe to say at present that the suprarenal cortex participates in some way in the control of water metabolism the state of hydration in the organism the fluid distribution and the volume of the blood the electrolytic content of the organism and especially in the physiological activity of sodium and potassium capillary permeability carbohydrate metabolism circulatory efficiency muscular function and the renal function particularly as it relates to the excretion of sodium chloride and potassium *The adrenal cortex favors the retention of* sodium and water while increasing the secretion of potassium

In the crises of adrenal insufficiency there occur dehydration hemoconcentration decreased blood volume lowering of the level of the sodium ions in the blood and a resulting state of shock characterized by circulatory failure (low blood pressure) increase in the level of blood urea nonprotein nitrogen sulfates and potassium etc Under these conditions the administration of salt water and above all cortical extract or hormone is essential to the best interests of the patient

Symptoms.—The disease usually presents three stages (1) unexplained weakness and exhaustion following upon some upper respiratory infection (2) the typical clinical syndrome so easily diagnosed (3) collapse in which nausea vomiting dehydration and toxemia dominate the picture

The onset is usually insidious occasionally acute The most prominent symptoms and signs in their usual order of appearance are (1) asthenia and fatigue (2) pigmentation of the skin and mucous membranes (3) anorexia nausea and vomiting (4) loss of weight (5) arterial hypotension (6) dizziness syncopal attacks (7) collapse with dehydration and circulatory failure

Asthenia debility and languor are usually the earliest symptoms However unexplained pigmentation may develop and persist for some weeks or months prior to the onset of asthenia In such cases the prognosis is unusually good The asthenia is invariably present is both subjective and objective and mental as well as physical in character When pronounced the patient is bedridden The remarkable feebleness of the heart s action is evidenced by hypotension circulatory failure coolness of the body surface fainting spells and dyspnea Mild hypotension is usually present throughout the disease systolic pressure being as a rule in the neighborhood of 90 to 100 and the diastolic 60 to 70 mm of mercury In the terminal phases and the crises the systolic pressure is often decreased to the neighborhood of 60 mm of mercury When hypertension has existed prior to the illness the blood pressure may remain elevated or normal until within a few hours of death

Gastro-intestinal Symptoms—The gastro intestinal symptoms are usually pronounced and include nausea vomiting gaseous distention and occasionally periods of intense diarrhea Nausea may be continuous but is usually more pronounced in the morning As the disease progresses vomiting becomes more marked so that little or no food is retained A striking loss of weight often 40 to 50 pounds results Because of retained elasticity the skin constantly fits snugly despite the weight loss hence emaciation has been underestimated by the majority of clinicians

Pigmentation of the Skin and Mucous Membranes—The most striking visible manifestation of Addison s disease is the pigmentation of the skin Attention is often called to it by friends and relatives who think the skin looks dirty It is frequently ascribed by patients to tanning by the sun a tan which fails to disappear on removal from exposure Addison described it as a

dingy or smoky appearance of various tints or shades of deep amber or chestnut brown *Pigmentation is most marked over* the exposed parts the face, neck and hands, at the points of pressure the buttocks, the elbows, the knees and at the points of contact with clothing corsets garters etc The palms of the hands and soles of the feet usually escape except for the creases Pigmentation of the genitalia is usually excessive Jet black freckles are very common especially on the backs of the ears A gray or white scurf is often seen over the pigmented areas particularly those on the elbows and knees

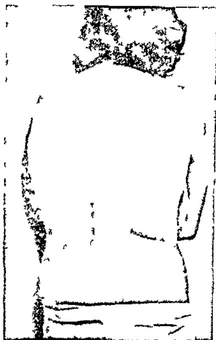

Fig 163—Addison s disease in a thirty two year old white female Note the scattered areas of pigmentation to the right of the dorsal spine and the diffuse pigmentation near the right flank (Courtesy of Dr H David Markman)

Pigmentation of the Mucous Membranes—This is of great diagnostic importance when accompanying pigmentation of the skin The addition of pigmentation of the mucous membrane of the mouth the lips the gums, the inner sides of the cheeks and on the tongue tremendously increases the probability of Addison s disease It is usually brownish or black in color although bluish tints are not *at all uncommon* particularly on the tongue

The cause of the pigmentation is not well understood The pigment itself is melanin Bloch suggests that pigmentation is due to the presence of a specific oxydase in the skin, which forms melanin from dioxyphenyl alanine (dopa), and has devised a biopsy test based on this assumption

Pain in the loins is more frequent than is usually realized As a rule it is dull and paroxysmal in character but occasionally it is intense the patient *groaning constantly* and holding a rigid abdomen

Nervous and mental symptoms are usually lacking though a psychosis due to exhaustion or toxemia is not infrequent Restlessness is apparent and apprehension is extreme at times the patient tossing about and apparently incapable of finding a position of rest

Sex changes are neither frequent nor marked Dysmenorrhea is not uncommon in the female and, when present is usually associated with marked menstrual exacerbations of the addisonian symptoms In the male there is a tendency to loss of libido and potentia Occasionally sex activity is *maintained and healthy children may* be born of fathers suffering from Addison s disease Conception is usually followed by abortion

Course—Addison s disease usually pursues a gradually downward course with striking remissions and acute exacerbations which may attain the severity of a crisis Crises and death often follow stress and strain overexertion exposure acute infections surgical procedures or administration of purgatives low salt or high potassium intake Occasionally the onset is acute and *the course short and rapid* Excruciating pain noisy delirium and dyspnea may precede death The shortest duration on record is eighteen days a dozen or so patients have survived ten years Remission simulating recovery has been encountered in two cases of Addison s disease where the clinical diagnosis was beyond question suggesting the possibility of temporary suppression of the function of the adrenals With modern methods of treatment *remissions are more* frequent pronounced and prolonged However the course is usually chronic nausea and vomiting become more pronounced and asthenia more marked until the patient is completely bedridden Eventually the eyelids droop the mouth hangs open drowsi

ness becomes more marked and the limbs hang limp The patient takes the contour of the bed and assumes the picture of complete exhaustion and helplessness The fire burns lower and lower, interrupted occasionally by fitful flickerings of life and consciousness until death ensues

Diagnosis —The diagnosis can usually be made on clinical grounds (1) progressive asthenia (2) gastro intestinal irritability (3) pigmentation of the skin and mucous membranes (4) feeble heart action especially as heard with a stethoscope (5) low blood pressure and (6) the occurrence of these symptoms in a patient who has or has had tuberculosis Complications often confuse the picture and result in failure to make a correct diagnosis

Laboratory findings of importance are (1) demonstration of melanin in the skin by biopsy (2) decrease in the sodium content in the blood below 130 milliequivalents, (3) increase in the blood urea nonprotein nitrogen sulfates and potassium in the blood, (4) decrease in the blood volume and hemoconcentration (5) decrease in basal metabolism (6) roentgenologic evidence of calcification in one or both adrenal areas

Where doubt exists resort may be had to (1) the effects of restricted sodium intake (2) the effects of a high salt diet (3) the administration of cortical hormone as a therapeutic test

In arriving at a diagnosis difficulty is often encountered in relation to pigmentation The greatest difficulty is on racial grounds Ethiopians Orientals, American Indians Levantines and Latins normally may show pigmentation which in light skinned individuals would be characteristic of Addison s disease In the Nordic the pigmentary quartet dermal buccal and labial pigmentation with the presence of jet black freckles is practically pathognomonic

In differential diagnosis metallic poisoning must be excluded particularly lead arsenic and silver In *acanthosis nigricans* the pigmented areas have the appearance and the feel of velvet rather than of satin as is found in Addison s disease The discovery of abdominal malignancy is of primary importance Hemochromatosis should be recognized through the presence of sugar in the urine and the enlargement of the liver Pregnancy sometimes offers a diagnostic problem Scleroderma should offer no difficulty although it is frequently accompanied by skin pigmentation which is very suggestive of Addison s disease In all these diseases skin biopsy should prove helpful Leukoderma frequently accompanies Addison s disease and its presence does not exclude the existence of Addison s disease Carotinemia and jaundice can be recognized through the presence of the abnormal pigmentation in the serum Cholasma malaria exophthalmic goiter and vagabond s disease should not offer undue difficulty Extreme weakness from other causes such as neurasthenia and postinfluenzal exhaustion is frequently considered early in the course of the disease

Fig 164 —Addison s disease Flat plate of abdomen showing almost complete calcification (presumably tuberculous) of left adrenal gland and beginning calcification of right adrenal (Courtesy of Dr H David Markman)

Complications —Tuberculosis in one form or another is present in 80 to 90 per cent of the cases and is a matter of paramount importance from the standpoint of diagnosis prognosis and treatment Syphilis frequently coexists and its treatment in the presence of Addison s disease should be along extremely conservative lines The incidence of leukoderma is higher than that of mere chance Upper respiratory infections and in fact infections of all kinds are dangerous because of the exacerbations induced

Prognosis—The prognosis in Addison's disease has been always and should continue to be regarded as extremely grave It is now largely the prognosis of tuberculosis This holds true regardless of the excellent immediate results from the use of extra salt or of cortical hormone In order to arrive at a prognosis the history of the case the clinical condition of the patient the location and activity of the tuberculosis, the laboratory findings the immediate response to treatment and the economic situation should all be considered

The indications for a grave prognosis are collapse extreme asthenia lowered bodily and surface temperature protracted vomiting extreme loss of weight, a sodium level of less than 130 milliequivalents systolic blood pressure of less than 70 mm of mercury, *concentration of urea of more than* 60 mg per 100 cc of blood a short rapid course without much pigmentation poor response to treatment, and the presence of active tuberculosis The most important single clinical prognostic index is the body weight only those who eat and gain weight, recover A dozen or more cases have been reported as surviving ten years or more The author has had three cases which have survived fifteen years or more Mildness of the disease and wise management rather than specific treatment would seem to be responsible for these results However with better and more modern treatment the prognosis is improving and when adequate cortical extract is available death from hormonal deficiency should be largely preventable

Treatment—The treatment of Addison's disease during the last decade has undergone radical changes with the introduction of an active cortical hormone and the recognition of the importance of salt Now as always emphasis must be placed upon adequate rest warmth control of activities and the avoidance of stress and strain purgation and exposure to cold Whereas formerly the management of this disease exhausted the therapeutic skill of the physician today with the use of cortical extract or hormone and a diet rich in salt the patients may be relatively free of symptoms Formerly the patient was more or less continually in a crisis while now he is often a semi invalid or even a fairly active ambulant patient capable of conducting considerable business Obviously the care of the underlying tuberculosis, if present is of paramount importance

Substitution Therapy.—The cortical extract of the adrenal gland as prepared by Swingle and Pfiffner, usually controls the clinical manifestations of adrenal insufficiency immediately if given in adequate amounts Of this preparation 1 to 5 cc daily given parenterally or 1 to 2 cc of a three- to five times concentrate given on alternate days usually suffices Unfortunately, this preparation is not generally available Eschatin a commercial product is less potent and should therefore be used in larger amounts In the terminal phases of the disease in crises, during intercurrent infections and when surgery is undertaken, the dose should be increased two to five times and *the extract given intravenously No danger* attends these larger amounts but unfortunately the cost of such treatment is often prohibitive As a matter of safety it is wise to employ cortical extract in small amounts on alternate days even during periods of remission This simple rule will prevent many deaths It should be remembered that large amounts of salt daily tend to decrease the need of cortical hormone thus permitting its use in smaller dosage

Salt Therapy—Sodium chloride has been found of unquestionable value in the treatment of this disease The diet should be rich in salt and in addition 5 to 10 Gm of sodium chloride may be given daily in the form of compressed tablets or capsules Sodium also in the form of sodium bicarbonate or citrate may be added up to 2 to 5 Gm daily Salt therapy is of special value because of its ready availability Because it decreases the hormonal need it renders the treatment of Addison's disease less expensive It must be remembered however that salt alone will not suffice To rely on salt alone is to court disaster

Combined Cortical Extract and Salt Therapy—This constitutes the best form of therapy to date With this regimen good results are almost uniform and the survival time prolonged The last five successive cases subjected by the author to Swingle's preparation of cortical extract and to high salt intake are all alive and comparatively well averaging almost nine years survival and

seven years on treatment All five are fairly well rehabilitated *

Foods rich in potassium should be avoided Water may be almost as important as salt *especially in overcoming dehydration* and during crises Loeb states that six of his patients have died a classic Addisonian death with a perfectly normal electrolytic pattern in their blood with the exception of dehydration '

Combined cortical extract and salt therapy thus offer tremendous advantages and should be employed in all cases throughout the whole course of the disease *Very occasionally* with adequate hormonal replacement the need of sodium and water is imperative In periods of crisis sodium chloride in 1 to 3 per cent solution should be used freely intravenously or normal saline with glucose up to 4 liters per day

Treatment with Desoxycorticosterone Acetate—Reichstein has not only isolated a crystalline hormone from the adrenal cortex but has synthesized desoxycorticosterone acetate which is potent both experimentally and clinically This product injected in sesame oil in doses of 5 to 10 mg daily, is now undergoing extensive clinical trial and is strikingly effective in many respects However its use or abuse may be attended with serious danger if salt therapy is also pushed *too vigorously* This may result in hypertension generalized edema and cardiac failure

A new method of administration is undergoing clinical trial by Levy Simpson in England and in this country by Thorn and his collaborators namely the surgical implantation in the fatty tissues of the back of pellets of this preparation which undergo continuous *absorption thereby supplying* the hormonal need of the patient over weeks or months While this pellet treatment is not generally available for general use the results obtained by Thorn have been most encouraging Desoxycorticosterone acetate in propylene glycol administered sublingually (7 drops held under the tongue for fifteen minutes seven times daily) is mildly helpful especially when combined with salt therapy This method is unduly costly

* One patient succumbed since this article was written having been under my care over a period of ten years

The effects of treatment may be summarized as follows the disappearance of nausea and vomiting the appearance in their place of hunger normal gastro intestinal activity *increase in weight* decrease in *pigmentation* increase in blood pressure (slight and delayed), access of hope and euphoria, increase in bodily resistance, and a desire to return to normal activity

The significant changes in laboratory findings are gain in weight with positive nitrogen balance increased level of blood sodium increased blood volume where it *has been depleted increase in basal metabolism* where it has been seriously depressed improved renal function with disappearance from the blood of undue accumulations of nitrogen urea sulfates etc The results in Addison s disease suggest that the cortical hormone exercises a fundamental influence from the standpoint of food ingestion and utilization The psychic effects of treatment are often as profound as the physical

In a large sense these results may be regarded as immediate in character the correction of hormonal deficiency and not as a cure of the disease which in the vast majority of instances is tuberculous in origin Occasionally failure to relieve hormonal deficiency is encountered particularly where the disease is far advanced Even in mod*erately ill patients inexplicable* resistance to substitution therapy is encountered at times Under such conditions the possibilities of both hormonal and sodium therapy should be exhausted

Dehydration may be primarily from hormone deficiency or secondary to continuous vomiting or diarrhea Fluids should be administered intravenously, or subcutaneously *as saline or glucose solutions They should* be used promptly and freely in crises as they often prove to be life-saving

Adrenal transplants have been almost universally unsuccessful but a glimmer of hope has been recently brought in to this field by E M Auslander who claims some success in fourteen cases thus treated

The Control of Tuberculosis—This now assumes larger proportions It *demands* often the consultation with some one expert in the diagnosis and general management of tuberculosis The nature and care of the local lesions must also be considered Here

tofore, the operative risk has practically excluded surgical treatment of tuberculous lesions of the gland itself or of genito urinary or osseous tuberculosis but since the advent of cortical hormone this difficulty has been largely overcome and patients may now be subjected more safely to surgical procedures if indicated In the management of the tuberculosis of the adrenal glands themselves, the judicious use locally of deep x ray therapy may be tried together with the administration of calcium and viosterol

DISEASES OF THE THYMUS GLAND

Definition—This subject could well be defined as The Thymus Problem Many functions have been attributed by various investigators to the thymus gland only to be denied by others and there has been much uncritical controversy concerning the symptomatology and treatment of disturbances of it Some of the functions which from time to time have been supposed to be carried on by the thymus are (1) influence on osseous development and regulation of calcium and phosphorus metabolism in health and in certain diseases of the bone (2) regulation of blood pressure (3) effect on coagulation of the blood (4) action as a reservoir of phagocytic cells (5) significance as part of the lymphatic system and (6) its influence on growth and development None of these possible functions has any relation to clinical practice in diagnosis and treatment That is to say no means are available to modify any such functions and no extract of the thymus gland has been used in human beings with any proved effect

Morbid Anatomy—The studies of Hammar Greenwood Boyd and others have clearly shown that earlier ideas and statements concerning the size of the normal thymus were erroneous They have demonstrated that the size varies correspondingly with the general nutritional state of the body that in acute illness and temporary inanition the organ decreases rapidly in size although there may be little loss of general body tissue and that even under normal conditions its dimensions and weight vary greatly Without detailing the weights usually found it may be stated that at no time of life can a weight of 30 Gm be considered enlargement and that during the period of growth weights of 50 Gm are within the limits of variability

Where there is actual enlargement it usually consists of simple hyperplasia in which medulla and cortex ordinarily share equally Hyperplasia may occur in exophthalmic

goiter and in acromegaly and there is an implication here that the thymus is a part of the endocrine system although the relationships are far from clear A nonmalignant enlargement associated perhaps with lesions in the suprarenal cortex may occur in myasthenia gravis and at times enlargement is present with other myopathies

Symptoms —With the exception of those to be specifically noted symptoms which have been attributed to alterations in the thymus are confined in age incidence to infancy and usually to the first few months of life

Pressure Symptoms —Can a normal or hypertrophied thymus compress the trachea the recurrent laryngeal nerve and certain blood vessels and cause symptoms such as dyspnea and suffocative attacks (thymic asthma) brassy cough and cyanosis? In favor of the possibility of pressure are (1) The demonstration through the bronchoscope or by lateral roentgenograms that tracheal compression may occur (2) the apparent cessation of symptoms after radiologic treatment of the thymus and (3) the occasional finding at necropsy which suggests that compression had occurred during life On the contrary it is evident that (1) It would be difficult for a soft organ such as the thymus to compress the cartilaginous trachea (2) that great neoplastic enlargement may occur without symptoms of compression (3) that there is no close correlation between the symptoms which might be attributed to pressure and the size of the roentgenographic shadow and (4) that careful clinical study will show other causes for such symptoms as dyspnea and cyanosis in most cases The answer probably belongs —as it usually does in such controversy—somewhere between the two extremes and it would appear possible that *rarely* an enlarged thymus may press on structures in the superior thoracic aperture and cause the symptoms described

Status Thymicolymphaticus —It is evident that the state of the thymus gland and lymphatic structures originally described as enlarged and associated with so called lymphatism actually represented only the normal structures in well developed subjects who died suddenly from some other cause Sudden death is not related to enlargement of the thymus as many studies have shown If there is any connection between sudden death and this organ it cannot be explained by such vague terms as hyperthymization or lymphotoxemia ' It remains to be proved whether the thymus might be secondarily affected by suprarenal insufficiency or in some other way and thus be directly concerned in certain rare instances of sudden death associated with hypoglycemia and rapid fall in blood pressure

Endocrine Symptoms —That the thymus is an endocrine organ is suggested by several facts for example adrenalectomy suprarenalectomy and gonadectomy are followed by delayed involution or hyperplasia of it These observations do not prove an incretory function since other types of tissue than those of the endocrine system might be so affected A hyperplastic thymus however may be found in pluriglandular syndromes involving the gonads the thyroid the suprarenals and the pituitary The experiments of Rowntree Einhorn and others have aroused new interest in this phase of the thymus problem Briefly these have shown that in the offspring of thymectomized rats a definite retardation of growth occurs as reflected by body weight and body length Furthermore after continuous intraperitoneal injection into rats of a thymus extract prepared by Hanson successive generations of their offspring show acceleration of growth and development

Some endocrinologists have described in association with persistence of thymus during adolescence and into adult life a type of person who is tall slender and loose-jointed exhibits fine texture of the skin a tendency to eczema scanty hair poor resistance to infection has thin walled blood vessels becomes easily fatigued and shows inferiority in the development of circulatory and endocrine organs It is not clear that if the persons so described have an enlarged thymus this is a relationship of cause and effect the combination may be but part of a syndrome due to some underlying cause probably of a pluriglandular nature Timme has termed the condition status hypoplasticus

Other Symptoms Sometimes Attributed to the Thymus —There is no good

reason to believe that so called "holding the breath spells' are associated with thymic hypertrophy That hypersusceptibility to disease is related to thymic dysfunction is only an hypothesis A possible connection between pylorospasm and the thymus has been postulated from time to time, the explanation being given that the enlarged thymus and the pylorospasm are dependent upon vagotonia, the result of insufficient suprarenalin production

Diagnosis—When such symptoms as dyspnea suffocative attacks brassy cough and cyanosis exist and no other cause can be found the question of thymic hyperplasia arises How can the presence of this be shown? Certainly the average clinician is seldom able to convince himself that he can outline an enlarged thymus by percussion nor can he often palpate it in the suprasternal notch If impaired resonance can be elicited over the manubrium this might be due to other intrathoracic structures and furthermore it is probably anteroposterior enlargement not lateral which could cause compression *Roentgenographic diagnosis* of an enlarged thymus is by no means a simple matter There is no mathematic formula which proves that the shadow cast is too large for the age or the size of the chest of the individual The size of the shadow is greater during deep expiration than during inspiration, and there are probably racial and geographic differences in the size of the thymus When the weight may vary so greatly under normal conditions it is certain that the roentgenographic shadow will also Lateral roentgenograms taken in both respiratory phases to determine compression or buckling of the trachea, and interpreted by an expert may have some value and perhaps the fluoroscope may occasionally be helpful

In *differential diagnosis* emphasis should be placed on the importance of searching always for some other cause for symptoms Dyspnea suffocative attacks or cough may be caused by foreign bodies cysts papillomata or other tumors in the air passages retropharyngeal abscess and tumors outside the air passages causing pressure on them Other causes for dyspnea which should be eliminated before the thymus is implicated are acute and diphtheritic laryngitis bronchitis, pneumonia, atelectasis asthma and the like Many of these conditions or even nasal obstruction and congenital laryngeal stridor are more likely to be the cause of cyanosis than is enlargement of the thymus It is difficult to believe that enlargement of the thymus or dysfunction of it could result in convulsions and in cases where this symptom has been attributed to the thymus a thorough search would usually have revealed some other condition such for example as meningitis, encephalitis intracranial hemorrhage or particularly in the age period from six months to two years, infantile spasmophilia or tetany

When the history examination or necropsy uncovers no reason for sudden death even though the impression exists that the thymus and lymphatic structures are enlarged, it is probably wiser in the present state of knowledge to conclude that the cause was unknown and not to catalogue it in the waste paper basket of status thymicolymphaticus"

Treatment—The philosophy of the treatment of what appears to be an enlarged thymus can be deduced from the previous statement Partial or total thymectomy may rarely be indicated for neoplastic growth or radiologic treatment may be given As shown by Friedlander radiologic treatment will reduce the size of the thymus There is certainly no reason for employing this form of treatment routinely in newborn infants as has occasionally been recommended and in fact there is no need to take routine roentgenograms of their chests With proper dosage and with protection of other structures there is no harmful result from roentgen or radium irradiation of the thymus The procedure can be allowed, then when careful study fails to reveal any other cause for the symptoms of dyspnea and cyanosis in infants occasionally it appears that such treatment is effective Whether this is coincidental or whether other intrathoracic structures which might have been operative have been decreased in size is not so certain

If obstructive symptoms were due to an enlarged thymus intubation or tracheotomy would not give relief since the tracheal stenosis would be too low to be affected

It can be stated categorically that radiologic treatment of the thymus would not

prevent sudden death even if this organ were in any way implicated There is no reason for radiologic treatment as a routine procedure before operation or anesthesia There is no extract of the thymus which is to be recommended for use in human beings

DISEASES OF THE PARATHYROID GLANDS

TETANY

Definition —Tetany is a result of abnormal inorganic salt metabolism manifested by increased irritability of the neuromuscular system It is a common disease in infancy but relatively rare in adult life Clinically there are distinguished (1) active tetany with tonic spasm of any muscle (more usually bilateral in the extremities and also in the glottis) and occasionally with generalized convulsions and (2) latent tetany which is demonstrated by neuromuscular responses elicited by very mild electrical or mechanical stimuli

Symptoms and Signs —There is a triad of well recognized clinical signs of latent or active tetany *Erb s sign is the most reliable* clinical sign of tetany It is based upon the neuromuscular response to electrical stimuli In both latent and active tetany with the stimulating electrode over a motor nerve there is a muscular response to far weaker stimuli than the minimal effective stimulus needed in normal individuals The cathodal opening response which normally requires more than 6 milliamperes, is obtained with stimulation by less than 5 milliamperes There is also a reversal of normal responses *for contraction occurs in tetany* with a weaker current on anodal opening than that *required for response to anodal closure* The Chvostek sign is easy to elicit It is a twitch *of the innervated muscles following gentle* tapping over the facial nerve at its exit *from the stylomastoid foramen, anterior to* the external auditory meatus The Trousseau *sign is the ability to precipitate a typical* paroxysm of tetany by temporary compression of an extremity either over a principal nerve trunk or, more easily by occluding the arterial blood supply to the extremity

The typical tonic muscular contractions of active tetany come spontaneously The hand becomes stiff with rigid fingers The thumb is markedly adducted and partially covered by the stiff fingers which are usually bent only at their metacarpophalangeal joints The palm of the hand is hollowed while the wrist and elbow are flexed In the lower limbs the toes are flexed and the sole becomes arched like the hand The heel is pulled up and the rest of the leg is fully extended The muscles all feel very tightly contracted Any muscles may be involved particularly those of the face eyes tongue and larynx The sympathetic nervous system as well as the motor nerves may be affected so that smooth muscles such as the bladder intestines and blood vessels are also occasionally involved The contractions are usually tonic in nature and may be prolonged When the glottis and laryngeal muscles contract breathing becomes very difficult with prolonged whistling inspiration and less noisy expiration (called laryngismus stridulus ") and very marked cyanosis Consciousness usually remains unimpaired The spasm may become so severe that breathing is not possible There may also be generalized tonic convulsions which may last for a long time and may result in death These spasms are pre

ceded both in eliciting the Trousseau sign and in spontaneous tetany by a feeling of tingling and diminished sensation marked stiffness, and difficulty of movement of the extremities The contraction after a short time becomes painful and is described by the patient as a cramp In severe tetany it may last for minutes or hours In active tetany other signs are usually preceded by a general sensation of unrest and impending catastrophe

If long continued tetany occurs during the period of growth the teeth are soft and poor and the healing of fractures of bone is said to be slow The lens of the eye is very prone to the formation of cataract

Etiology —The increased neuromuscular irritability which produces tetany is usually dependent upon the following causes

1 Parathyroid deficiency usually follows radical operation upon the thyroid gland with simultaneous removal or damage of several parathyroid glands It then may begin after approximately twenty four hours and may last for days or years Occasionally the disease occurs spontaneously Tetany appears when the calcium content of the blood serum falls from the normal value of 10 to 7 5 mg per cent unless this reduction is due to protein bound calcium (as in the nephrotic syndrome)

2 Inadequate calcium in the diet or persistent fatty diarrhea (steatorrhea or celiac disease) with the excretion of excessive calcium soaps or prolonged and repeated lactation with inadequate calcium intake (formerly called 'nurse s contracture) causes osteomalacia and eventually this progresses to tetany

3 The injection or ingestion of alkaline phosphate salts also produces tetany with a low blood calcium possibly because of the precipitating effect of the phosphate ion possibly because of alkalosis

4 Vitamin D deficiency with the eventual appearance of tetany is not infrequently seen in children and occasionally occurs in adults This may also account for the tetany sometimes seen after prolonged postoperative loss of bile

5 Signs of tetany will result from alkalosis of various origins such as hyperventilation with its resulting uncompensated CO_2 deficit persistent vomiting with its excessive loss of HCl or ingestion of excessive amounts of alkalis

6 Tetany and spasmophilia are not infrequently seen in children less than two years of age They occur more frequently in late winter and spring The recovery from rickets following viosterol administration may be complicated by tetany because of the rapid deposition of calcium phosphate in the bones Convulsions with a very low blood calcium may occur as early as the ninth day of life without evidence of rickets

7 There is a tetany of unknown origin which involves sedentary trades chiefly cobblers and tailors This occurs in epidemics usually in the springtime in central Europe

Diagnosis.—Active tetany is so characteristic that its clinical diagnosis usually offers no difficulty It is distinguished from other neuromuscular diseases by its temporary bilateral spasms and by the characteristic blood findings The three signs of which Erb s phenomenon is the most reliable are also characteristic Final diagnosis of the type of tetany is dependent upon the clinical picture but also upon the laboratory findings summarized in the Table

Prognosis —With recent modern methods of therapy the prognosis of tetany has been greatly improved Acute attacks of low calcium tetany need very careful therapy but by means of intravenous injections of calcium salts patients can usually be kept alive After some days the disease often improves Chronic tetany also has a good prognosis with careful therapy There are of course occasional cases of such severity that the laryngeal spasm or general convulsions result in death

Tetany due to alkalosis has an excellent prognosis With the elimination of the causative factor and ingestion of the needed acid producing salts the tetany promptly disappears If intestinal obstruction is the primary cause of the tetany it must be alleviated

Treatment —Treatment of tetany depends upon its cause Acid producing salts however are good for all forms of tetany Aqueous solutions of ammonium chloride or calcium chloride in 1 Gm doses up to 6 or 8 Gm a day are beneficial whether the tetany is due to low blood calcium or alkalosis Hydrochloric acid may also be used Milk is also highly desirable as a basis for

food because of its high calcium and phosphorus content

Specific therapy for tetanies associated with a low blood calcium is as follows slow intravenous injection of calcium chloride (10–20 cc of a sterile 5 per cent solution) or calcium gluconate (10 cc of a 20 per cent solution) Only the latter solution may be given intramuscularly This therapy gives almost immediate but transient relief though the injection may be repeated after an hour

More permanent effects can be obtained by the following methods

1 The parathyroid hormone may be given intramuscularly (up to 500 units daily) Its effect begins four hours after injection and lasts twenty hours Continued dosage must be controlled by repeated determination of the blood calcium level for overdosage will result in dangerous hypercalcemia This agent has the disadvantage of losing its influence after several months of use and therefore is better kept in reserve for emergencies

2 High vitamin D ingestion which can now be given as irradiated ergosterol in amounts five to ten times the usual antirachitic doses By this means calcium absorption from the intestines is improved and calcium is also liberated from the bones This effect is obtained only after several days This treatment is of value in all tetanies with low blood calcium particularly in cases of steatorrhea Highly irradiated ergosterol, such as dihydroxytachysterol, increases calcium absorption from the intestines and mimics the action of parathyroid hormone in raising the blood calcium level No immunity to it appears to develop It is, therefore a drug of great value in the treatment of tetany Its effects last for several weeks so that overdosage is undesirable Repeated blood calcium determinations are essential in the first few weeks of its use in order to establish the proper dosage

ANALYTICAL FINDINGS IN VARIOUS TETANIES AND RELATED DISORDERS

DISEASE	BLOOD PLASMA VALUES				EXCRETION DURING LOW CALCIUM DIET			
					URINE		FECES	
	CALCIUM	PHOSPHORUS	pH	PHOSPHATASE	CA	P	CA	P
Tetany due to parathyroid deficiency	low	high	normal	normal	low	low	normal	normal
Hyperparathyroidism	high	low	normal	high	high	high	normal	normal
Steatorrhea—difficulty in absorbing calcium from the intestines	normal or low	low	normal	normal or slightly high	low	high	high	normal
Osteomalacia from deficiencies and rickets	normal or low	low	normal	high	low	low	low	low
Hyperthyroidism	normal	normal	normal	high	very high	very high	high	high
Paget's disease (osteitis deformans)	normal	normal	normal	very high	No marked abnormality			
Gastric tetany	normal	normal	increased					
Hyperventilation	normal	normal	increased					
Excessive bicarbonate ingestion	normal	normal	increased					

3 Thyroid extract increases the calcium exchange and is of considerable value in elevating the blood calcium in tetany

4 *A high calcium intake best obtained* through milk and calcium lactate or gluconate (10–12 Gm a day) is essential High protein diets should be avoided

5 For tetanies caused by alkalosis the treatment consists of eliminating the cause and correcting the alkalosis by the ingestion of therapeutic doses of hydrochloric acid ammonium chloride or acid phosphates Sodium chloride in large amounts of fluid may be used if the kidney function is adequate to retain the acid radicle

HYPERPARATHYROIDISM

(Osteitis Fibrosa Cystica)

From our present knowledge, it is obvious that a definite abnormality of calcium and phosphorus metabolism must be established before a diagnosis of parathyroid disease can be made Since the original observation of Mandl, the clinical condition of generalized osteitis fibrosa cystica of von Recklinghausen is recognized as due to adenoma or hyperplasia of the parathyroid glands

Symptoms and Signs—Hyperparathyroidism is characterized by

1 Thinning of the skeleton but not the teeth frequently with multiple bone cysts

Fig 165—X ray of the femur showing the rarefaction and expansion of the bone with coarse trabeculation characteristic of osteitis fibrosa cystica

so that spontaneous fractures may occur Great milk drinkers do not show this thinning as the heavy demands for calcium are obtained from the food

2 Increase of bone osteoclasts with the formation of giant cell bone tumors and epulis about the teeth

3 Muscular weakness hypotonia lack of appetite nausea constipation and pain in the bones Polyuria is usually present

4 Renal stones are fairly common in the disease because of the high urinary calcium excretion Unexplained and particularly recurrent stones are reasons for suspecting hyperparathyroidism and looking for a high blood calcium Chronic nephritis develops in the more chronic cases a nephritis produced by the body s own secretions

5 The laboratory findings which are essential to establish the diagnosis, are shown in the Table (see page 1249) In severe cases, when the blood calcium is above 15 mg per cent, the blood phosphorus also rises above normal

6 The increased viscosity of the blood which is seen in experimental hyperparathyroidism is usually not seen in clinical cases

7 Because of great fibrosis in the bone marrow an occasional case of anemia and leukopenia may be encountered

Pathology—The enlarged parathyroid glands are either adenomatous or hyperplastic in appearance They can be palpated only rarely before operation because of their small size and soft consistency and because they are molded into crevices The gross diagnosis is made by their position and salmon or yellow color

Adenomas are usually single but have occasionally been found in more than one gland Chief cells are always present in these tumors though oxyphil or wasserhelle cells may also be present in high proportions In hyperplasia the parathyroids are all enlarged because of generalized wasserhelle cell proliferation The differential diagnosis must be made at operation

The bones show decalcification with a great increase of osteoclasts osteoblasts and fibrous tissue As a result of these cellular changes there may be found osteoclastomas and also multiple cysts with fibrous walls

Prognosis—When the disease is discovered early and the tumor removed prognosis is excellent for marked recovery The giant cell tumors tend to disappear the bone cysts fill in slowly and the bones become heavier The bone pains and general lassitude promptly disappear There is a prompt and marked increase in appetite and a definite reduction in polydipsia and polyuria The grave postoperative risk lies in the appearance of tetany which is more apt to occur in cases with severe bone decalcification If the tumor is not removed the disease progresses The bones become so thin

that there are spontaneous fractures and collapse of the vertebrae the patients become bedridden and die with a renal insufficiency

Treatment —Surgical removal of the enlarged parathyroid tissue is indicated It is preferable to visualize all glands This is *especially important when hyperplasia* is indicated by frozen section, for then a subtotal parathyroidectomy should be done After removal, the blood calcium and phosphorus levels return toward normal The correction may be too great so that tetany may appear A marked storage of calcium *and phosphorus in the bones* follows the operation and this continues for many months The blood phosphatase level returns to normal only after some months

A diet with adequate vitamin D and very high in calcium and phosphorus should be maintained for many months

DISEASES OF THE PINEAL GLAND

SINCE the turn of the present century the number of investigations concerning the pineal gland has increased steadily but the function of this small structure remains a source of speculation as was true when Descartes believed it to be the seat of the soul The anatomy of the pineal is fairly well agreed upon by most contemporary investigators but there is still a wide divergence of opinion concerning its physiologic significance

Anatomy.—The pineal gland (epiphysis conarium) is a small firm body, approximately 7 by 4 mm in size in the adult It lies at the posterior and superior extremity of the third cerebral ventricle between the splenium of the corpus callosum and the corpora quadrigemina In some of the lower vertebrates it is a parietal organ with the structure of a primitive eye but it is present in all mammals as a separate and internal organ a part of the brain, with a constant location at the posterior border of the roof of the third ventricle In the human embryo the pineal *anlagen* appear at the second month as folds in the diencephalic roof and there is a continuous metamorphosis of the organ until its more or less definitive form is attained at one year after birth Microscopically the pineal gland consists of characteristic parenchymal cells varying amounts of neurologic substance a few nervous elements and blood vessels Seldom before puberty but frequently after adolescence calcium salts may be deposited in the gland

Physiology —Most of the present-day disagreements on the physiology of the pineal concern the secretory potentialities of the parenchymal cells Of all investigations to date Tilney's work was painstakingly done and is classic On the basis of comparative anatomy and histologic structure he unequivocally placed the organ among the true glands with the likelihood of its having an actual endocrinal function Based upon anatomic experimental (extract feeding extirpation transplantation) and clinical observations Krabbe Hortega Horrax Foa Izawa McCord *and many others* also believe the pineal body to be essentially a glandular structure with corresponding function and purpose in the organism Directly opposed interpretations may be found in the opinions of Dandy Bailey and other investigators

Extirpation of the gland in young animals

transplantation experiments electrical stimulation of the organ feeding pineal substance or extract to immature animals, clinical studies of patients suffering from pineal tumors and the therapeutic effects of the administration of pineal extracts to patients have been the various investigative methods employed As is true in the attempts to determine the function of other glands belonging to the endocrine group feeding experiments in the laboratory or clinic have been followed by many uncritical and worthless reports in the literature

As a result of these experiments the epiphysis thus far has been assigned many roles a stimulator of sexual growth, an inhibitor of sexual growth a rudimentary third eye carried over from the reptile stage a true endocrine gland and a nonglandular structure with regressive characteristics as the phyla ascend and with no function whatever With the preponderant evidence available at the present time it cannot be denied that the pineal body is developmentally and structurally a gland with potentialities of glandular function What the effect of the pineal secretion (assuming its existence) may be alone or in conjunction with the other endocrine glands has not as yet been discovered

Recently Davis and Martin extirpated the pineal gland in young rats cats and dogs Adequate litter mate controls of each sex were used for comparison of their development No behavior changes were noted in the pinealectomized rats and sexual maturity was attained at the same age in both control and lesion animals There was some indication of an increased somatic development in the male rats at puberty There was no somatic or sexual maturation differences in the female control and pinealectomized cats Both experienced normal estrus and both conceived normal pregnancies but their offspring sired by pinealectomized males were weak The pinealectomized mothers showed a lack of maternal instinct and lactated inadequately The pinealectomized males matured sexually four to five months earlier than their controls and they showed a precocious somatic development being still larger than their controls at the time of full maturity of the normal cats No significant differences were noted in the histologic picture of the thyroid, adrenal glands, or ovaries between the mature control and lesion animals The testes and hypophyses of the pinealectomized males were larger than those of the control males and the histologic picture of these organs reflected the gross appearance

Symptomatology—It has been noted repeatedly in reviews of the histories of patients with pinealomas pineoblastomas or teratomas of the pineal gland that the great preponderance of the patients are of the male sex A high percentage of these individuals are found to have developed their symptoms prepubertally, and of these many show the syndrome of precocious puberty (Pellizzi syndrome, macrogenitosomia praecox) Such patients may show signs of premature development as early as eighteen months of age and many cases are reported in children with pineal tumors who as young as five years have grown to an unusually large stature with adult body configuration and hair distribution and with genitalia of adult size Signs of sexual function such as erections emissions masturbation, and interest in members of the opposite sex often accompany such evidence of premature somatic and sexual maturation It is extremely rare for tumors of the pineal gland to hasten the advent of puberty in females in all but a few rare cases the syndrome has been limited to boys This is entirely in keeping with most of the results of the experimental removal of the gland in young animals sexual and somatic overgrowth being produced in males but rarely or irregularly so in females Pineal tumors occurring past the age of puberty have been found to occur in males in 75 per cent of the cases in what is the largest collection of such tumors in this country * so that it becomes a matter of particular interest that all ages considered pineal tumors occur preponderantly in the male sex Of course pineal tumors occurring after puberty do not involve the question of the role of the pineal gland in the sexual and somatic growth of the individual

While not every prepubertal patient with a pineal tumor shows the signs of precocious puberty practically every patient with such

* Brain Tumor Registry Yale University Medical School

a tumor does present a more or less uniform set of symptoms such as would be expected to follow the presence of any expanding lesion in the location of the pineal gland Almost invariably there is a marked and progressive internal hydrocephalus because of the interference by the tumor with the circulation of the cerebrospinal fluid through the aqueduct of Sylvius In the preterminal state due to the increasing intracranial pressure headache (sometimes frontal but most frequently suboccipital) suboccipital tenderness neck rigidity vomiting and weakness are among the most outstanding signs With the continued effects of the increased pressure and invasion by the tumor of the surrounding brain the patient suffers progressive loss of vision due to destruction of the optic chiasm and tracts or quadrigeminal plate or both various paralyses of the extra-ocular muscles deafness loss of weight increasing stupor and slowness of cerebration convulsions and finally coma with death Due either to implantation of pineal tumor nodules in the floor and walls of the dilated third ventricle and infundibulum or due to pressure effects in the pituitary gland and its stalk it is very frequently true that for the last few months of life these patients may develop a severe diabetes insipidus consuming as much as 5 to 6 gallons of water daily

Other secondary pituitary and hypothalamic signs may arise as well There may be blotchy pigmentation of the skin a subnormal body temperature bradycardia very low blood pressure increasingly long periods of somnolence and marked cachexia Frequently those children who are precocious both mentally and physically early in the disease become very dull and show peculiar behavior patterns several weeks before death Adults may suffer sexual debility Amenorrhea is a common symptom in females Some children with pineal tumors may show signs within the first year or two of life of premature development yet may live for several years with no signs of the disease other than those referable to this precocious growth Indeed such a patient may not die until much later when the tumor has grown to sufficient proportions to produce the terminal symptoms mentioned so that though his disturbance may have been originally due entirely to pineal disease, it may later become confused with symptoms of hypothalamic and pituitary disease as well

Treatment—It was Marburg who first popularized the conception that the pineal gland delays and inhibits the onset of sexual maturation and that in the absence of its inhibitory hormone due to removal or destruction by a tumor the body is free to proceed rapidly to puberty Many case history reports (Horrax Timme and others) lend support to this idea but other accounts are correspondingly contradictory from both the clinical and experimental standpoints In line with the suggestions of Marburg and Timme the feeding of pineal substance has been empirically used for clinical purposes in cases of pineal deficiency in the past two decades Recently it has again become a popular but not scientifically accepted therapeutic agent in certain clinics Before there is actual evidence of increased intracranial pressure from a tumor or when only functional signs of pineal insufficiency are present glandular extract or substance may be used hopefully

A tumor of the pineal gland is definitely a surgical problem Because of its location and the usual poor condition of the patient when surgery is accepted complete removal is difficult and frequently impossible Many successful removals of pineal tumors have been reported and with the constant progress in neurologic surgery improved results in the future may be expected

The physiology of the pineal gland remains an unsolved problem and therefore the significance of its pathologic state before the appearance of signs of a space occupying tumor is but poorly understood Whether it is a true endocrine gland with a secretion of its own what its relationship to other glands of internal secretion is and what the functional implications of its peculiar histologic anatomy may be are still matters of investigation Only further and more conclusive research will prove whether it is to be classified eventually in hormonic relationship to the other endocrine glands—gonads hypophysis adrenals thymus and thyroid

DISEASES OF THE SEX GLANDS

DISEASES OF THE MALE GONADS

EMBRYOLOGY

The undifferentiated sex gland develops about the fifth week from the medial surface of the mesonephros Differentiation into testis or ovary occurs during the sixth or seventh week Whether a male or female will develop seems to depend upon the type of spermatozoon with which the egg is fertilized, those with the so called Y chromosome giving rise to males In some instances *gonadal* tissue of both sexes may appear in the same individuals It may occur unilaterally or bilaterally and give rise to a true hermaphrodite *i e* an individual with the internal and external genitalia of both sexes True hermaphroditism is very rare and is *not* to be confused with pseudohermaphroditism, in which the individual is born with the gonads of one sex but has the secondary sex characteristics of the opposite sex Testicular tissue may appear in virilizing arrhenoblastomas of the ovary The Wolffian and Mullerian structures both appear in each individual possibly as relics of very early vertebrate life when all individuals produced both sperm and eggs If a testis develops, the Wolffian body and duct give rise to a vas deferens seminal vesicles epididymis and ejaculatory duct At the same time the Mullerian structure atrophies but vestiges remain (appendix testis and utriculus masculinus) From the urogenital sinus and genital tubercle there develop a prostate gland Cowper s glands a male type of urethra a scrotum and a penis If an ovary develops the Mullerian ducts give rise to oviducts, uterus and upper vagina while the Wolffian structures atrophy The urogenital sinus and genital tubercle develop into the lower vagina female urethra Bartholin s glands and external female genitalia According to Ivy Greene and Burrill the differentiation of the external genitalia takes place a little later than that of the internal and abnormal hormone stimulation may result in their assuming the characteristics of the opposite sex In this way they believe the development of pseudohermaphroditism may be explained It follows that every individual is in a sense bisexual throughout life One sex usually predominates but vestigial organs of the opposite sex remain and their development may be stimulated by sex hormones Ivy *et al* have shown that if this stimulation is applied sufficiently early in embryonic life all sorts of interesting bisexual developments may result

Many details of descent of the testis are still to be worked out The consensus among embryologists is that the cells of the proximal portion of the genital mass atrophy while those of the distal portion proliferate

at the same time the fetus grows so that the testis appears to descend to the level of the inguinal ring which is being prepared for it By the fourth month, the testis lies just inside the internal inguinal ring by the seventh month at the lower end of the canal and during the last month of intra uterine life it descends into the scrotum The pouch of peritoneum which later be comes the tunica vaginalis precedes the testis into the scrotum The gubernaculum is sup posed to play an important role in directing the course of descent It is attached very early to the genital ridge as it develops downward and in the beginning has attach ments to the abdominal muscles the root of the penis Scarpa s triangle the base of the scrotum and the perineum

ANATOMY AND PHYSIOLOGY

The testis consists essentially of two parts (1) the seminiferous tubules which produce spermatozoa and (2) the inter stitial cells which produce male sex hormone (Fig 160) What relationship if any exist between these two structures is unknown The production of the male sex hormone results in the development of secondary sex characteristics namely change in pitch of voice the growth of the penis scrotum pros tate seminal vesicles epididymis vas de ferens body hair, beard and to some extent skeletal growth including contour of the body A delicate balance exists between the anterior lobe of the pituitary and the gonads the best example of which is seen in the menstrual cycle in the female The pituitary stimulates the activity of the gonads and the production of sex hormones by them may serve as a check on the pituitary itself The factor or factors responsible for the in itiation of the pituitary stimulus are not clearly understood There is some evidence that there may be two gonadotropic prin ciples corresponding to two gonadotropic ef fects of the anterior lobe of the pituitary One causes development of the follicles of the ovary and influences the function of the seminiferous tubules in the testis (the so called follicle stimulating hormone) and the other causes luteinization of the follicles in the ovary and influences the activity of the interstitial cells in the testis (the so called luteinizing hormone) Menopausal and castrate urines contain primarily the follicle stimulating material while human pregnancy urine contains largely the lutein izing factor which is available under a va riety of trade names (Korotrin Follutein, A P L Antuitrin S Pranturon, etc) Gonadotropic material from the serum of the pregnant mare (Gonadogen, Anteron, etc) and commercial preparations from the pituitary itself contain both factors It is thus theoretically possible to stimulate the testis selectively although in actual practice the gonadotropic material from human preg nancy urine (chorionic gonadotropin) is the only one with which adequate stimulation

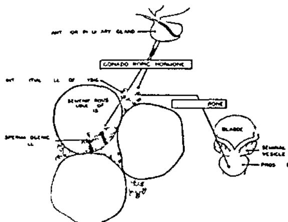

Fig 160—Diagram showing the action of gonadotropic factors of the anterior pituitary on the testis. The gonadotropic hormone stimulates the testis, causing it to secrete male hormone which maintains the secretory activity of the accessory glands (From Engle, E T Male Reproductive System in Cowdry s Problems of Ageing Williams & Wilkins Co Baltimore, 1939)

of the testis has been produced up to the present time The material from the serum of the pregnant mare produces only slight stimulation in the doses commonly used Pituitary preparations are not of much value at present and the material from meno pausal and castrate urines is not available in sufficiently large quantities

The form in which the male sex hormone is secreted by the testis is unknown The most active substance isolated so far is testosterone which is six times as potent as androsterone the first androgenic material isolated from urine Some esters of testos terone are more potent than testosterone

itself and in clinical work the propionic acid ester (testosterone propionate) is used *Trade* names for this product are Oreton Perandren and Neo Hombreol For therapeutic purposes testosterone is made synthetically Twenty nine related compounds (including androsterone and dehydroandrosterone which have been isolated from urine) *have also been prepared synthetically* by the degradation of sterols but they are not used therapeutically *In July 1935* the League of Nations Committee decided that one international unit of male sex hormone would be *100* micrograms of crystalline androsterone

Very little androgenic material has been recovered from the urine of young boys and girls from six to ten years of age—only from 0 7 to 2 0 international units per liter A marked increase in the amount found in urine begins at about the time of puberty the urine of an adult male containing about 40 to 100 international units in twenty four hours The amount secreted appears to diminish with advancing years but accurate data are not available The production of spermatozoa also appears to diminish in later *life but the change is variable, and* again accurate data are not available What role if any sex hormones play in embryonic development has not been established but they may be responsible for the develop *ment of secondary sex characteristics*

For some reason not clearly understood estrogenic material is found in male urine (the equivalent of 10 micrograms of theelin per day) and female urine is just as rich a source of male hormone as male urine and contains from 30 to 100 international units in twenty four hours Koch has pointed out that human *urine is almost unique in* its androgenic content the urine of the stallion bull ram and rat containing very little

W O Thompson

PUBERTY IN THE MALE

Following the disappearance of prenatal enlargement and engorgement the genitalia remain relatively stationary in size until the eleventh to the thirteenth year when the changes of puberty begin to appear in association with a *marked* increase in the excretion of androgenic material in the urine What role, *if any* the gonads play in somatic development from birth to puberty is un*known* During puberty the external genitalia *gradually increase in size, the skeleton grows rapidly* and the emotional changes associated *with the* increase in sexual function appear The prostate which is usually *not palpable in young boys begins to* develop reaching its adult size at about the same time as the external genitalia Hair begins to appear on various *parts of the body* The pubic hair at first is usually feminine in distribution but after a period of several *months* fine short hairs begin to appear in the lower midline of the abdomen and then often all over the abdomen chest back arms and legs However the amount of body hair is very variable many apparently normal men having very little and exhibiting an almost feminine distribution of pubic hair The beard appears as a fine fuzz and *then gradually increases in length and stiff*ness The pitch of the voice gradually becomes lower Marked alterations in body contour may take place The amount of fat in the abdomen and thighs may diminish *and the shoulders become broader* The relation between the length of the trunk and the length of the extremities is affected absence of testicular function during the age of normal puberty resulting in long extremities and a comparatively short trunk Skeletal growth may at first be stimulated but epiphyseal union is nearly complete about the end of the *pubertal period* In men this usually occurs during the sixteenth or seventeenth year and in women between the fourteenth and sixteenth years *The* epiphyses of the vertebrae pelvis and clavicles do not unite until a little later In man and lower animals spermatogenesis occurs at a somewhat later time than the corresponding first *menstruation or* first estrus Familial instances of puberty occurring prematurely at the age of five to nine years are described although the condition is rare In a similar manner the onset of puberty may be greatly delayed although this disturbance usually indicates a deficiency of pituitary function

While the changes of puberty depend upon the production of male sex *hormone* the stimulus for the increased activity of the

testis is provided by gonadotropic material from the anterior lobe of the pituitary It is not definitely established why puberty occurs when it does According to Engle the seminiferous tubules in the testis and the follicles in the ovary can respond to gonad activators only after the gonads have undergone a certain amount of ripening which may be independent of the hypophysis In the age of puberty suggests that the pituitary stimulus itself may be held in abeyance.

W O THOMPSON

PRECOCIOUS SEXUAL DEVELOPMENT

In the course of treating young boys for undescended testes with chorionic gonadotropin striking genital growth may be observed The changes may be so marked that

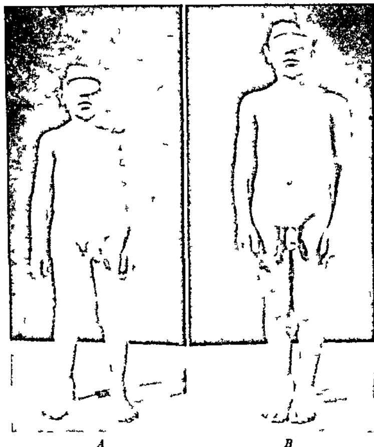

Fig 167—Precocious sexual development and rapid skeletal growth during treatment with chorionic gonadtropin

A July 18 1936 before treatment, age six years seven months Weight 19.5 kg (43 pounds) Ht. 114 8 cm (44¾ inches)

B July 24 1937 after eleven and one-half months of treatment with follutein (total dose 56.5 0 rat units) Weight 27.8 kg (61¼ pounds) Ht 128 0 cm (50 inches) (Thompson and Heckel, J.A.M.A., *110* 1813, 1938)

the case of the interstitial cells of the testis this conclusion does not appear to apply They may be stimulated to increased activity at any age before puberty by gonadotropic material from human pregnancy urine and a condition simulating premature puberty produced (see section on Precocious Sexual Development) The fact that these changes do not occur normally until

a condition resembling premature puberty is produced This phenomenon is illustrated in the accompanying photographs of a six and one half year old boy who was treated for a right undescended testis and an inguinal hernia In the course of a few months his penis became larger than that of his father There was an increase in the size of the scrotum and prostate a growth of pubic hair a

marked increase in the frequency of erections a change in the pitch of the voice and some growth of hair on the sides of the face although a true beard did not develop His height increased rapidly The testes increased little if any in size during treatment, presumably because this material stimulates *primarily the interstitial cells* and not the seminiferous tubules The right testis descended but remained smaller than the left and the associated hernia did not disappear but became strangulated and had to be corrected by operation No change was noted in basal metabolism during treatment

When treatment was discontinued some regression in size occurred The penis became slightly smaller and much less engorged but remained much larger than before treatment was started The prostate became flat and much smaller in diameter and the body weight and height which had increased more rapidly than normal during treatment increased only very slowly for the next two and one half years The pubic hair decreased to about one third of its maximum amount but did not disappear completely Whether or not this treatment will result in premature closure of his epiphyses is unknown Precocious sexual development associated with interstitial cell tumors of the testis is said to stimulate skeletal growth at first but ultimately to cause the individual to become shorter than he might otherwise have been because of premature epiphyseal union If treatment with chorionic gonadotropin is carried out for a sufficiently long period young boys may sometimes be made very large for their age but the final height does not appear to be altered unless pituitary dwarfism is present

The susceptibility to this growth stimulus varies markedly but it appears probable that precocious genital growth may be produced with it in most normal young boys if sufficiently large doses are used Premature sexual development is also said to be produced in man by tumors of the adrenal cortex and pineal gland and occasionally by tumors of the testis and lesions of the mid brain Its relation to pituitary disturbances is open to question There are cases which can be explained only by a marked familial tendency to precocious development In animals thymus extracts are reported to be powerful sex stimulants It would be desirable to know whether the mechanism involved in the production of premature sexual development in these pathologic conditions is similar to the mechanism involved in its production from the administration of chorionic gonadotropin The association of premature puberty with interstitial cell tumors of the testis is of interest in view of the fact that chorionic gonadotropin is known to stimulate the interstitial cells It is also of interest that, in patients showing precocious development of the genitalia associated with tumors of the adrenal cortex, the testis shows little or no increase in size and spermatogenesis may not occur

W O THOMPSON

HYPERGONADISM AND HYPOGONADISM

As in the case of other glands of internal secretion the testis may theoretically show various degrees of hyperfunction and hypofunction States of hyperfunction associated with increased production of male sex hormone undoubtedly occur but are not clearly defined It is difficult to differentiate the effects of overproduction of sex hormone from those of overactivity of the sympathetic nervous system For the most part disorders of function requiring treatment are those associated with hypofunction of the testis In most instances both portions of the testis are affected

PRIMARY AND SECONDARY HYPOGONADISM

The testis, like the ovary may fail to function properly because of some defect inherent in the testis itself (primary hypogonadism) or because of lack of adequate stimulation notably by the anterior lobe of the pituitary (secondary hypogonadism) As in the case of the thyroid normal pituitary function is necessary for normal testicular function and in its absence atrophy of the testes and genitalia occurs, with decrease in or disappearance of spermatogenesis and production of male sex hormone Secondary hypogonadism appears to be more common than the primary type although there is some question at present

as to just how some disorders should be classified Cases of undescended testes in which descent is prevented by mechanical factors and cases in which the testes are removed or destroyed by various agents represent examples of the primary type, while all cases associated with hypopituitarism and cases of undescended testes in which descent is prevented by some hormonal deficiency appear to be of the secondary type

W O THOMPSON

TYPES OF THERAPY IN HYPOGONADISM

Two types of therapy are now possible in hypofunction of the testis (1) substitution therapy with male sex hormone and (2) stimulation therapy with gonadotropic material In substitution therapy the male sex hormone which the testis is not capable of producing in sufficient quantity when stimulated is supplied artificially Examples of conditions in which it is indicated are eunuchism and most cases of eunuchoidism The male sex hormone has also been reported to produce improvement in patients with benign prostatic hypertrophy and to rejuvenate old men It appears to alter the function of the normal testis as judged by a decrease in spermatogenesis during its administration and should be used only in those instances in which the testis is incapable of responding to stimulation With gonadotropic material the testis is stimulated to increased activity so that the testis itself produces more male sex hormone and it is to be preferred in most instances in which the testis is capable of responding to stimulation Examples of conditions in which stimulation is indicated are undescended testes and hypopituitarism with secondary hypogonadism including the Frohlich syndrome

CONDITIONS IN WHICH SUBSTITUTION THERAPY IS INDICATED

Eunuchism — *Definition* — Eunuchism represents complete loss of testicular function from castration inflammation or mechanical injury

Pathologic Physiology —The basal metabolism often shows a moderate depression but is usually not lower than minus 20 to minus 25 per cent The urine shows a marked decrease in its content of androgenic material

Symptoms —The symptoms depend to some extent upon whether the condition develops before or after puberty the chief difference being the effect on body contour The effect of loss of function on skeletal development does not show up until about the time of puberty, when the extremities become very long in proportion to the comparatively short trunk the voice remains high pitched and the secondary sex characteristics fail to develop The individuals affected are usually tall and have a narrow chest and shoulders They are usually very shy effeminate and high strung Pubic and axillary hair fail to develop there is no growth of beard and no development of hair on the chest abdomen arms or legs The genitalia remain infantile The prostate is usually not palpable The muscles are small and feminine in type There may or may not be slight development of breast tissue but it is much less marked than in individuals of the Frohlich type Obesity may be an associated phenomenon but it often is not present In fact the patients may weigh less than normal in contrast to the condition presented by patients of the Frohlich type who may be excessively fat When testicular function is lost after normal masculine development has taken place the skeleton is not affected and many of the secondary sex characteristics tend to persist The penis and scrotum become slightly smaller but remain nearly as large as before loss of function the prostate usually atrophies the growth of hair on the face, pubes axillae and other regions may decrease markedly but usually does not disappear completely The pitch of the voice may become slightly higher but usually retains much of its masculine quality There is decrease in sexual desire but ability to perform the sexual act is often not completely lost There is a marked decrease in bodily vigor and muscle strength decrease in ambition and the development of a somewhat placid and listless individual There are sometimes nervous phenomena resembling those of the climacteric in women

Eunuchoidism —*Definition* —Eunuchoidism is the term applied to partial loss of testicular function The decrease in func

tion may vary from a slight deficiency to almost complete loss The eunuchoid state may result from a primary defect in the testes themselves or from inadequate stimulation of the testes by the anterior lobe of the pituitary

Pathologic Physiology —Moore has pointed out that the testes can develop normally only in the environment of the scrotum When they are deflected over the external oblique they appear to function better than when they remain in the abdominal cavity When both testes fail to descend both testes in the scrotum The testes are usually small and show varying degrees of function

Symptoms —When the secondary sex characteristics develop normally the body contour is usually normal even though both testes remain within the abdomen, and when the secondary sex characteristics do not develop, the skeleton seems to assume the typical eunuchoid character (Fig 168) These facts indicate that the male sex hormone is necessary for normal skeletal growth Other functions of this hormone in

Fig 168 —Eunuchoidism (bilateral intra abdominal cryptorchidism) in a man aged twenty nine showing no effect from treatment with chorionic gonadotropin and a marked effect with testost rone propionate

A July 22 1937 before treatment Patient had extremely small genitalia and the prostate was not palpable He was effeminate smooth skinned had no beard and no hair on his abdomen or extremities There was a small amount of pubic hair His voice was high pitched and he had a marked inferiority complex

B February 25 1933 after 1 024 000 rats units of A P L Practically no change in genitalia Prostate not palpable He had gained 2½ kg Contrast this lack of effect with the marked effect of A P L in Fig 172

C September 26 1939 after 8800 mg of Oreton Marked growth of genitalia Prostate 3 cm in diameter Increased growth of hair on body and development of a more normal body contour in spite of a gain of 9 0 kg The patient grew a beard requiring him to shave every other day His voice became masculine and he became much more energetic and aggressive

from the abdominal cavity virtually complete lack of testicular function often results However evidence of feeble attempts at function are often noted in the appearance of a few pubic hairs and the condition is probably best referred to as eunuchoid in type The interstitial cells are apparently less susceptible to damage from the environment of the abdominal cavity and may show almost normal function even though both testes remain in the abdomen Between these two extremes all variations are possible Eunuchoidism may also be present with the body are illustrated by its effect in patients showing complete loss of function

TREATMENT OF EUNUCHISM AND EUNUCHOIDISM

Substitution therapy is required in all cases of eunuchism and most cases of eunuchoidism because of inability of the testis to respond to stimulation Large doses of testosterone propionate are indicated (25 0 mg daily) The doses originally recommended (from 1 to 5 mg daily) are in

adequate The compound methyl testosterone produces some effect by mouth but it is better in all eunuch and eunuchoid individuals to give testosterone propionate parenterally, at least until maximum changes have been produced In order to simulate natural phenomena and to prevent the development of the skeletal characteristics of the eunuchoid state it is probably desirable in all castrates and in all patients with bilateral intra abdominal cryptorchidism to begin treatment just before the age of normal puberty namely at about the age of eleven years When this is not done and the typical eunuch or eunuchoid changes have been allowed to develop Thompson and Heckel have demonstrated the following effects with large doses of testosterone propionate

1 The gradual appearance of the secondary sex characteristics of the adult male (Fig 168) The infantile penis may become normal in size the prostate develops and hair grows in the pubic and axillary regions on the face and on other parts of the body The pitch of the voice rapidly assumes its characteristic masculine quality Erections and seminal emissions become very frequent Priapism has been described

2 A marked increase in appetite and body weight (as much as 40 pounds [18 Kg] in four months) The patients do not become obese but show an enormous increase in the size firmness and strength of muscles The material appears to stimulate development of the muscular characteristics of the normal male whereas in the eunuchoid state the muscle development resembles that of the female This change is very dramatic

3 An increase in basal metabolism of as much as 30 points

4 An increase in vigor and sense of well being The patients are capable of and have the initiative to do much more work both mental and physical They seek and become much more proficient in games involving muscle coordination and physical stamina

5 Loss of their effeminate characteristics Whereas before treatment they tend to run away from arguments and physical combat after treatment they tend to welcome opportunities to demonstrate their physical prowess

A typical example of what may be accomplished with this treatment is illustrated in Figure 168 As in all conditions involving substitution the response is determined not only by the substance employed but also by the susceptibility of the organ involved There are thus variations in the amount of growth of the penis that may be produced with this material and development usually stops before the size becomes completely normal Observations appear to indicate that the rate at which development of secondary sex characteristics can be induced cannot be accelerated beyond a certain point This is not surprising in view of the fact that the changes associated with normal puberty occur gradually over a period of several years The details of treatment in eunuch and eunuchoid individuals are still to be worked out When there is complete lack of sex development it is probably necessary to give intensive treatment for between one and two years and then continue with maintenance therapy for the rest of the patient s life In individuals whose testicular function disappears after normal development has taken place a shorter period of intensive therapy may be necessary What the maintenance dose will prove to be in both conditions is still to be determined (possibly 25 0 mg once or twice weekly)

The doses of testosterone propionate recorded refer to the preparation in oil for subcutaneous or intramuscular injection The compound is relatively insoluble in body fluids and may therefore be implanted subcutaneously in the form of pellets just as desoxycorticosterone has been in the treatment of Addison s disease It is still to be determined however whether enough absorption for adequate therapy will occur from pellets

OTHER APPLICATIONS OF SUBSTITUTION THERAPY

The Male Climacteric —A condition has been described in some males resembling the female climacteric and characterized by vasomotor and emotional instability The condition is not common and there is no definite period of loss of sexual function in the male like the menopause in the female More than 50 per cent of men over seventy

years of age are reported to show spermatozoa Nevertheless the meager observations that are available on spermatozoa counts and excretion of androgenic and gonadotropic material in the urine suggest that some waning of sexual activity occurs with advancing years, the age of onset varying tremendously from individual to individual Brown Sequard and others have associated the fatigue and decreased vitality of advancing age with decrease in sexual vigor However, the problem of aging is a complex one and probably involves all glands of internal secretion and the tissues which they stimulate While there probably is in some men a true climacteric which is relieved by the administration of testosterone propionate the characteristics of this disorder and the details of its treatment are still to be worked out

Impotence—The most important point in the management of impotence is to determine its cause Many cases are psychogenic in origin and the promiscuous use of glandular therapy is to be deplored When impotence is associated with a gradual decline in sexual function with advancing years or when the onset is associated with injury to the testes or with atrophy secondary to hypopituitarism then some improvement may be expected from glandular therapy This may be of the substitution or stimulation variety depending upon the capacity of the testes to respond

Sterility—In sterility the spermatozoa may be absent greatly decreased in numbers or deficient in quality It may be produced by obstruction to the discharge of spermatozoa or by hypofunction of the seminiferous tubules Testosterone propionate depresses rather than stimulates the function of the testis and has no place in the treatment of this condition Heckel has been able to depress the number of spermatozoa in men with normal counts almost to the point of azoospermia by the administration of testosterone propionate the count returning to normal some time after treatment was discontinued In other words it would appear that testosterone propionate produces at least a temporary injury to the seminiferous tubules of the normal testis and its use is contraindicated in most patients in whom the testes are capable of producing spermatozoa Sterility presents a complicated problem and its treatment at present is unsatisfactory In some instances deficiencies in quantity and quality of spermatozoa appear to be related to deficiencies in the function of the anterior lobe of the pituitary Some improvement in therapy may be expected from the development of a more potent gonadotropic factor from the pituitary The gonadotropic material from the serum of the pregnant mare should theoretically be of value because it contains material which stimulates the seminiferous tubules but in actual practice it is not very effective Chorionic gonadotropin does not represent adequate therapy because it stimulates primarily the interstitial cells

Benign Prostatic Hypertrophy—In contrast to the numerous reports of beneficial results from the use of male sex hormone in benign prostatic hypertrophy, the experience of Heckel and Thompson with this material in such cases has been disappointing Since the male sex hormone causes development of the prostate in the first place it is not easy to understand how its use in benign prostatic hypertrophy would be beneficial It should also be emphasized that castration causes atrophy and that stimulation of the testes of young animals with gonadotropic principles causes growth of the prostate These facts do not seem to support the hypothesis that testosterone propionate improves benign prostatic hypertrophy

Complications of Treatment with Testosterone Propionate—In young men of the eunuchoid type receiving large doses of testosterone propionate Thompson and Heckel have observed edema of the ankles and marked acne The edema is usually temporary in spite of continued treatment and the younger men usually feel well while it is present One patient complained that palpitation and tachycardia were so marked that he had to discontinue treatment for a short period of time Three old men with prostatic hypertrophy developed edema of the ankles and shortness of breath during treatment K W Thompson has reported the development of generalized puffy edema acne of the face and precordial pain In one of his patients precordial pain was so marked that treatment had to be discontinued In

the younger men the edema may be caused by retention of sodium and other electrolytes while in older men an added factor may be cardiac failure resulting from increased activity It is of interest that desoxycorticosterone which is so closely related chemically to testosterone produces edema of the ankles and occasionally generalized edema in patients with Addison s disease Some retention of water and electrolytes is also noted following the administration of the female sex hormone estradiol Testosterone propionate is a very important therapeutic agent but its use should be restricted to the conditions in which it is indicated and patients receiving it must be followed for long periods of time to determine whether or not there are any untoward late complications

CONDITIONS IN WHICH STIMULATION THERAPY IS INDICATED

Undescended Testes (Cryptorchidism)

—*Definition*—True cryptorchidism is present when it is impossible on repeated examination to displace the testis into the scrotum in any position of the body It is to be distinguished from pseudocryptorchidism in which the testes are migratory and move back and forth spontaneously from the canal to the scrotum The condition is bilateral in from 25 to 40 per cent of the cases The importance of failure of descent of the testis lies in the fact that it cannot function normally except in the environment of the scrotum

Incidence—The highest recorded incidence for adults is 3 1 per 1000 reported by the U S War Department The figures for children appear to be much higher but it is not certain whether or not migratory testes are included in them Drake reports thirty eight cases among 1050 boys from various schools and Williams fifty nine cases among 2104 boys in boarding schools Both observers report descent in about two thirds of the cases during the school age

Pathologic Anatomy—The testis may theoretically be stopped at any point along its so called line of descent In most instances undescended testes are found just inside the internal ring in the inguinal canal or deflected from the external ring in various abnormal positions, usually those in which fibers of the gubernaculum are found early in its development The most common site of abnormal deflection is over the external oblique Undescended testes are occasionally deflected toward the base of the penis and in rare instances in the perineum In some instances intra abdominal testes cannot be found at operation Undescended testes may be associated with actual or potential hernia and sometimes the patient first consults a physician because of strangulated hernia The testis itself is often found to be defective at operation No satisfactory figures are available showing the spermatogenic function of undescended testes after glandular treatment or surgical correction or a combination of both

Pathologic Physiology—The response to treatment in successful cases and the findings at operation in unsuccessful cases indicate that descent of the testis depends upon anatomic integrity of the parts involved and upon hormonal stimulation There is some evidence that increased production of male sex hormone from stimulation of the interstitial cell mass by chorionic gonadotropin may play a role Prenatal hypertrophy and postnatal involution of the interstitial cells of the testis have been demonstrated There is an associated prenatal hypertrophy and engorgement of the genitalia and a postnatal decrease in size The only mammals in which prenatal descent of the testis occurs are those in which chorionic gonadotropin appears in the circulation during pregnancy namely in man and in the great apes In other mammals descent occurs just before or early in puberty but in such animals precocious descent may be induced by administration of gonadotropic material from human pregnancy urine It follows that failure of descent of the testis may be caused by

1 An anatomic deficiency
2 A hormonal deficiency

In other words the condition may be caused by primary or secondary hypogonadism With all the recent work on glandular therapy there has been too much tendency to neglect anatomic defects which appear to play an important role in many cases of undescended testes

Signs and Symptoms —The absence of one or both testes from the scrotum is usually first noted by the child s parents Not infrequently a painful swelling representing an associated inguinal hernia first brings the patient to a physician The effect of deficient testicular function does not become evident until about the time of puberty although some of the boys are rather effeminate The body contour of young boys with undescended testes is usually normal and only occasionally of the Frohlich type When the condition is bilateral and intra abdominal and persists beyond the age of puberty, a eunuchoid condition commonly develops although even the intra abdominal testis may secrete some male sex hormone and preserve normal body contour When the condition is unilateral and persists beyond the age of puberty the scrotal testis usually produces enough male sex hormone to cause normal development of secondary sex characteristics although in some instances the testicular function is deficient and appears to be associated with hypopituitarism The basal metabolism in patients with undescended testes is usually normal but may be moderately depressed In about one third of the cases the condition is associated with other abnormalities among which may be mentioned hypospadias slipping of epiphyses infantile sacrum club feet poorly developed abdominal muscles pilonidal sinus and defective cerebral development

Diagnosis —It is important to distinguish true cryptorchidism from pseudocryptorchidism Migratory testes namely those that move back and forth from the canal to the scrotum are not true undescended testes tend to remain in the scrotum after puberty and therefore require no treatment It is common for the inexperienced observer to consider testes of this type as true undescended testes In distinguishing between true cryptorchidism and pseudo cryptorchidism *it is important that the examiner* have a thorough knowledge of the pathologic anatomy of undescended testes and that the testes be carefully manipulated on more than one occasion with the patient in the upright position The location of an undescended testis cannot be determined accurately with the patient in the recumbent position and a testis cannot be considered intra abdominal unless it is impossible to palpate it by any method of examination A testis which appears to be in the abdominal cavity in the recumbent position is often found in the inguinal canal in the erect position or after straining It should also be pointed out that, in any position of the body it may occasionally be impossible because of retraction to palpate testes that at other times can be palpated Testes which are deflected in abnormal positions notably those over the external oblique can usually be distinguished from those in the inguinal canal by the fact that they lie more superficially and can be moved readily under the skin Those in the upper part of the canal can often be displaced into the abdominal cavity It is important to define the position of the testis accurately because it has an important bearing on the response to glandular treatment

Treatment —The best form of treatment at the present time appears to be the intelligent combination of glandular therapy and surgical procedures In the past few years interest has been aroused in the treatment of undescended testes with the anterior pituitary like principle of human pregnancy urine—also called gonadotropic factor of pregnancy urine or chorionic gonadotropin because of its apparent origin from the chorionic villi in the placenta This material was discovered by Aschheim and Zondek and first tried clinically by Schapiro in young boys with hypogenitalism and undescended testes It is available under a variety of trade names—Korotrin Follutein A P L Pranturon Antuitrin S *etc The preparations* containing 500 and 1000 rat units per cubic centimeter are more practical than weaker concentrations This material stimu*lates the interstitial cells of* the testis to produce male sex hormone This in turn causes enlargement of all parts involved in descent and if pushed too far, precocious sexual development resembling premature puberty (Fig 167)

Hamilton has demonstrated that descent of the testis may be produced by male sex hormone itself but since this may injure the normal testis it is contraindicated unless both testes are within the abdominal cavity Gonadotropic material from the pituitary and from the serum of the pregnant mare

have also been reported to cause descent but the data available are not very convincing At the present time the gonadotropic material from human pregnancy urine is in most instances the best for glandular therapy Since Schapiro s report thirteen years ago a large number of observations have appeared on its use in undescended testes most of which appear to be over enthusiastic A review of all available reports about four years ago by Thompson and Heckel showed that descent was claimed in 61 per cent of the cases on the average including successful results in 55 per cent of 150 intra abdominal testes In contrast to these high percentages of successful results Thompson and Heckel were able to produce descent in only 20 per cent of all their cases and in only 27 per cent of those occurring in patients under sixteen years of age The difference in results may be attributed in part to their exclusion except in the beginning of the study of all testes of the migratory or retracted types

In successful cases descent usually occurs within two months after starting treatment although in occasional instances it may take as long as twenty-one months It is easier to produce descent before than after the age of puberty (27 per cent as compared with 6 per cent in the series of Thompson and Heckel) Descent has been produced however as late as the age of thirty two years

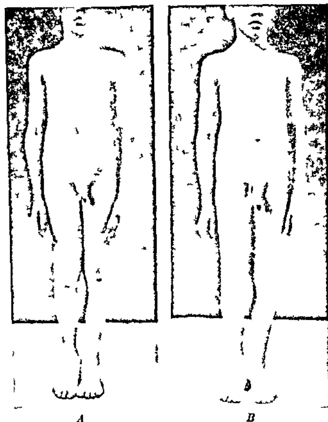

Fig 169—Bilateral undescended testes Growth of genitalia and descent of both testes during treatment with chorionic gonadotropin

A June 11 1938 before treatment, at the age of ten years

B November 19 1938 after 15 000 rat units of A P L showing both testes in the scrotum The left testis became migratory after treatment was discontinued

The position of the testis has an important bearing on the result of treatment According to Thompson and Heckel Descent was produced in nine of twenty one instances (43 per cent) in which the testis was in the inguinal canal in only one of nine instances (11 per cent) in which it was deflected in an abnormal position outside the canal and in none of twenty instances in which it was within the abdominal cavity Descent was produced in one in

stance in which the testis was deflected in the fold of skin to the left of the scrotum

Descent was not produced in any instance in which the testis was deflected over the external oblique muscle or toward the base of the penis Our failure to produce descent in our cases of intra abdominal testes is in striking contrast to the results of some other observers In five of our ten successful cases the testis could either be pulled into the upper end of the scrotum or to a level between the lower end of the canal and the upper end of the scrotum before treatment was started In other words the testes were of the type that commonly descends at puberty In the other five cases there could be little doubt of the influence of the treatment in causing descent

The influence of chorionic gonadotropin on genital growth is more striking than its influence on descent of the testis Marked development of the genitalia may occur without any change in the position of the testis just as during normal puberty illustrating the importance of anatomic factors in preventing descent Examples of genital growth with and without descent are recorded in Figs 169 and 170

W O THOMPSON

RELATION OF GLANDULAR THERAPY TO OPERATIVE PROCEDURES

Treatment with chorionic gonadotropin may be of value before and after surgical procedures Before operation it stimulates genital growth and makes it easier to bring the testis into the scrotum This is important because Thompson and Heckel have demonstrated that operative procedures are necessary in about three fourths of all cases of true cryptorchidism After operation the material may be of value in cases in which the testis is not brought to a sufficiently low level When hernia is present it is not corrected by glandular therapy even if descent of the testis is produced

When glandular therapy is not successful orchidopexy will usually reveal anatomic factors which prevent descent In eleven

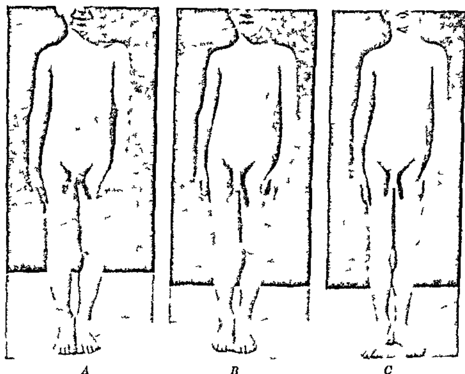

Fig 170—Bilateral undescended testes Marked growth of penis without descent of testes during treatment with chorionic gonadotropin Recession in size after omission of treatment

A November 1 1937 before treatment at the age of five and one-half years

B June 6 1938 after 55 000 rat units of A P L showing marked increase in size of penis but no descent of testes

C July 21 1939 ten and one-half months after omission of treatment, showing decrease in size of penis

patients in the series of Thompson and Heckel these anatomic factors were found to be (1) fibrous bands (all patients) (2) shortness of the structures to which the cord and testis were attached namely the peritoneal process, the transversalis fascia the intercolumnar fascia and the cremasteric muscle and fascia (all patients) (3) abnormal direction of the peritoneal process (four patients), which in three patients was turned upward on the external oblique muscle and in one lay over the rectus sheath and (4) absence of the external ring (one patient)'

W O THOMPSON

STATUS OF GLANDULAR THERAPY

The following facts suggest that chorionic gonadotropin may cause descent only of those testes which would descend normally without treatment at the time of puberty

1 The high percentage of failures with treatment

2 In unsuccessful cases operation has shown anatomic factors which prevent descent

3 The decrease in the incidence of undescended testes after the age of puberty in untreated cases

Influences similar to those introduced artificially come into play during normal development and might be expected to result in descent of those testes not retained by mechanical factors If no more is accomplished with glandular therapy than is accomplished by natural processes at a later age it is pertinent to inquire whether the treatment is worth while The crux of the problem is whether a testis made to descend at an early age with treatment is more likely to be normal than one which descends later without treatment The consensus appears to be that the testis should be brought into the scrotum at an early age although there is some difference of opinion on this question The following points are in favor of glandular therapy

1 It makes it possible to tell at an early age what patients will require surgical intervention by distinguishing between those cases in which descent is prevented by anatomic factors and those in which it is not

2 It causes the testis to move into the scrotum at an early age without operation in one fourth of the cases

3 It facilitates subsequent operative procedures by enlarging the parts involved even when it does not produce descent

If the importance of bringing the testis into the scrotum at the earliest possible age has not been overestimated then perhaps the wisest course to follow in boys with undescended testes is to administer chorionic gonadotropin cautiously and carry out operative procedures if descent fails to occur The age at which treatment should be started is uncertain but if it is to be given at all it should probably be given early perhaps at the age of three years The effective dose and the duration of treatment vary from patient to patient In successful cases descent of the testis usually occurs within two months after the daily administration of from 100 to 1000 rat units is begun After the age of puberty larger doses (as much as 2500 rat units daily) are required The patients must be observed carefully and treatment discontinued before genital growth becomes excessive It has already been pointed out that if treatment is pushed too far a condition simulating premature puberty may result However a moderate amount of genital growth usually must be induced to accomplish the result desired It must be emphasized that little is known about the effect of premature stimulation of the testis with this material on subsequent spermatogenesis and skeletal growth

W O THOMPSON

HYPOGONADISM SECONDARY TO HYPOPITUITARISM

The production of genital growth with chorionic gonadotropin has an important application in the treatment of individuals with hypopituitarism particularly in those of the Frohlich type It may be pointed out that the Frohlich syndrome is characterized by obesity and hypogonadism and often a low basal metabolism There is a marked deposition of fat in the abdomen and thighs with a transverse ridge in the

lower abdomen tending to produce an apron of fat genu valgus and in males the feminine type of breasts The case originally described by Frohlich had a craniopharyngioma of the pituitary but in most instances the sella turcica is normal in size The pituitary appears to be involved and perhaps also the hypothalamic area This condition is described in more detail in the section on the Pituitary but examples of what may be accomplished with chorionic gonadotropin are recorded here in a boy ten years old and in a man thirty seven years old (Figs 171 172) because of their bearing on the conditions already described The susceptibility of this stimulus appears to be less after than before the age of puberty Nevertheless with large doses striking genital growth may be produced in older men It appears that the smaller the genitalia are after the age of puberty the greater the likelihood of influencing their size and the more nearly they approach the normal in size the less the likelihood of doing so If the treatment is given before the age of puberty the fat in the abdomen and thighs may decrease markedly as the genital growth occurs and the skeleton increases in length so that normal body contour is produced Adequate therapy usually produces increased physical and mental vigor In the thirty seven year old man lack of energy and ambition appeared when treatment was discontinued necessitating readministration of the material Without treatment he felt that something was lacking just as a patient with myxedema feels when thyroid is not administered

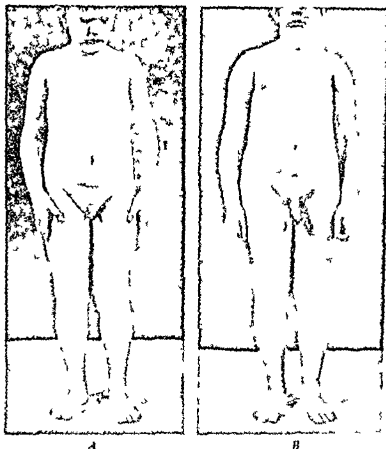

Fig 171 —Effect of chorionic gonadotropin in a boy of the Frohlich type
A September 28 1936 before treatment, at the age of ten years Extremely small genitalia

TUMORS OF THE TESTIS

Tumors of the testis are rare and occur mostly between the ages of twenty and forty years Their incidence is said to be higher in the cryptorchid testis than in the normal testis although there is some controversy

on this point The tumors may be classified as follows

Malignant.
1 Carcinoma
2 Embryonal teratoma or mixed tumor type including chorionepithelioma

Benign
1 Adult teratoma or dermoid
2 Adenoma of the seminal tubules
3 Interstitial cell tumor
4 Fibroma, lipoma, myxoma

The teratomata may form growths resembling rudimentary fetuses, including the chorion These growths are counterparts of the chorionepitheliomas seen in the female and are just as malignant.

Feminizing Tumors of the Testis.—Chorionepithelioma of the testis is especially interesting to the endocrinologist because in about 10 per cent of the cases there is evi-

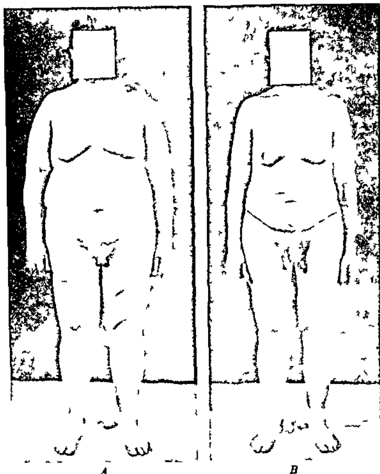

Fig 1 2 —Effect of chorionic gonadotropin in a man aged thirty seven of the Frohlich type, with an undescended right testis

A January 27 1937 before treatment Weight 145 kg Extremely small genitalia No hair on face chest or extremities High pitched voice

B May 16 1938 after 1,325 750 rat units of A P L in two courses Marked increase in size of genitalia Some growth of hair on arms and legs and a moderate amount on the face Voice much lower pitched Greatly increased energy and physical endurance (Contrast with lack of effect upon A P L in Fig 168) After omission of medication decrease in energy and endurance necessitated resumption of treatment (Thompson and Heckel Endocrinology 1940)

The teratoma is the most common form of testicular tumor Next is the carcinoma which has its origin in the adult tubule cells Malignant tumors of the testis are noted for early metastasis by way of the blood or lymph vessels

dence of a feminizing influence This is expressed by enlargement of the breasts sometimes painful and sometimes associated with the secretion of colostrum The Aschheim Zondek test is often positive and in some instances where the pituitary has been

examined, its cells have shown the condition typical of pregnancy In some instances of feminizing tumors, the histology is that of teratoma without the chorionic element

Interstitial Cell Tumors—In any condition involving overgrowth of these cells hypermasculinity would be expected as they are the cells concerned with elaboration of male sex hormone It is *only in children*, however that the full blown picture of the masculinizing effect of these tumors can be noted In adults the effects are not so spectacular as the secondary sex characteristics are already present In the infant or young boy the *genitalia become as large* as those of an adult, accompanied by the rapid skeletal growth muscular development and voice changes that normally occur at puberty Only rare instances have been noted in children although several cases are recorded as developing after puberty

Symptoms of Testicular Tumor—The enlargement is often painless usually develops rapidly and is firm and symmetric There may be quiescent periods There are apt to be enlarged inguinal lymph glands and even the *periaortic lymph glands in the* abdomen are often involved early

Diagnosis—Tumor must be differentiated from tuberculosis which can usually be done by considering the personal and family history and by the fact that in tuberculosis the epididymis and vas are usually hard and nodular Syphilis, with a history of chancre may cause some difficulty in differtial diagnosis because a malignant necrosing growth may give a positive Wassermann reaction although it usually does not affect the result of the Kahn test If in doubt the effect of antisyphilitic treatment should be evident within a short time If there is difficulty in differentiating hydrocele from a tumor, transillumination should be used Hydrocele and tumor may coexist

Treatment.—In the benign types surgical removal is indicated In the malignant types the only hope of cure is an early radical operation with removal of the retroperitoneal lymph nodes along the abdominal aorta This should be done before metastases have formed Irradiation should then be used Provided metastases have not developed teratomata which are resistant to irradiation are the best types for radical surgery Malignant tumors of the testis are usually fatal although life may be prolonged by treatment

W O Thompson

MISCELLANEOUS DISEASES OF THE TESTIS

Orchitis—*Acute Orchitis*—A systemic infection such as typhoid or pneumonia may be followed by acute orchitis (inflammation of the testis), but the chief offender in this respect is mumps Orchitis occurs *in about 12 per cent of patients with this* disease There is marked swelling of one or both testes which are very sensitive to palpation This lasts from three to five days and is associated with a sudden rise in temperature The importance of the condition lies in the fact that in about one third of the cases atrophy of the testis occurs, with subsequent sterility

Chronic orchitis on the other hand is not painful, although the testis slowly becomes swollen and hard The most common cause is tertiary syphilis It may also be caused by tuberculosis, glanders leprosy and certain parasitic diseases

Treatment is directed at the systemic disease of which the orchitis is a manifestation In some instances surgery may have to be resorted to

Hydrocele—This is caused by excessive accumulation of fluid in the tunica vaginalis It may be congenital When acute it is always secondary to inflammation of the epididymis or of the testis as for example in syphilitic infection The chronic type is usually seen in men of middle age Hydrocele caused by such diseases as filariasis may reach an enormous size

Treatment—If the condition is not marked no treatment is indicated Immediate relief in acute cases can be produced by aspiration of the fluid In marked cases surgical procedures are often necessary

Conditions Arising from Interference with Blood Supply—*Extravasation of blood* into the testes is usually caused by injury Sometimes it occurs during breech deliveries The blood supply may be cut off by torsion of the spermatic cord

Infarction of the testis may occur Often

there is no apparent cause It is accompanied by severe pain, *nausea and vomiting* and some fever although the latter is not so high as that noted in mumps The testicular swelling subsides within a week Treatment is palliative

Atrophy —Atrophy may be caused by a variety of conditions *e g* infections, derangement of function of some other gland of internal secretion as for example hypo function of the pituitary, exposure to roentgen rays or radium, permanent interference *with blood supply, pressure such as* that from large varicoceles syphilis etc One of the most important causes is the orchitis which is associated with mumps

Treatment —Depending on the capacity of the testes to respond either substitution or replacement therapy as outlined above is indicated

DISEASES OF THE FEMALE GONADS

INTRODUCTION

THE ovary serves the function of procreation in women Under stimulus of the anterior *lobe of the pituitary it initiates and* maintains the changes which begin with the onset of puberty and culminate in the full sexual development of the adult woman These changes include the development of the external genitalia of the breasts and secondary sexual characters and the attainment of adult psychosexual status In the adult woman the ripening of the ovum is accompanied by the secretion from the follicular cells of estrogen which causes growth of the endometrium and also prepares the vaginal wall for coitus With the extrusion of the ovum the area of rupture closes and the cells previously follicular take on the character of thecal cells to form the corpus luteum These cells secrete progestin the *function of which is to cause further growth* of the endometrium and increased secretory activity in preparation for the nidation of the *fertilized ovum* In the absence of conception the progestational endometrium breaks down leaving only the basal layer This is accompanied by the flow of nonclotting blood *i e* menstruation

The hormonal control of the ovarian cycle is best understood with reference to artificial menstruation This has been produced by

synthetic hormones both in the castrate monkey and in the castrate woman by the injection of estrogen followed by the injection of progesterone The former produces the type of endometrium associated in the menstruating woman with the ripening of the ovarian follicle, and the latter is the type which is seen premenstrually The former is often referred to as the interval or better the proliferative endometrium The latter is characterized by activity of the secretory glands and is often known as a glandular endometrium A better term is progestational endometrium because of its property of forming decidual tissue for the implantation of the ovum

In monkeys when estrogen and progestin are given together following a preliminary treatment with the former there is a more typical progestational phase than when they are given separately (Engle and Smith 1938) This corresponds to the normal events in the ovary in which the change from follicular to luteal activity is a gradual one Thus in a sense the two hormones act synergistically In another sense they are antagonistic as either tends to inhibit the action of the other This is particularly true of the action of progesterone which produces its characteristic type of endometrium in spite of the simultaneous administration of large doses of estrogen

The changes in the vaginal epithelium can be readily observed by the examination of the vaginal fluid by the method of Papanicolaou (1933) as modified by Shorr (1941) The findings at the time of ovulation consist in a typical appearance of the epithelial cells the disappearance of the polymorphonuclear leukocytes a clean appearance of the smears and the presence of mucus which causes a streaky appearance in the slides (Fig 175) Occasionally red corpuscles are found These may even be visible as overt bleeding and accompanied by pain the well known 'Mittelschmerz' The epithelial cells become navicular in shape, then more square, and discrete in arrangement The nuclei become shrunken and pyknotic and the cells take on the stain for cornification In other words the vaginal mucous membrane takes on the quality of skin These changes are the same as those which occur in other mammals under the designation of 'heat' or estrus Other events in the ovarian cycle can also be followed by the vaginal smears

Menstruation runs parallel as a rule to ovulation That menstruation is not fundamental to ovarian activity is shown by the fact that it occurs only in primates and not in other mammals, whereas estrus and the rest of the ovarian cycle is common to all That menstruation is not directly associated with ovulation can also be demonstrated in the human Anovulatory menstruation is now well known, and the reverse is shown by instances in which conception occurs without menstruation Thus pregnancy has been known to occur in a hypogonadal dwarf Furthermore, a mass of evidence makes it clear that ovulation occurs not simultaneously with menstruation but far from it in the menstrual cycle

This evidence is in general agreement by various methods such as examination of the vaginal fluid, observation of ova in the tubes at operation, pathologic evidence time of a single coitus producing conception, or by estimation of hormones in the blood or urine According to the evidence of the vaginal smears (Papanicolaou 1933) ovulation takes place in most instances on the twelfth or thirteenth day although wide variations occur in individual cases

Since menstruation is the visible event in the ovarian cycle, it is natural that both doctor and patient should focus their attention on it to the exclusion of more fundamental events In fact classification of ovarian diseases is made here and elsewhere on the basis of menstrual disturbances Such a mental habit may lead however to misinterpretations unless the events of the ovarian cycle are kept in mind

The clinical determination of ovarian function includes the history and the physical examination The time of onset of menses length of cycle, duration amount and character of the flow are routine in any history It is important to note the relation of emotional stress obesity malnutrition and other influences to the onset of menstrual disturbances In the physical examination especial attention is paid to secondary sexual characteristics The development of the skeleton figure breasts mammary tissue areolae and the distribution of

body hair is noted The development of the external and internal genitalia is observed Expert gynecologic examination is required to rule out major lesions of the genital tract

HENRY B RICHARDSON

OVARIAN INSUFFICIENCY

This term implies deficiency in the supply or action of estrogen The simplest example is the complete form of insufficiency resulting from castration whether by surgical procedure or radiation This is followed of course by cessation of the menses The endometrium becomes atrophic and cells from the deeper layer appear in the vaginal fluid These are small rounded deeply stained with large nuclei Occasionally no symptoms are noted but ordinarily hot flushes occur These consist of a sensation of warmth starting somewhere in the trunk and spreading over the face causing visible redness and often sweating The latter is sometimes sufficient to require a change of clothing The characteristic which differentiates the flushes from other vasomotor symptoms is the rapid onset and offset usually about five minutes each These are repeated in severe cases many times a day They constitute in themselves a great social disability and in addition to the discomfort are often the inciting cause of repeated upper respiratory infections The next most common symptom is the headache which presents no unusual features A very common complaint is loss of well being often described by the patient as not being her self Nervous disturbances are extremely common as illustrated by inability to cope with situations which formerly presented no special difficulty Any pre existing emotional or psychic difficulty is accentuated such as feeling of inadequacy anxiety state or recurrent mild depressions Occasionally outspoken psychoses are observed including involution melancholia and other disorders

Menopause—The effects of the menopause are extremely variable It may take place with no disturbance whatever particularly in well adjusted persons or it may cause severe symptoms In the severe cases the symptoms are the same as after castration

In contrast to a prevalent assumption the menopause does not necessarily imply a complete cessation of ovarian activity According to the evidence of the vaginal smears a cycle persists in some individuals although this is of slow development and exceedingly long duration A complete follicular reaction may occur, with spontaneous remission of symptoms This may explain the common observation that prior removal of one ovary or part of an ovary accentuates ovarian insufficiency whether due to the climacteric or other cause Removal of the uterus or even partial hysterectomy may be followed by a premature menopause

Amenorrhea—Amenorrhea is the absence of the menstrual cycle at a time of life when menstruation is to be expected One group of cases is that in which the menarche is never established This is referred to as *primary amenorrhea* When this occurs with dwarfism the disease is considered to be pituitary in origin and is best discussed under that section When the skeletal growth is normal there is usually no indication of pituitary disorder beyond minor variations in skeleton and figure For the present these cases are best classified as ovarian in origin since there is no good evidence to the contrary Such individuals continue to have the childish type of figure skeleton genitalia and lack of secondary sexual characteristics They may be obese thus mimicking Frohlich s syndrome or they may be normal in nutrition or thin

Amenorrhea after the establishment of the menarche is known as *secondary amenorrhea* It occurs from a variety of causes of which the chief are emotional disturbances malnutrition obesity and hypothyroidism The striking example of emotional disturbances producing amenorrhea is anorexia nervosa which was formerly confused with Simmonds disease or destruction of the anterior lobe of the pituitary Ordinarily in these cases the amenorrhea is the result of malnutrition but not infrequently precedes it (Richardson 1939 Rahman Richardson and Ripley 1939) The disease occurs in young single women typically within half a dozen years after the onset of the menarche in individuals who show evidence of prior ovarian insufficiency in the form of menstrual disturbances Rarely males are

affected Such individuals lose appetite or more commonly diet to reduce their weight for psychologic reasons The dieting has a compulsive quality as shown by the effect of attempts to increase the weight of the patient against her will This attempt is met by resentment evasions and subterfuges Compulsive behavior in other fields is also evident Most of these patients have gastro intestinal symptoms in the form of ob stinate constipation inordinate use of cathartics and often abdominal pain On recovery of a normal degree of nutrition menstruation is resumed as a rule but in a minority of cases amenorrhea persists

Women who become obese tend to have ovarian insufficiency It is customary to think of the glandular disturbance as pri mary and the result of pituitary disease More often it appears however that the obesity in itself has an adverse effect on the ovarian function Reduction in weight is notoriously difficult particularly when the obesity serves a psychologic function but when accomplished is not infrequently ac companied by a resumption of menses In married women conception following a long period of sterility is occasionally observed after reduction in weight

The cases of amenorrhea associated with pronounced insufficiency of the thyroid gland require no comment here There is a group however in which the evidences of thyroid insufficiency are slight and atypical They have sparse hair a transparent ap pearance of the skin of the face fulness of tissue in the face and legs muscular weak ness and an undue sensitivity to cold, with or without depression of the basal metab olism Such patients often resume menstrua tion with the use of thyroid extract

Ovarian Insufficiency with Persistence of the Menstrual Cycle —This group com prises the great bulk of patients with ova rian insufficiency They are the ones in whom there is a disturbance of the menstrual function alterations in the rhythm or dura tion or quantity of the menstrual flow It is precisely in this group that it is most dif- ficult to arrive at a diagnosis When the menses become infrequent scant or of short duration this may be taken as evidence of ovarian insufficiency and the diagnosis can be confirmed by vaginal smears taken at the time of expected ovulation Confusion arises when the menstrual flow is excessive, as will be described below

Treatment of Ovarian Insufficiency — Ovarian insufficiency, in the sense of a lack of estrogen is treated by supplying the missing hormone Stimulation of the ovary by means of extracts of the anterior lobe is theoretically sound but the dosage is greatly limited by the local reaction which such extracts often produce The extract of preg nancy urine is gonadotropic in animals but in man appears to be predominantly a male principle which finds its most striking ap- plication in the treatment of undescended testicle or in gonadotropic stimulation of the male Androgens produce complete ovarian insufficiency Progesterone has but one function and that is to form a progesta tional endometrium Thyroid is useful in appropriate cases For the most part how ever, the choice of preparations is limited to estrogens

The basic principle of treatment in ova rian insufficiency is the same as in other diseases to give enough of the preparation to produce the intended effect as demon strated by objective criteria The latter are conveniently furnished by the examina tion of the vaginal smears (Figs 173-176) The *aim of treatment* is best attained by the use of injections and is concerned with the nature of the preparation dosage method of administration and schedule whether continuous or intermittent Either of the estrogens may be used estrone or estradiol The dosage is expressed in rat units rather than milligrams That amount of the agent is given which produces the vaginal smear which is found in normal women at the time of ovulation *i.e* the follicular type This amount varies from case to case even in complete ovarian insufficiency The ordinary range is 2000 rat units three to five times a week occasionally higher The material comes dissolved in sesame oil and is injected by means of a size 22 needle 1½ inches in length Injections are best made into the upper part of the buttock although other sites may be used particularly if the pa tien is to give the injections herself When enough hormone is given to produce the typical follicular smear the remission of symptoms may be noted and subsequent

Fig 176

Figs 173-176.—Primary amenorrhea The use of the vaginal smear as a guide to estrogenic therapy (Courtesy of Drs Papanicolaou and Shorr) This series to illustrate also the castrate and postmenopausal cases in which the same initial smear and the same reaction to therapy are observed

Fig 173—Atrophic smear in primary amenorrhea

Fig 174.—Change in smear following estrogenic therapy

Fig 175.—Follicular smear maximum effect induced by estrogenic therapy This is referred to as a follicular reaction because it is the normal accompaniment of the full development of the ovarian follicle in a menstruating woman

Fig 176—Pseudomenstrual or withdrawal bleeding This occurs regularly when treatment is stopped at an interval which is usually five days after cessation of estrogenic therapy

treatment given by the oral route on a more empiric basis

Besides establishing the dose it is necessary to decide whether or not the treatment should be continuous To imitate as far as possible the normal events in the ovarian cycle it is necessary to give the injections intermittently Further compelling reasons

for this are several Continuous treatment results in hyperplasia of the genital organs and may cause bleeding even while the treatment is being *continued* When the medication is discontinued after long periods the bleeding which results from the with drawal may be profuse and even alarming Further the possibility of inducing cancer by large doses though remote cannot be *disregarded* It is best therefore to give a course of injections over three weeks or at the most four weeks to discontinue them for ten days or so and then to resume

The *danger of the induction of cancer* need not be overemphasized It has been produced in animals by estrogenic therapy only by huge doses consisting of many units relative to the animal used By the above method the effect is to give one human unit and no more Cancer occurs spontaneously in women in the fourth decade or later that is after twenty years or more of periodic secretion of one human unit of estrin It is a question therefore whether cancer is related in women to estrogenic activity or the lack of it Reports of cancer in the course of estrogenic treatment are so rare as to suggest that it occurs as a coincidence

The advent of efficient preparations for *oral use* does not alter the fundamental principles of estrogenic treatment These preparations can be used to replace injections even when it is desirable to produce a maximum effect as demonstrated in the vaginal smears Their practical use however is affected by the fact that often a follicular reaction for reasons to be stated below cannot be reached promptly if at all Oral therapy may be inadequate for cases which need rapid relief for instance when the ovarian insufficiency is associated with mental symptoms When the menopausal syndrome is atypical or occurs with nervous manifestations such as anxiety or depression the relation of the symptoms to ovarian insufficiency is often obscure and can be established only by a therapeutic test This consists as stated in giving enough treatment to produce a follicular reaction in the vaginal smear In such cases the most efficient treatment is often to give injections from the start In other instances a less rigid procedure is sufficient Many women are completely relieved of symptoms with only a partial follicular response In such cases no object is gained by increasing the dose

It is fortunate that this is so because the physiologic effects which can be produced by oral treatment are often limited With the natural estrogens or their derivatives the limiting factor is the absorption through the intestinal wall which is only 5 to 10 per cent of the oral dose on the average To allow for the partial absorption the price has been adjusted and the dosage increased The effects of injections can thus be obtained but not in all cases

The newer preparations of stilbestrol or its compounds have been widely studied (See Shorr *et al* 1939 Taylor and Thompson 1941) These are cheap and are readily absorbed when given by mouth moreover they produce all the effects of the natural estrogens On the other hand they often cause unpleasant symptoms among which nausea and vomiting are by far the most common Drowsiness skin rashes vertigo and thrombocytopenia have also been observed Permanent damage as the result of stilbestrol therapy has not been demonstrated One case at least of hepatitis has been observed but this was thought to be a coincidence The incidence of the untoward effects varies in different reports from a small minority to the figure of 80 per cent given by Shorr *et al* (1939) My own experience is between these extremes Occasional patients react unfavorably even to small doses but in general the greater the dose the greater the likelihood of unpleasant effects In practice the usual dose is 1 to 2 mg every twenty four hours

The principle of giving the treatment intermittently is just as important in oral therapy as it is with injections and is much more difficult to enforce because of the convenience of the oral route Just enough stilbestrol should be prescribed to cover the intended period of treatment Apart from other considerations mentioned above any effective estrogen in big enough doses is likely to produce uterine bleeding during prolonged administration or serious hemorrhage when the treatment is stopped The efficiency of stilbestrol makes this a very practical problem For instance Taylor and Thompson (1941) in their series of thirty

cases report four patients who had severe uterine bleeding in the course of the treatment or immediately afterward The doses with one possible exception were distinctly moderate but were continued over a period of eight to nine months

Application of Treatment to Special Disorders —The treatment of *castration* and the *menopause* has been indicated in the preceding paragraph The results which may be expected are first the relief of hot flushes In nearly all cases this is solely a question of adequate dosage The same often applies to headaches which are associated with the menopause It is probable also that there will be a more or less complete restoration of the sense of well being Other symptoms which occur with the menopause may or may not be relieved No object is gained by pushing the dose beyond the quantity necessary to produce a follicular type of smear but if symptoms persist the treatment should be continued with the intermissions mentioned over a period of two or three months before passing judgment as to its efficacy The estimate of the effect on psychic disturbances is complicated of course by the influence of suggestion Pronounced effects are observed in some cases and none whatever in others apparently exactly similar

In the cases of patients with *primary ovarian insufficiency* who fail to undergo puberty and never menstruate the question arises whether to treat them or not The problem is individual and social Often there is a strong sense of inadequacy the patient naturally feels very incomplete as a woman This is one indication for treatment Much depends also on the social economic status If the patient can support herself in a sheltered position without much professional contact with other people there is less reason for treatment If on the other hand she is dependent on her parents as is usually the case the physician must look forward to the time when the parents will no longer be living The status of a patient with inadequate physical and emotional equipment alone in an adult world is not enviable It is usually wise therefore to recommend a prolonged trial with replacement therapy emphasizing the fact that it is replacement therapy and nothing more After full doses have been given over a prolonged period of perhaps a year and a half the patient will be in a position to judge whether to continue It should be pointed out that menstruation is not to be expected as the result of the treatment and that regression will take place on cessation There is a possibility however that the ovaries will assume their own cyclic activity

The treatment of *amenorrhea occurring after puberty* varies with the cause The patients with anorexia nervosa respond little to glandular treatment of any kind Psychotherapy is effective in the milder cases particularly those in which a situational factor is predominant These individuals benefit by the opportunity to talk out their personal problems The more severe cases are the result of a prolonged and deep seated neurosis are resistant to psychotherapy and improve if at all only after a prolonged course of psychiatric treatment

Women who stop menstruating when they become obese are best treated with reduction of weight as indicated in a preceding paragraph Amenorrhea in unsuspected thyroid insufficiency has also been referred to

Patients with *mild ovarian insufficiency* as indicated by scant irregular or infrequent menstruation may be treated by replacement therapy when the symptoms warrant it The demonstration of the insufficiency by the technic of the vaginal smears requires examinations over a long period and it is in these cases that the estimation of the smears is difficult The treatment is complicated by the fact that when the menstrual cycle is present the use of the hormone even in physiologic doses may disturb it Treatment is best reserved for the intermenstrual period beginning after the cessation of flow and ending about five days before the expected onset of the next bleeding In these cases of mild insufficiency attention to psychogenic and dietary factors is particularly fruitful

The hormonal treatment of *dysmenorrhea* is tentative Estrogens and progestin have been used There is no uniform agreement as to the results

Masculinization —Masculinization might be regarded as a form of ovarian insufficiency relative to an excessive supply of androgens Such a concept serves to call attention to the fact that just as the male

secretes estrogen, the female secretes androgen Sexual characteristics depend on the predominance of the respective hormone Masculinization occurs as the result of excessive production of androgens by the female usually in the adrenal cortex as the result of hyperplasia or tumor Corroborative evidence of a lesion in this location is a substantial rise in the urinary excretion of 17 ketosteroids (Fraser *et al* 1941) Masculinizing tumors occur less commonly in aberrant adrenal tissue in the ovaries or attached to them and have also been reported elsewhere in the midbrain pituitary pineal gland and in the thymus In young girls the disease is known as *pseudosexual precocity* (Reilly *et al* 1939) because of the growth of pubic hair and enlargement of the clitoris but the development of adult female characteristics which is the function of estrogen is usually lacking In the adult woman frank masculinization takes place with changes in the voice hirsutism and enlargement of the clitoris The *treatment* is removal of the tumor

Minor grades of excessive androgenic activity are frequently observed or rather suspected in the clinic Possibly a manifestation of this is the hypertrichosis which is so frequently observed androgens are known to produce this It is also possible that excessive hair is an atavistic survival It occurs in a great number of individuals without any necessary relation to their status as women There is also an ill defined group in which the skeleton musculature body hair and voice approach the male type These cases are not sufficiently understood for discussion at the present time

Henry B Richardson

DISEASES OF HYPERSECRETION

Prolonged or excessive action of estrogen is thought to be one of the causes of functional uterine bleeding Otherwise evidence of such excess is rare It is detectable mainly before puberty or after the menopause In young girls it is caused by *neoplasms* of the ovary the granuloma cell tumors The result is a true sexual precocity with all the evidences of estrogenic effects plus menstruation (Reilly *et al* 1939) Genital and sexual development approaches the adult type Rare cases of sexual precocity with disseminated osteitis fibrosa and skin lesions both of peculiar distribution have been described (Albright *et al* 1938) In older women mostly after the menopause thecal cell tumors of the ovary have been described The hormonal effects of these tumors are not clear cut The treatment is removal

Henry B Richardson

FUNCTIONAL UTERINE BLEEDING

Functional uterine bleeding may be defined as that which occurs in excessive amounts or at unexpected times in the absence of gross lesions It is due to dysfunction of one or more of the hormones ovarian or pituitary which are concerned in the ovarian cycle

Bleeding occurs experimentally and clinically as the result of any procedure by which the supply of estrogen to the body is diminished (Engle *et al* 1935) Thus it is observed after ovariectomy and is a regular occurrence on the interruption of therapy with estrogens (see Fig 176) Complete withdrawal is not necessary since diminution of the supply to a lower level suffices to produce bleeding On the other hand prolonged administration of estrin to castrated monkeys results in bleeding even while the administration is being continued The bleeding which occurs experimentally from a decrease in the supply of estrogen can be inhibited by the administration of progestin and this effect is not prevented by the simultaneous administration of estrogens (Engle *et al* 1935) When the administration of progestin is discontinued bleeding takes place in the form of menstruation

It is not clear to what extent this mechanism applies to spontaneous bleeding in the human In fact the opposite theory namely excessive action of estrogen is the one which is most frequently upheld Attempts have been made to establish the etiology on the basis of the endometrium as studied histologically The greatest emphasis has been put on the hyperplastic endometrium an exaggeration of the type which normally is observed with the development of the ovarian follicle Such bleeding is associated with

follicular cysts of the ovary and usually but far from invariably with the absence of corpora lutea The theory is that because of the failure of ovulation the follicles of the ovary secrete estrogen continuously instead of intermittently and that as the result the endometrium becomes fixed in the hyperplastic stage Bleeding therefore takes place without the formation of a progestational endometrium and without the rapid desquamation of the latter which is characteristic of normal menstruation Bleeding may occur, however with any type of endometrium atrophic proliferative hyperplastic or progestational In addition irregular shedding and irregular ripening has been described The incidence of the hyperplastic type according to Jeffcoate (1937) has been overestimated and does not exceed one third of all the cases

Classification of bleeding by hormonal assay has been attempted but the results are uncertain More knowledge is needed concerning the chemical changes which occur in the metabolism of the sex sterols Vaginal smears may be done but require long experience for interpretation in these patients

Bleeding may occur with cyclic ovary activity whether the cycle is prolonged short or normal When it occurs twice a month the alternate bleedings are probably associated with the follicular stage of the ovary and are of no great clinical significance the Mittelschmerz of the German writers This phenomenon does however demonstrate the fact that bleeding can occur as the result of the action of estrogens Bleeding in excess at or following menstruation is known as *menorrhagia* and bleeding which is noncyclic as *metrorrhagia*

Attempts to classify bleeding with respect to age or the menstrual history in terms of the etiology have not been widely accepted Bleeding from a hyperplastic endometrium occurs however most frequently with puberty and often with the menopause (Jeffcoate 1937) and that which is associated with a progestational endometrium nearly a decade earlier than the latter It may take place however at any time during the child bearing age

Functional uterine bleeding is very common At best it is a social and marital disability, and at worst produces chronic anemia and not infrequently threatens life The indications for treatment are to stop the bleeding and if possible to prevent operations on the pelvic organs or radiation and the distressing effects which so often follow in their wake Since the clinical and pathologic classifications leave much to be desired the treatment is empiric

Treatment —The hormones may be discussed in the order of the frequency with which they have been used The indications have been stated at length by Jeffcoate (1937) and Hamblem (1939) The use of *anterior pituitary like extract* of pregnancy urine has been reported most extensively with good results by most authors and no benefit by a few Some of the cases in each series, usually a minority fail to receive benefit This was first employed with the idea that it would stimulate the corpus luteum and thus convert a bleeding hyperplastic endometrium into the progestational type which precedes normal menstruation The human being is not however one of the species in which this extract has a pronounced luteinizing effect on the contrary this action is said to be slight The androgenic effect of this extract on the male suggests an action similar to testosterone of this however there is no evidence Such extracts may produce local irritation and even a constitutional reaction with fever These effects seem to have been more common with the earlier preparations than at present If time permits it is advisable to give a preliminary dose of 0 2 cc This may be followed on the second day with 250 rat units to be repeated on the next day and three times a week Kurzrok (1937) recommends 200 to 500 rat units daily during active bleeding Any standardized preparation from a reliable company may be used Bleeding often ceases within a few days

Androgens have been used more recently but with a greater unanimity as to their action and a higher proportion of successes (See Geist *et al* 1938) *Testosterone* inhibits experimental bleeding and suppresses menstruation in the monkey also in the normal menstruating woman (Papanicolaou Ripley and Shorr 1939) It decreases the size of the ovaries and inhibits follicular activity Thus it produces a temporary men

opause It may cause hirsutism lowering of the pitch of the voice and enlargement of the clitoris but so far no lasting ill effects have been detected experimentally or clinically except for the persistence of slight excess of hair There are numerous androgens which vary in their chemical constitution and in their effects some of them approaching the estrogens The dosage in terms of testosterone propionate is 25 to 50 mg three times a week Bleeding should stop in a few days

The effect of *estrogen* has been little studied as it is contrary to theoretic indications in cases with hyperplastic endometrium (Jeffcoate 1937) It is said to be indicated only in the presence of an atrophic endometrium Scattered reports of its use are available with dramatic cessation of bleeding in some cases The dosage may be chosen as that which is effective in the menopausal syndrome namely from 2000 rat units intramuscularly three times a week to 3000 rat units daily Either estradiol or the estrone form may be used

The use of *progestin* has been suggested for several years but it has become available on a large scale only recently It is still very expensive It inhibits experimental uterine bleeding in monkeys and has been urged on theoretic grounds in cases of hyperplastic endometrium The treatment is expected to inhibit the bleeding and on cessation to be followed by a normal menstruation The dosage is much less than the amount necessary to produce a progestational endometrium in a castrate woman One Corner-Allen rabbit unit = 1 mg Doses of 5 to 10 mg daily have been used

From the preceding discussion it is evident that the hormonal treatment of bleeding is in the empirical stage with respect both to the selection of cases and the choice of preparation and dosage Unlike the estrogenic treatment of the menopausal syndrome there is no convenient method for determining the size of the dose necessary to produce the optimum effect

The choice lies at present between testosterone and anterior pituitary like extract of pregnancy urine with perhaps a slight advantage in the former If one preparation fails another may be tried Progesterone is theoretically sound in cases except those which already have a progestational type of endometrium Recommendation for general use would be premature Estrogens have a dramatic effect in a small group of cases which cannot be selected in advance If effective the bleeding stops in three or four days The *evaluation on empirical grounds* of any form of therapy is difficult This has been emphasized by Geist (1935) who attributes all the reported beneficial effects of extract of pregnancy urine to coincidence. This again calls attention to the intermittent nature of the bleeding and the necessity for conservative treatment

By definition the type of bleeding under discussion is that in which no gross lesions can be demonstrated The presence of certain lesions is not however a contraindication to hormonal therapy The relation between fibromyomata and endometrial bleeding has been discussed by Blair (1936)

Treatment without Hormones —This may be mentioned though well known Rest in bed ice bags and attempts to increase the coagulability of the blood are used For the latter purpose a high calcium diet mainly milk calcium lactate 5 grains (0.3 Gm) 2 tablets three times a day and viosterol 5 to 10 drops daily may be used. Snake venom is mentioned in the literature Curettage may be necessary to stop alarming hemorrhage Bleeding is spontaneously intermittent and repeated curettage is preferable for the reasons mentioned to more radical procedures

Bleeding occurs in association with ovarian dysfunction of some sort under the same conditions as menstrual irregularity or secondary amenorrhea Attention to the same etiologic factors may be very fruitful in functional bleeding These include psychogenic factors caloric undernutrition avitaminosis and thyroid insufficiency Such treatment has the advantage of being directed at the cause rather than the symptom

PUBERTY

Puberty is the change from childhood to maturity The physiologic and psychosexual adjustments required during this process are difficult at best The emotional disturbances occurring at this time are varied and often reawaken maladjustments which existed in early childhood The problem is frequently complicated by the attitude of the parents in particular the mother, who tends to reinforce the natural reluctance of the growing child to assume adult status

To puberty in general is added the psychologic effect of the menarche itself that is of genital bleeding To many girls this is alarming particularly if unexpected For instance a child may be too ashamed to tell anyone about it

Puberty is a very gradual process which becomes complete only after the lapse of several years (Fluhmann 1939) It is initiated by the pituitary The first change is the increase in the size of the follicles of the ovary together with the appearance of secondary sexual characteristics as in the breast and appearance of estrogens in the urine This initiation of estrogenic activity occurs in the eighth to tenth year *i e* three to five years before the average menarche Further evidence of estrogenic activity is the menarche Ovulation may or may not occur anovulatory menstruation is common in the first few cycles Further development of genitalia and secondary characteristics is very gradual Complete fertility is not attained until the sixteenth to the nineteenth year Thus the physiologic changes may require ten years Psychosexual maturity comes last and may not be complete until the early twenties even in well adjusted individuals

Anxiety of parents is usually aroused by absence of menstruation at the expected time failure to grow according to preconceived standards or by obesity They usually attribute the last to endocrine disturbances The probable age of onset of menstruation may be judged first from statistics and second from the age of menarche of the relatives Statistically a peak is observed at thirteen years (Engle and Shelesnyak 1934 Fluhmann 1939) The curve falls off rapidly in either direction Five to 10 per cent of normal individuals begin to menstruate between eleven and twelve years of age but menarche before ten or eleven years is outside the normal range At the other end of the scale also more than 5 per cent of normal girls begin to menstruate at fifteen to

sixteen years of age Delay to sixteen, seventeen, or even twenty years is compatible with childbearing

Anxiety concerning height is warranted if growth stops Ordinarily this is not the case but rather the height is less than the parents think it should be In estimating the future height of the child a rough guess may be made from the height of the relatives Further growth may be predicted if the epiphyses remain open Increase in height beyond the limits fixed by heredity is improbable

Delayed menarche is of more concern when accompanied by other evidences of retarded development and of less moment when associated with normal growth and sexual characteristics When both menstruation and sexual development are delayed beyond the probable range of normal a pronounced ovarian insufficiency may be inferred When the growth factor is also lacking a probable diagnosis of pituitary insufficiency may be made

At puberty ovarian function may be depressed by the same influences which operate during adult life namely emotional disturbances overnutrition or undernutrition avitaminosis and thyroid insufficiency A common syndrome is obesity, moderately low basal metabolism and amenorrhea This is usually unrelated to thyroid insufficiency Shelton (1933) has called attention to a group of children in whom retardation of epiphyseal growth is the only indication of thyroid insufficiency In the absence of retarded bone development the diagnosis of thyroid insufficiency is not warranted unless the basal metabolism is minus 20% or below or clinical signs of thyroid disease are present

Functional uterine bleeding is common shortly after the establishment of the menarche and has been discussed in an earlier section

Treatment—Most problems at puberty are concerned primarily with anxiety of the parents In the great majority of cases puberty progresses to maturity regardless of interference on the part of the physician The indications are, therefore in favor of extreme conservatism General measures are to be preferred to endocrine therapy directed at the stimulation of ovarian function They are also more effective The most important of these, as well as the most difficult, is *psychotherapy* This should be begun by the mother long before the menarche by explanation designed to prepare the daughter for this event Many women have bizarre notions about menstruation reminiscent of the beliefs of savage peoples They have the idea that menstruation is a means of getting rid of bad blood Thus, delayed menarche to them is not only a defect but also a positive threat to health Explanation of the physiology of menstruation is therefore in order Fortunately, in many cases reassurances at frequent intervals is all the psychotherapy that is needed

Correction of nutritional disorders is frequently called for *Reduction of weight* is best accomplished by dietary means This may encounter resistance from the mother who excuses herself on the ground that dieting may be injurious to the child It may be necessary to support the child against the mother Explanation should be given that the only danger is avitaminosis and directions should be given for combating the latter Malnutrition due to external causes and avitaminosis should be corrected malnutrition from psychic causes is extremely difficult to overcome Thyroid extract may be given for thyroid insufficiency The daily dose may be started at 1 grain (0 06 Gm) and increased ½ grain each week until minor toxic symptoms occur It should then be reduced to about two thirds of the toxic dose and continued for months except for intermissions of one week per month When the physician is under pressure to give some form of glandular treatment thyroid extract is to be preferred to injections of estrogens or gonadotropic preparations

If *puberty* is *delayed* to a *pathologic extent* it may be necessary to try gonadotropic or estrogenic preparations First it is necessary to know whether or not pubertal changes are taking place For this purpose permanent records are indispensable This applies obviously to height and weight which may be compared with previous observations at school Photographs of the figure and genitalia are extremely valuable for reference and accurate descriptions of sexual hair and development of breasts are very helpful Rectopelvic examinations are useful

in skilful hands Objective evidence of growth may save the child from the necessity of injections Apart from possible injurious effects on the developing pelvic organs these are undesirable because they suggest to the child inadequacy or illness They are best postponed to the age of fifteen or sixteen depending on the age of the menarche in the relatives The specifications for treatment are the same as in the adult

Functional uterine bleeding occurring shortly after puberty is commonly reported in gynecologic practice It is said to be more readily controlled by glandular treatment than any other group of cases Spontaneous improvement may be suspected The necessity for conservatism in respect to surgical measures or radiation is obvious

DISEASES OF THE LOCOMOTOR SYSTEM

DISEASES OF THE MUSCLES

CLASSIFICATION OF DISEASES OF THE MUSCLES

I Parenchymatous myositis
- (A) Suppurative myositis
  - 1 Primary suppurative myositis
  - 2 Secondary suppurative myositis
- (B) Nonsuppurative myositis
  - 1 Dermatomyositis
  - 2 Primary myositis fibrosa
  - 3 *Trichinous myositis*

II Myopathies

III Interstitial myositis
- (A) Myositis ossificans
  - 1 *Progressiva*
  - 2 Traumatica
  - 3 Circumscripta
- (B) Intramuscular fibrositis
  - 1 Primary intramuscular fibrositis (muscular rheumatism lumbago torticollis)
  - 2 Secondary intramuscular fibrositis

Myositis signifies an inflammation of muscle myopathy means any disease of muscles The term myositis is generally used however to indicate inflammatory presumably infectious diseases of muscles The term myopathy is usually reserved to designate a group of disorders which is associated with slow progressive loss of power and atrophy or hypertrophy of the muscles the main lesion is in the muscles and not in the somatic motor system but the relation with the autonomic nervous system is not well understood Myalgia merely indicates pain in the muscles It is a symptom of many diseases such as influenza Malta fever and dengue and of poisoning with lead and arsenic When used as a diagnosis it is a confession that nothing is known regarding the disease except that the patient complains of painful muscles

Considering the fact that everyone is affected with some disease of the muscles at least once but usually many times in his life and in view of the relative availability of the muscles for biopsy it is strange that so little is known about diseases of the muscles even about the most common type muscular rheumatism

A distinction should be made between diseases which primarily affect muscle cells and the supporting fibrous tissues simultaneously and those which primarily affect the supporting fibrous structure of the muscle and in which the muscle cells remain unaffected or are *only* secondarily involved Thus a distinction should be made between parenchymatous myositis the myopathies *and the much* more *common interstitial* myositis

Charles H Slocumb

PARENCHYMATOUS MYOSITIS

Parenchymatous myositis is a disease of the muscles which simultaneously affects the muscle cells and the intramuscular fibrous supporting tissue It may be suppurative or nonsuppurative It may appear without localized infection elsewhere but in most cases it is part of a systemic infection or pyemia or it results from extension from an infected viscus bone joint or wound

SUPPURATIVE MYOSITIS

Primary Suppurative Myositis—Primary suppurative myositis may affect one or more muscular regions It is of bacterial origin and its course may be acute or chronic It has been called a primary disease because the mode of entry of the infection has not been found Certain special forms are observed in the tropics (Miyake Sayers and others)

Etiology—Trauma bruising strain and exposure to cold or dampness have been regarded as predisposing causes of primary suppurative myositis *Staphylococcus aureus* is the organism most frequently found in the abscesses in the muscles however other organisms have been found Either sex and any age group may be affected although in most cases the patients are young men

Morbid Anatomy—There may be one or multiple abscesses or there may be a diffuse infiltration in the muscles When the abscess is close to the surface the skin and

subcutaneous tissue may also be inflamed The affected muscle is edematous friable and appears red or gray Microscopic examination of the walls of the abscess during the acute stage reveals bacteria and evidences of acute serous serofibrinous or purulent inflammation The abscess contains pus fragments of necrotic tissue and blood During the chronic stage granulation tissue is present Healing takes place by scar formation

Symptoms—The onset of symptoms is usually sudden Headache fever chills and sweating are soon followed by localization of pain and swelling in the affected muscles Fluctuation occurs in four to ten days and the abscess rarely resolves without evacuation of pus A single abscess well drained may heal in a few weeks When multiple abscesses occur the patient may be confined to bed for months

Diagnosis—The localized painful fluctuant swelling in a muscle usually makes an early diagnosis relatively easy but if the affected region is juxta articular a diagnosis of pyoarthrosis is sometimes entertained

Prognosis—The prognosis is good if the abscesses are drained early Miyake reported one death in thirty three cases and Sayers reported two deaths in twenty six cases After the abscess heals the muscle usually recovers good function In severe cases there is much destruction of muscle with replacement by scar tissue which may lead to deformity when it contracts

Treatment—Hot applications may be applied during the early stage of the infection to hasten localization As soon as fluctuation is present the abscess should be freely drained by a broad incision It is better to err by opening an indurated region than to allow an unrecognized collection of pus from suppurative myositis to infiltrate the surrounding tissue Earle (1939) treated eighteen patients with sulfapyridine giving 2 Gm a day for five days and repeating the course if necessary All of the patients improved rapidly and recovered Surgical procedures may not be necessary if the patient responds well to sulfapyridine If contractures ensue massage and orthopedic corrections should be used

Secondary Suppurative Myositis—Secondary suppurative myositis is associated with other dominant infection elsewhere in the body The infection may reach the muscle because of a pyemia or by extension from an adjacent infected viscus bone joint or wound The most common causative organisms are the staphylococcus, streptococcus tubercle bacillus and *Treponema pallidum* The disease may be associated with actinomycosis gas gangrene and erysipelas

CHARLES H SLOCUMB

NONSUPPURATIVE MYOSITIS

Dermatomyositis—Dermatomyositis is a nonsuppurative inflammation of the skin subcutaneous tissue and skeletal muscles which begins with vague and indefinite prodromata It may have an acute subacute or chronic course but generally is chronic

Etiology—The etiology is unknown but most investigators believe that some infection is the cause Chilling exposure and fatigue may also be of etiologic importance The disease usually affects persons who are between the ages of twenty and forty years although it may occur in any decade of life Sex and season have no apparent influence

Morbid Anatomy—Characteristic pathologic changes are found in the skin and in the skeletal muscles At first the skin becomes thickened firm and edematous The affected muscles become pale yellow or red appear swollen and permeated with yellowish serum, and may feel soft or firm Microscopic examination reveals perivascular lymphocytic inflammatory reaction in the affected muscles and subcutaneous tissue, and parenchymatous degeneration of muscles The increase in connective tissue and thickening walls of the blood vessels are slight

Symptoms—Early acute symptoms may be fever prostration dermatitis with or without edema and muscular weakness and pain More often the onset is subacute or insidious with general malaise weakness low fever dermatitis and muscular aching from myositis The signs of dermatitis or myositis may assume the dominant role and the other be overlooked however within a few months both are usually apparent

The dermatitis may be a prominent finding or may be transitory it may appear as

a dusky erythema with or without edema or it may simulate pellagra toxic erythema urticaria poikiloderma light sensitivity, or other conditions Edema especially around the eyes and face and over the affected muscles, may be transitorily present The dermatitis may be persistently present or may disappear leaving the skin normal or pigmented The eyelids often are a dusky erythematous color and may be edematous The fingers occasionally have a similar color but rarely present a Raynaud like syndrome

The affected muscles are usually weak moderately tender and firm or boggy to palpation and moderately painful with use During an acute stage the affected muscles may be too weak and painful to use painful even during rest and very tender to pressure Muscle atrophy and fibrous contractures may limit the range of movement of joints but demonstrable intra articular disease does not occur The temperature may be as high as 102° to 104° F or as low as 99° to 101° F The patient may not be aware of the fever Subjective symptoms of stiffness and aching made worse by inactivity may be present but are minimal considering the amount of disability present The course may be rapid terminating fatally in a few weeks but more often relapses and remissions occur over a period of months or years Microscopic study of a biopsy specimen of the affected muscle and skin is usually necessary to substantiate the suspicion of the clinical diagnosis Less significant findings which are occasionally present are dysphagia transitory eosinophilia decreased electric reaction of muscles decreased tendon reflexes splenomegaly lymphadenopathy sensory changes and abnormalities of creatine creatinine excretion

Polymyositis hemorrhagica is probably a form of dermatomyositis but it differs from the usual form of this disease in that there are hemorrhages in the muscles and into the skin The onset is more sudden and the course more acute and this form of the disease is more frequently associated with nephritis and cardiac involvement than is the more common type of dermatomyositis

Diagnosis—When symptoms and signs are well established they are usually sufficiently characteristic of dermatomyositis but in the early stages of the disease a biopsy of skin and muscle is usually necessary to establish the diagnosis Not infrequently it is difficult to distinguish dermatomyositis from scleroderma, scleredema or lupus erythematosus In scleroderma the course is usually more uniformly chronic and there is little or no fever, a Raynaud like syndrome sclerodactylia possibly trophic ulcers the microscopic findings of thickened blood vessel walls and more increase in fibrous tissue and less inflammatory infiltration than in dermatomyositis (Brock) In scleredema the edema and skin changes clear completely In lupus erythematosus the dermatitis is more limited to exposed parts of the body and there are leukopenia kidney irritation arthralgia stomatitis and characteristic biopsy findings

Prognosis—The prognosis is unfavorable Steiner collected from the literature seventeen out of twenty eight cases and Brock forty out of seventy five cases in which the disease proved fatal There often are remissions and exacerbations of symptoms Spontaneous arrest of the disease for more than ten years has been observed (O Leary) Death may result from bronchopneumonia, or from respiratory or cardiac failure resulting from involvement of respiratory muscles muscles of deglutition or the cardiac muscle

Treatment—Treatment is for the most part symptomatic It consists of rest in bed local application of heat light massage and special therapeutic exercises to minimize contractures For relief of pain salicylates acetylsalicylic acid or aminopyrine are usually adequate, when symptoms are severe morphine may be required Brock recommended removal of obviously infected foci and injection of typhoid vaccine Glycine, prostigmin pilocarpine and ephedrine have been tried without apparent help (Turner Marcus and Weinstein)

Progressive Myositis Fibrosa—Progressive myositis fibrosa is a localized or generalized subacute or chronic inflammation of a muscle and its fibrous tissue The muscles that are involved atrophy and are eventually almost completely replaced by fibrous tissue There have been only thirteen cases of generalized myositis fibrosa reported in the literature

Etiology—The etiology is unknown The

incidence of the disease bears no apparent relation to sex

Morbid Anatomy.—Muscle most recently affected may appear swollen Later, the muscles atrophy, feel firm and when cut grate on the knife The muscles chiefly involved appear white, those which are less severely affected are reddish yellow On microscopic examination some muscle fibers are seen to be larger than normal others are atrophied Hyaline and hydropic degenerations occur and there is a loss of transverse striations There are local increases in fibroblasts and lymphocytes with a few plasma cells and neutrophilic polymorphonuclear leukocytes Fibrous tissue eventually replaces the diseased muscles Schwab Brindley Bodansky and Harris report a marked creatinuria, decreased ability to store creatine in the muscles and a low creatine content in the affected muscles Ornsteen however did not find creatinuria in the case which he reported

Symptoms.—The onset is insidious A voluntary muscle or a group of such muscles usually in the lower extremities is first involved Clinical features are weakness sweating rapid pulse and respiration loss of weight stiffness of the muscles and clumsiness At first there is a doughy feel to muscles but later a boardlike hardness is observed Severe muscle spasms may occur

Finally the muscles atrophy and are replaced by fibrous tissue Severe contractures may occur Pain and tenderness are not prominent in the early stage of the disease except during muscle cramps In cases in which the disease is advanced movements of affected muscles may produce considerable pain There is no fever In cases which have been reported the ages of the patients have varied from nine months to forty eight years Electric reaction is diminished or absent Until the disease is well advanced the diagnosis cannot be made definitely without a biopsy

Prognosis.—The course of generalized myositis may be rapid and last only a few months or it may be very slowly progressive as in the case reported by Burton Cowan and Fleming in which the patient was still physically active after having had the disease ten years

Treatment.—Specific treatment is unknown Massage and electric treatment may relieve symptoms somewhat Drugs are of little help

Trichinous Myositis (Trichiniasis).—This is a myositis resulting from the invasion of voluntary muscles by *Trichinella* Trichinellae have been recovered from the diaphragm in from 3.5 to 27.6 per cent of cases at necropsy The condition is only recognized in cases in which the infestation is severe and associated with diarrhea acutely painful muscles edema of the muscles and subcutaneous tissues and eosinophilia Further details will be found in the section on Trichiniasis

CHARLES H SLOCUMB

MYOPATHIES

Myopathies include the diseases which are regarded as primary diseases of muscles but which are associated with secondary changes in the somatic nervous system The relation between the myopathies and the autonomic nervous system is not understood A consideration of the myopathies will be found elsewhere

CHARLES H SLOCUMB

INTERSTITIAL MYOSITIS

MYOSITIS OSSIFICANS

There are three types of myositis ossificans namely progressive circumscribed, and traumatic The traumatic type is associated with the formation of bone in a traumatized region Myositis ossificans circumscripta is usually associated with the formation of bone in a scar The progressive form will be considered more in detail

Progressive Myositis Ossificans.—Progressive myositis ossificans is a disease of unknown etiology which is characterized by proliferative inflammation in portions of the fibrous tissue of muscles tendons aponeuroses fasciae and ligaments It progresses to the formation of bone which eventually leads to destruction of the involved muscles and ankyloses of adjacent joints

Etiology and Incidence.—The etiology is unknown In 102 of 112 cases collected by Nutt the disease started before the age of

ten years It can start later in life, however Males are more frequently affected than are females Microdactylia of the thumbs or great toes, and occasionally of other toes or fingers, is an accompaniment in most of the cases

Morbid Anatomy—Rosenstirn and Mair regard the inflammation as a fibrositis rather than a parenchymatous myositis, hence it is here listed under interstitial myositis Three stages have been recognized Swelling edema and hemorrhage in the fibrous tissue in and around the involved muscles and proliferation of fibrous tissue are present in the first stage The skin and subcutaneous tissue may appear normal or may be swollen and red In the second stage the newly formed fibrous tissue contracts and forms a firm mass Bundles of muscle fibers are caught in the fibrous tissue and undergo degeneration In the fibrous tissue there appear cells resembling cartilage and clefts which resemble osteoid trabeculae and contain cells which later become osteoblasts and bone corpuscles When calcification occurs the parts enclosed by trabeculae form bone marrow In the third stage ossification occurs The new bone has been regarded as chemically and structurally the same as normal bone No abnormalities have been found in studies of the chemical constituents of the blood Wilkins Regen and Carpenter reported that the phosphatase activity of muscles in the preossification stage was 800 to 1600 times that of normal muscle and several times that of normal bone that of the heterotopic bone was much greater than that of normal bone

Symptoms—Progressive myositis ossificans may be present for years before it is recognized that limitations in the movements of certain muscles or joints are the result of bony deposits in muscle It may start as a soft doughy swelling in a muscle usually of the neck or back There may or may not have been an antecedent trauma Fever local tenderness and pain and edema and redness of the overlying skin and subcutaneous tissues may or may not be present After a few days the edema disappears leaving a firm nodule Other similar nodules may develop in adjacent muscles and fibrous tissues These firm nodules usually increase in size for a variable period and then regress but they seldom disappear completely Within about two to eight months deposits of bone in the involved regions can often be demonstrated by roentgenograms or by palpating a hard bony mass When the disease is extensive the deformities that develop usually stiffen the spinal column in the position of kyphosis, the scapulae are attached to the thorax by bony ridges which limit movements of the shoulders, the neck is rigidly anteflexed, and the arms legs and jaws may become ankylosed Amenorrhea and atrophy of the testes and scrotum have been noted in some cases

Diagnosis—The diagnosis is not difficult in advanced cases In early cases the early onset of swelling in the muscles, gradual progression of the disease, microdactylia and formation of hard masses in muscles and fibrous tissue should make one suspect the diagnosis which may be confirmed by roentgenographic examination or by microscopic evidence of the bone deposited in muscles Myositis ossificans traumatica and myositis ossificans circumscripta are distinguished from the progressive form by the absence of progression to other regions the presence of the ossification in injured regions or in regions in which a scar is present or an incision has been made Spondylitis deformans can be readily distinguished from progressive myositis ossificans, in cases of spondylitis there is generally early roentgenographic evidence of arthritis of the sacro iliac joints and there is an absence of the formation of bone in muscles

Prognosis—The disease may progress with remissions and exacerbations but the tendency is for the inflammation to spread progressively and irregularly into surrounding muscles fibrous tissue and bones producing destruction of muscles limitation of movements of joints and ankyloses Exostoses develop especially over fibrous and tendinous attachments to bones Death usually results from intercurrent infection from edema of the glottis or from suffocation as a result of limitation of costal breathing

Treatment—No medical treatment has been of help Excision of the bony deposits is sometimes advised in cases in which localized ossification interferes with function of the joints but this procedure is useless in cases of generalized myositis ossificans

surgical removal of new bone may be followed by the formation of more bone in the same region Protection against cold and dampness may prevent some exacerbations

CHARLES H SLOCUMB

INTRAMUSCULAR FIBROSITIS

Intramuscular fibrositis may be primary or secondary Primary intramuscular fibrositis is unaccompanied by and independent of any other recognized disease It is presumably attributable to an unidentified infection or toxemia Secondary intramuscular fibrositis is incidental or secondary to some known general infection or dominant primary condition such as rheumatic fever gout gonorrhea rheumatoid (atrophic) arthritis trauma and so forth

Secondary Intramuscular Fibrositis.—Secondary intramuscular fibrositis is likely to be disregarded in many cases or lost sight of while attention is paid to more painful symptoms Thus in acute rheumatic fever no special attention may be paid to muscles because during the active phase of the disease articular or cardiac symptoms may dominate and during convalescence the muscular symptoms may disappear rapidly Secondary intramuscular fibrositis is commonly associated with senescent (hypertrophic) arthritis but is most frequently encountered as a part of the syndrome of rheumatoid (atrophic) arthritis In the early stages of the latter disease the secondary fibrositis may for a while at least provide the chief symptomatic features Secondary fibrositis is frequently encountered in cases of gout and gonorrhea in which diseases one frequently encounters involvement of muscles but more particularly involvement of muscle tendons such as the Achilles tendons

The treatment of secondary intramuscular (or tendinous) fibrositis is chiefly that of the dominant disease of which the fibrositis is but a part

Primary Intramuscular Fibrositis (Muscular Rheumatism).—Primary intramuscular fibrositis may exist alone It is generally associated however at some time or other with other anatomic forms of primary fibrositis chiefly with tendinous fibrositis or periarticular fibrositis Of 100 cases of primary fibrositis studied by Slocumb twenty five were cases of primary intramuscular fibrositis alone twenty five were cases of primary periarticular fibrositis alone (without muscular symptoms) and fifty were cases in which symptoms of both intramuscular and periarticular fibrositis were present Primary intramuscular fibrositis will therefore, be considered further under the general consideration Primary Fibrositis '

CHARLES H SLOCUMB

PRIMARY FIBROSITIS

Primary fibrositis is a nonsuppurative inflammation of fibrous tissue anywhere in the body and is unrelated to any known disease. It has an acute subacute or chronic onset and course and produces minimal systemic reactions It may result in complete recovery or may become chronic with the production of long-continued aching and subjective stiffness

Etiology.—The etiology is unknown However many patients notice a direct relation between exacerbations of muscular symptoms and infections of the upper part of the respiratory tract influenza exposure to damp or cold weather fatigue and over exertion Some physicians regard infected foci constipation and colitis of importance in causing fibrositis Either sex and any age group may be affected Coates and Delicati (1932) reported that 25 per cent of the patients at a hospital for rheumatic diseases in Bath England were there for the treatment of fibrositis

Morbid Anatomy.—The pathologic reaction consists of an inflammatory hyperplasia of white fibrous tissue anywhere in the body that is in fasciae aponeuroses sheaths of muscles and nerves tendons ligaments articular capsules subcutaneous tissue and periosteum There are available very little data on the inflammatory reaction as it affects muscles or articular capsules Stockman who has made the most thorough study of the changes which take place in this disease confined his study to the histopathologic appearance of localized nodules and indurated regions Three types of nod

ing and arthritis of the hip occasionally must be excluded

Panniculitis —Panniculitis is fibrositis of the subcutaneous tissue The subcutaneous fat is separated by coarse bands of fibrous tissue and is tender to pressure Ecchymosis in the skin and subcutaneous tissues appears after minor trauma Fatigue and aching are the usual symptoms associated with panniculitis

Primary Fibrositis of Aponeuroses and Tendons —This generally is associated with other anatomic types of fibrositis There is local tenderness over the affected regions and tender nodules may be palpable Symptoms are usually aggravated by local pressure and by overuse of the affected part Favorite sites of involvement are the scalp especially the occipital region (indurative headaches) and lumbar region where the primary fibrositis of the aponeurosis is associated with intramuscular fibrositis

Primary Fibrositis of the Subacromial Bursa (Subdeltoid Bursitis, Periarthritis of the Shoulder) —This is an inflammation of the subacromial bursa adjacent tendons or capsule of the shoulder joint If the bursitis' is severe limitation of movement and pain are most noticeable when the shoulder is abducted or rotated internally Pressure over the bursa may cause pain The onset may be acute or insidious The condition may have been present for a few days or several months

Differential Diagnosis —Primary fibrositis of the shoulder is only one of several causes of subacromial bursitis and the condition cannot be diagnosed as primary fibrositis with reasonable certainty without evidence of primary fibrositis elsewhere Partial or complete rupture of the tendons of the supraspinatus infraspinatus biceps or teres muscles is distinguished from primary fibrositis of the shoulder by its association with strain or trauma, by roentgenographic evidence of atrophy of the humerus at the point of attachment of the affected tendons by reference of the pain into the muscles attached to the affected *tendons and into the* arm and by the absence of fibrositis elsewhere in the body Deposits of calcium in the tendons around the shoulder can be excluded by roentgenographic examination Necrosis in the tendons of the shoulder and serofibrinous subacromial bursitis, which have been described by Codman and by Dickson and Crosby are difficult to diagnose but are not associated with fibrositis elsewhere in the body Rheumatoid arthritis of the shoulder can be distinguished from primary fibrositis of the shoulder by the evidences of rheumatoid arthritis elsewhere in the body

Special Form of Primary Fibrositis, Jaccoud's Rheumatisme Fibreux —A form of severe chronic progressive fibrositis has been described by Jaccoud and others and has been given the name chronic rheumatisme fibreux' It is characterized by an abrupt or slow onset and course by the presence of swelling, tenderness and pain over the involved fibrous tissue of the tendons muscles and joints and by atrophy of the muscles The reaction in the synovial membrane is slight or absent Fibrous contractures produce articular deformities Jaccoud s disease may be a separate disease from primary fibrositis it may be a severe form of primary fibrositis or, as Stockman has suggested it may be an atypical rheumatoid arthritis

Prognosis —Acute attacks of primary fibrositis usually may last a few days or weeks but may recur Chronic primary intramuscular and periarticular fibrositis may persist for years but the patients are usually able to continue their work with only slight inconvenience Seldom is there sufficient contracture of fibrous tissue in periarticular and fascial fibrositis to limit the movement of joints however primary fibrositis of the palmar fascia occasionally produces a Dupuytren s contracture and primary fibrositis of the shoulder may limit the movement of the joint if systematic exercises are not practiced Most patients who have chronic primary fibrositis obtain considerable relief with treatment

Treatment —When an acute attack of primary fibrositis occurs the affected part should be rested protected from cold and kept warm Acetylsalicyclic acid in doses of *10 to 15 grains (0 6–1 Gm)* usually produces partial relief Counterirritants over the involved regions help to control the pain in severe cases *An acute attack* may sometimes be shortened by intravenous injections of typhoid vaccine in sufficiently large doses

to produce a fever of 101° to 103° F A cathartic should be given if the patient is constipated As soon as the acuteness of the attack is over the applications of heat should be followed by massage with firm pressure over the tender regions A careful search should be made for foci of infection especially in the teeth, tonsils prostate gland and uterine cervix In chronic primary fibrositis daily applications of heat should be followed by firm massage over the tender nodules and tender regions Firm massage may cause a transitory increase in pain for a few hours after the treatment but within two to ten days the patients will often notice definite improvement Treatment of infected foci protection against respiratory infections against chilling, dampness or sudden changes in temperature are important For fibrositis of the subdeltoid bursa and tendons of the shoulder local roentgen ray treatments may control an acute attack Subdeltoid bursitis resistant to conservative treatment may warrant a local injection of 3 to 10 cc of 0.5 per cent to 1 per cent novocain into the subdeltoid bursa

DISEASES OF THE JOINTS

ARTHRITIS

Arthritis occurs in a number of different forms depending on various etiologic agents Some of these groups are characterized by certain pathologic and clinical features which make their differentiation comparatively easy In other instances only the most careful study will determine the etiology

Arthritis may occur in either an acute or chronic form However almost any type of acute arthritis may pass into a subacute or chronic form, and many cases of chronic arthritis are subject to acute exacerbations

The crucial point to determine in any case of arthritis is whether it is infectious or noninfectious in character Once this point has been settled a long step in advance will have been made in the handling of the case

The following classification of diseases involving the joints has been recommended by the New York City Committee on Arthritis Clinics

Classification of Diseases Involving the Joints

A Infectional arthritis of proved etiology
B *Probably infectional etiology unproved*
  1 Arthritis of rheumatic fever
  2 Rheumatoid arthritis (atrophic arthritis chronic infectious arthritis)
    (a) Adult type
    (b) Juvenile type (Still's disease)
    (c) Ankylosing spondylitis (Marie Strümpell)
    (d) Psoriatic arthritis
  3 Arthritis associated with various infections

C Degenerative joint disease
 1 Osteo arthritis (hypertrophic arthritis degenerative arthritis osteo arthrosis)
  (a) Generalized
  (b) Localized
   1 Secondary to previous trauma
   2 Secondary to structural abnormality
   3 Secondary to previous infectional arthritis
   4 Cause unknown
D Arthritis associated with disturbance of metabolism
 1 Gout
 2 Arthritic manifestations of other metabolic diseases
E Arthritis of neuropathic *origin*
 1 Secondary to tabes dorsalis
 2 Secondary to syringomyelia
F Neoplasms of joints
 (Cyst xanthoma hemangioma giant-celled tumors synovioma)
G Mechanical derangements of joints
 1 Traumatic arthritis
 2 Joint disturbance secondary to abnormal postural strain
H *Miscellaneous forms*
 1 Manifestations of systemic disease
  (a) Arthritis of serum sickness
  (b) Arthritis of hemophilia
  (c) Intermittent hydrarthrosis
  (d) Pulmonary osteoarthropathy
  (e) Hysterical joints
 2 Local joint disturbances
  (a) Aseptic bone necrosis
   1 Secondary to contusion fracture dislocation or air embolism
   2 Of unknown etiology (Juvenile osteochondritis Legg Calve Perthes disease Kohler's disease Freiberg's disease Osgood Schlatter's disease)
  (b) Osteochondritis dissecans
  (c) Osteochondromatosis

RUSSELL L CECIL

INFECTIONAL ARTHRITIS OF KNOWN ETIOLOGY

Gonococcal Arthritis—Gonococcal arthritis is an acute inflammation of a joint caused by the gonococcus Gonococcal arthritis has been described in full in the section on Gonococcal Infections page 166

Pneumococcal Arthritis—Pneumococcal arthritis usually occurs as a complication of lobar pneumonia although occasionally cases are seen in which it is secondary to some other primary focus

The majority of cases occur in children or young people The incidence of pneumococcal arthritis in pneumonia varies from 0 5 to 1 per cent In cases not associated with pneumonia most of the patients give a preceding history of tonsillitis otitis sinusitis or some other such focus of pneumococcal origin

Pneumococcal arthritis is usually monarticular, though it may occur in a polyarticular form as well The large joints are usually affected, and the condition is seen in all grades of severity In the milder cases there is nothing more than a serous effusion into the joint and a mild degree of periarticular inflammation which clears up spontaneously In the majority of cases however the process goes on to suppuration with partial or complete erosion of the cartilage

Pneumococcal arthritis should be strongly suspected in any patient who in the course of lobar pneumonia develops an acutely swollen joint In every case however the final diagnosis must depend upon joint puncture and the demonstration of pneumococci in the fluid

Very mild cases will clear up spontaneously Others will be relieved by sulfonamides or by aspiration and irrigation with some germicidal solution If joint puncture reveals frank pus surgical measures are necessary

Suppurative Arthritis—Suppurative arthritis or surgical joint ' may occur at any age but is particularly common in children It is usually caused by the *Streptococcus haemolyticus* or the *Staphylococcus aureus*

In suppurative arthritis infection of the joint may follow a penetrating wound of the joint or may develop *as a secondary* complication in a patient with bacteremia Occasionally the arthritis is secondary to an adjacent osteomyelitis which involves one of the bones entering into the formation of the joint By far the largest number are secondary to some form of bacteremia, the original focus being a furuncle, an infected wound a mastoid infection or some other localized inflammatory focus

Like most joint infections suppurative arthritis starts in the synovial membrane This rapidly becomes swollen and inflamed, and an exudate rich in polymorphonuclear leukocytes forms in the joint cavity and soon takes on the properties of pus Many of the patients give a history of trauma to the affected joint a day or two after which there is sudden pain and swelling in the joint and excessive pain on movement

There may be an initial chill and a rise in temperature to 102° or 103° F. The joint is hot, swollen and tender and in a short time fluctuation is present.

Aspiration of the joint reveals purulent fluid, cultures from which usually show streptococci or staphylococci.

The treatment is always surgical.

Syphilitic Arthritis.—Syphilis may manifest itself in the joints during either the secondary or the tertiary stages of the disease.

The arthritis of *secondary syphilis* is associated with the other symptoms of secondary lues and is characterized by swelling, tenderness and limitation of motion of several of the larger joints.

The arthritis of *tertiary syphilis* is usually monarticular. It develops late in the disease and is characterized by gummatous thickening of the synovial membrane and capsule. Clinically this form of arthritis runs a chronic course similar in many respects to tuberculous arthritis. There is considerable swelling but no redness, and fluctuation is usually demonstrable. The knee is particularly prone to involvement. Chesney, Kemp and Baetjer state that hydrops of the knee joint associated with periostitis immediately adjacent to the joint is strongly suggestive of syphilis, especially when the patient gives no history of trauma.

The treatment of luetic arthritis is that of syphilis elsewhere in the body. In a case which has not been too long neglected, specific treatment usually yields excellent results.

Tuberculous Arthritis.—Tuberculous arthritis occurs most frequently in children. It is usually monarticular. Almost any joint in the body may be involved, but tuberculosis of the hip joint and tuberculosis of the spine are the two most common forms.

The treatment of tuberculous arthritis is largely surgical and orthopedic. For a full discussion of tuberculous arthritis the reader is referred to any standard treatise on surgery or orthopedics.

Other Forms of Infectional Arthritis.—In addition to the common forms of infectional arthritis already described, other bacteria occasionally localize in the joints and set up inflammation. Among these may be mentioned:

1. *The Arthritis of Scarlet Fever.*—This occurs in two types: (*a*) so-called 'scarlatinal rheumatism'; (*b*) septic arthritis caused by the *Streptococcus haemolyticus* and differing in no respect from the ordinary surgical joint.

2. *The arthritis of cerebrospinal fever*, which also occurs in two forms, one resembling rheumatic fever and usually running a transitory course, the other a true meningococcal infection of the joint and characterized by the formation of a seropurulent exudate rich in pus cells and meningococci.

3. *The Arthritis of Influenza.*—Several cases of influenzal arthritis, monarticular in type, have been reported. Most cases have occurred in children. The affected joint contains a seropurulent fluid, cultures from which yield *Hemophilus influenzae*.

4. *The Arthritis of Puerperal Fever.*—In many patients with puerperal fever, the *Streptococcus haemolyticus* can be isolated from the blood. When this organism localizes in the joint, a suppurative arthritis develops.

5. *The Arthritis of Brucellosis.*—Arthritis is a frequent and characteristic symptom of brucellosis. Several of the large joints are usually affected, and the acute manifestations migrate from joint to joint. Eventually the joints clear up spontaneously.

6. *The Arthritis of Subacute Bacterial Endocarditis.*—In the course of this disease the patient may complain of pain and stiffness in some of the joints. This may be fleeting and of a mild character, or the joints may be swollen and red and the symptoms persist for some time. The symptoms suggest a mild form of rheumatic fever. The treatment is that of bacterial endocarditis and is entirely symptomatic.

7. *The Arthritis of Typhoid Fever.*—Typhoid arthritis is a rare condition and has already been described in the section on Typhoid Fever, page 199.

8. *The Arthritis of Bacillary Dysentery.*—Arthritis is one of the commonest complications of bacillary dysentery and usually affects the knee, though other joints may be involved. It develops after the acute stage of dysentery is over and is accompanied by a recrudescence of fever and serous effusion into the joint.

RUSSELL L. CECIL

THE ARTHRITIS OF RHEUMATIC FEVER

Rheumatic fever is a generalized infection characterized in most instances by acute inflammation of the joints Rheumatic fever is described in detail on page 435

RHEUMATOID ARTHRITIS

(*Chronic Infectious Arthritis Atrophic Arthritis Arthritis Deformans*)

Definition—Rheumatoid arthritis is a chronic disease of the joints characterized by inflammatory changes in the synovial membrane and periarticular structures, and by atrophy and rarefaction of the bones In the earlier stages the disease manifests itself as a migratory swelling and stiffness of the joints, in the later stages by more or less deformity and ankylosis

Incidence—Unfortunately we have no accurate figures concerning the incidence of rheumatoid arthritis It is known however to be quite prevalent in the temperate zone and almost unknown in the tropics It is fairly common in the southern portion of the United States Dawson points out that a large proportion of cases observed in New York City have their onset in the spring months particularly the month of March Rheumatoid arthritis is three times as common in females as in males It is essentially a disease of young people the average age of onset being thirty five years

Etiology—The etiology of rheumatoid arthritis has not been finally determined In spite however, of the lack of knowledge concerning the exact cause of the disease there are certain predisposing factors which are universally accepted as being conducive to its development

Predisposing Causes—Among the more important predisposing factors may be mentioned

SHOCK—A severe physical or emotional shock often precedes the onset of rheumatoid arthritis A death in the family a difficult labor, a surgical operation or some business calamity is often mentioned as having occurred just before arthritis developed

FATIGUE—Fatigue, either mental or physical is another important predisposing cause

TRAUMA—Infectious arthritis frequently makes its first appearance in a joint which has previously been the seat of trauma A sprained ankle, a fracture or a gunshot wound lowers the local resistance, and the rheumatoid process is initiated at this particular point The disease may occasionally remain localized in one joint, but more frequently other joints subsequently become involved It has been shown experimentally in rabbits that when a joint is injured and streptococci are then injected into the blood stream the bacteria show a strong predilection for the injured tissue

INFECTIONS—Rheumatoid arthritis occasionally makes its first appearance shortly after an acute infection particularly the more common ones such as acute coryza tonsillitis sinus infection influenza pneumonia or typhoid fever

EXPOSURE—Sudden or repeated exposure to dampness rain and cold is one of the commonest predisposing causes of rheumatoid arthritis This was well shown by Pemberton in his statistical study of arthritis in soldiers A high percentage of the men who developed chronic arthritis gave a definite history of standing in water, marching or sleeping in the rain, or of prolonged exposure to cold weather

CONSTITUTIONAL INFERIORITY—Osgood has stressed the high incidence of rheumatoid arthritis in the thin visceroptotic type of individual The muscles are poor the thoracic cage is narrow the chest expansion small, the weight bearing lines of the joints are not true and because of poor muscle tone the patient is easily fatigued

HEREDITY—Rheumatoid arthritis is said to run in families The writer has been rather impressed with the frequent tendency of the disease to develop in the offspring of arthritic patients

CLIMATE—Rheumatoid arthritis is a disease of the temperate zones It is rarely encountered in the tropics

Exciting Causes—The exciting cause of rheumatoid arthritis is still very much under debate The fundamental question is is rheumatoid arthritis an infectious disease? Most students of the disease accept the infectious theory although there are some who still do not The evidence in support of the infectious theory is considerable The

clinical course of rheumatoid arthritis is strongly suggestive of an infectious disease and the lesions in the joints are essentially inflammatory similar in many respects to those in other well known infections of the joints

In 1912 Billings and his co workers first called attention to focal infection as an etiologic factor in chronic arthritis These foci were found most frequently in the tonsils or sinuses or at the roots of devitalized teeth At times foci of infection were also found in other parts of the body such as the gall bladder or genito urinary tract During the thirty years which have elapsed since the publication of Billings' article focal infection has come to occupy a very important place in the activities of medical and surgical practice especially in relation to the various forms of arthritis and rheumatism However *in a recent study reported by* Cecil and Angevine on 200 cases of rheumatoid arthritis definite evidence of focal infection was present in only 20 per cent of the cases and careful investigation revealed that removal of foci either before or after the patient came under observation, rarely produced any permanent benefit on the course of the disease At the present time there is a feeling among students of arthritis that the theory of focal infection has been overstressed in the etiology of rheumatoid arthritis and the author concurs in this view One thing seems to be quite certain and that is that foci of infection are not any more frequently encountered in rheumatoid arthritis than they are in other diseases or in healthy individuals

Bacteriology—Considerable research has been directed toward the bacteriology of rheumatoid arthritis but little of it has thrown much light on the real nature of the condition *The frequent presence of strepto*cocci in the various infections which are sometimes associated with arthritis has naturally focused the interest of bacteriologists on this micro organism and a number of investigators have reported the isolation of streptococci from both the blood and joints of patients with rheumatoid arthritis the percentage of positive results varying widely in different studies Carefully controlled studies have seemed to indicate that in the great majority of cases the streptococci which have been recovered from the blood and joints of rheumatoid patients are accidental contaminations

Agglutination and Precipitation Reactions—Agglutinins for the *Streptococcus haemolyticus* were first demonstrated in the serums of patients with rheumatoid arthritis in 1931 by Cecil Nicholls and Stainsby, who showed that most of the attenuated hemolytic strains recovered from arthritic patients were agglutinable with rheumatoid serum even in very high dilutions Nicholls and Stainsby noted that hemolytic streptococci from other sources such as scarlet fever and erysipelas were often agglutinable with arthritic serum These results have been confirmed by numerous observers It has also been found that the serums of patients with rheumatoid arthritis frequently give a positive precipitation reaction with the *protein fractions of S haemolyticus*

Experimental Arthritis—When strains of streptococci which have been isolated from patients with rheumatoid arthritis are injected into rabbits a large proportion of them develop signs of arthritis in one or more joints If repeated intravenous injections of streptococci are made a chronic progressive arthritis often develops The condition then resembles the rheumatoid arthritis of man Indeed microscopic sections from the two conditions are hardly distinguishable In rabbits with experimental streptococcus arthritis the streptococci can often be recovered from the blood stream and from the affected joints and the blood of the arthritic rabbit shows high agglutinins for the homologous streptococci Sabin has produced a subacute proliferative polyarthritis in mice by the intravenous injection of a filtrable micro organism of the pleuropneumonia like group

In conclusion it must be admitted that the etiology of rheumatoid arthritis has not yet been determined The disease certainly presents the picture of a chronic low grade infection and there is a certain amount of evidence that it is of streptococcal origin however the proof of this theory is still lacking

Morbid Anatomy—The tissue changes which take place in rheumatoid arthritis proceed in a certain sequence In the early stages *swelling of the joint is* the most char

acteristic feature This swelling is due to active inflammation in the various parts of the joint, particularly in the synovial membrane, the capsule and the surrounding soft tissue The synovial membrane is swollen and deep red in color and the villous processes show marked hypertrophy In advanced cases, granulation tissue extends over the articular surfaces of the joint in the form of a pannus which eventually is converted into dense fibrous tissue This binds the two contiguous articulating surfaces together in fibrous ankylosis In other *instances ankylosis does not occur but the* cartilage ulcerates and there is an increase of fluid in the joint cavity Finally, subluxations and distortions of the affected joints lead to deformities so characteristic of the disease

In addition to the destructive changes in the joint itself a certain amount of atrophy occurs in the long bones in the muscles and in the skin In an advanced case of rheumatoid arthritis the bones are smaller and more brittle than normal the muscles show marked wasting and the skin over the affected parts is thin tight and glossy

Microscopically the histologic changes in the joints are those of a chronic infectious process In a section taken through the synovial membrane the surface is often found covered with a thin layer of necrotic material densely infiltrated with leukocytes, beneath which there is vascular granulation tissue rich in fibroblasts monocytes and leukocytes of various kinds

Allison and Ghormley maintain that rheumatoid arthritis has a specific micropathology In addition to the chronic granulation tissue which occurs in the synovial membrane and which in itself is rather characteristic there is a more specific lesion consisting of peculiar clumps of lymphoid cells, which they claim are not encountered in other forms of chronic *arthritis*

Perhaps the most interesting pathologic lesion in rheumatoid arthritis is the subcutaneous nodule which occurs in about 10 per cent of the cases Microscopic sections of these nodules show small granulomatous foci somewhat suggestive of miliary tubercles, which consist of an area of central necrosis surrounded by a zone of large mononuclear cells arranged in characteristic radial fashion, and an enveloping area of dense fibrous connective tissue McEwen has shown that these cells are of the same type as *those which occur* in the granulomata of rheumatic fever and that they are quite distinct from the epithelioid cells of tuberculosis and syphilis The changes in the heart are usually insignificant except in those cases of rheumatoid arthritis in which there is a history of rheumatic fever In such cases the various lesions characteristic of rheumatic fever may be found on the valves or in the heart muscle.

Physiology—*There are surprisingly few* chemical changes in the blood of arthritic patients Pemberton and Foster have shown that the blood urea and the nonprotein nitrogen are well within normal figures The *same authors estimated* the carbon dioxide combining power for blood the calcium of the circulating blood and the total fat and cholesterol of the fasting blood in arthritics and in all cases found the figures within normal limits

Pemberton and Foster reported a diminished sugar tolerance in rheumatoid arthritis Their observations were supported by the investigations of Fletcher who found a diminished sugar tolerance in a large majority of cases of rheumatoid arthritis Bauer has found that the delayed rate of sugar removal is secondary to circulatory changes

The basal metabolism in rheumatoid arthritis is close to the average normal level The respiratory quotient is also *normal and* there is no evidence of abnormal respiratory metabolism following the ingestion of large test meals of glucose and protein The calcium and phosphorus metabolism are both normal in rheumatoid arthritis

Symptoms—The patient with rheumatoid arthritis can often date the onset of symptoms from some disturbance of his physical equilibrium such as an acute in*fection exposure to cold* a surgical operation fatigue from overwork or an emotional strain Certain prodromal symptoms may first be noted the more common of which are weakness and fatigue loss of weight, anemia and vasomotor disturbances particularly tingling and numbness in *the hands* and feet The onset may be sudden or gradual When the onset is acute the pain and swelling of the joints come on rapidly and

are associated with chills fever prostration and other features of acute infection but in a great majority of cases the disease makes its appearance very insidiously

When the onset is gradual symptoms usually appear first in only one joint Often *there is pain and stiffness in this particular* joint for weeks or even months before other joints are affected Very gradually the joint begins to swell The temperature is normal or only slightly elevated often running for weeks from 99° to 100° F The pulse is somewhat accelerated and even early in the disease there may be some anemia

Regardless of whether the symptoms develop suddenly or gradually the disease eventually assumes a chronic course The constant involvement of the adjacent nerves

In the majority of patients the hands are sooner or later involved and present a characteristic appearance In the fingers one sees the badge of the disease a pod shaped swelling *of the proximal interphalangeal joint*, the so called fusiform or sausage finger The distal interphalangeal joints are rarely involved As the disease progresses many or all of the fingers may be implicated and swelling appears in the knuckles and wrists The knees are nearly always affected and usually early in the disease The joint becomes *swollen warm* and contains a moderate excess of fluid There is considerable tenderness on pressure and flexion is painful

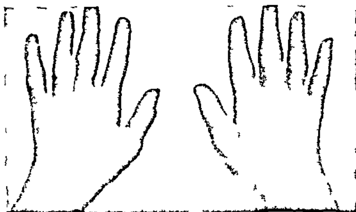

Fig 177—Hands of a young woman with early rheumatoid arthritis showing typical fusiform swelling of the proximal interphalangeal joints Notice the symmetric distribution of the joint swelling (From Oxford Monograph, Cecil s Diagnosis and Treatment of Arthritis courtesy of the Editor Dr Henry A Christian and Oxford University Press)

characteristic features of rheumatoid arthritis are the swelling of the joints particularly those of the fingers hands and knees the symmetrical distribution of the arthritic manifestations the migratory character of the joint *symptoms especially in the early* stages the tendency of the disease to progress into a chronic state and the eventual ankylosis and deformity of the joints if the disease is not arrested

The degree of pain in the affected joints varies considerably and is not entirely proportional to the amount of swelling in the joint With many of these patients there is comparatively little pain except with exercise Arthritis of the hip and of the spine are perhaps the two most painful forms of the disease probably because of the almost and limited The ankles are frequently affected but the toes are often spared possibly because they are subject to so little exercise The temporomandibular joint is more frequently involved in rheumatoid arthritis than in *any other form of joint* disease and causes the patient considerable pain and discomfort when the jaw is exercised

As the disease progresses flexion deformities take place in the elbows and knees as well as in the fingers and wrists At first these muscle spasms can be overcome under anesthesia but as time goes on the joints become fixed in this position and extension becomes more and more difficult Marked muscular atrophy and wasting lead to still more deformities and subluxations In the

hands lateral deflection and subluxation at the metacarpophalangeal joints produces the characteristic ulnar deviation which is one of the earmarks of the disease

The heart is rarely affected in rheumatoid arthritis In those cases where valvular dis ease is present the patient usually gives a history of a preceding rheumatic fever The pulse rate is usually accelerated running between 90 and 100

Among the most remarkable accompani ments of rheumatoid arthritis are the so called 'subcutaneous nodules' which occur in 10 per cent of all cases They are usually found about the elbows wrists or fingers occasionally over the ankles and appear as hard movable nodules which vary in size from that of a pea to that of a walnut They may disappear in a short time or persist for months Iritis is a rather rare complication

Physical Signs —The typical arthritic presents certain *constitutional signs that are* striking These patients are usually anemic averaging about 70 per cent of hemoglobin many of them appear chronically ill and undernourished some are markedly emaci ated, particularly those in whom the disease has lasted for some time A few patients however show excellent nutrition and no anemia

Examination of the tonsils *may show* chronic infection The gums may be the seat of various *grades of gingivitis or pyorrhea* Transillumination of sinuses may reveal a chronic sinusitis In the experience of the writer however the demonstration of frank focal infection is an unusual experience in these patients and certainly no more prev alent than in patients suffering from other ailments

In the early stages the joints affected usu ally present a characteristic appearance There is more or less swelling of the soft parts and the overlying skin is warm and sometimes reddened In some cases there is an increase in synovial fluid The swelling is due for the most part to the outpouring of inflammatory exudate into the periarticu lar structures Tenderness is *usually present* and is most marked on the lateral aspects of the joints Motion either active or passive is painful In the early stages of the disease *there is no crepitation*

In the later stages some of the swelling may disappear but a certain amount of thickening persists about the joint due to a new growth of fibrous tissue in this region In the joint itself the *granulation tissue* may become converted into adhesions which eventually lead to partial or complete fibrous ankylosis In those cases in which *proliferation of the perichondrium* predomi

Fig 178—*Hands of an elderly man with advanced rheumatoid arthritis showing the characteristic deformities and ulnar deviation of fingers Most of the swelling has disappeared from the joints*

nates, bony ankylosis is apt to occur Ankylosis is usually associated with considerable atrophy of the neighboring muscles

The longer the duration of the disease the more frequently bony changes can be demonstrated in the joints In patients who are seen early there may be no swelling or bony changes present and the disease is manifested solely by subjective sensations of pain In these cases examination of the joint reveals nothing abnormal except possibly slight tenderness on pressure Fusiform finger joints are a common finding and when seen are almost pathognomonic The cold clammy hands of the rheumatoid patient are particularly characteristic

Clinical Course —When the onset of rheumatoid arthritis is acute the disease may run a comparatively short course with complete disappearance of symptoms The patient may then be entirely free from joint trouble for several months or even years In a majority of cases however the condition returns after a lapse of time and with each recurring attack takes on a more chronic course

In those cases where the onset is gradual the disease usually runs a chronic course extending over years There may be periods of comparative comfort alternating with periods of active advance With each exacerbation the joints become progressively stiffer and more permanently injured With loss of function muscular atrophy becomes more and more pronounced and flexion deformities especially in the elbows and knees make their appearance

If the process is checked in its early stages all of the symptoms of arthritis may disappear with complete return of normal function in the affected joints Even in well established cases recovery sometimes occurs either spontaneously or as a result of treatment. In such cases the patient may recover partial or complete use of the affected joints even where swelling and deformity do not entirely disappear If the disease is not checked the patient eventually becomes a bedridden cripple presenting a pitiful picture with his contracted deformed limbs and markedly wasted muscles

X Ray Findings —In the early stages of rheumatoid arthritis radiographs of the affected joints may be entirely negative Later on as the process advances there is haziness and narrowing of the interarticular space Still later in the disease as the inflammatory tissue destroys the cartilage the adjacent articular surfaces come into actual contact so that the two bones appear to be fused together At this stage there is considerable atrophy and rarefaction of the cancellous bone due to the diminished calcium content, and small areas of bone destruction frequently referred to as punched-out areas are often demonstrable These areas of erosion are smaller than those which occur in gout In the last stages of the disease when the bone itself is partially destroyed and ankylosis has occurred the markings of the joint are replaced completely by a diffuse shadow which merges with the adjacent bone. Late in the disease the bone may undergo some hypertrophic changes Such hypertrophy however is almost never seen in the early stages

Fig 1"9 —Rheumatoid arthritis in an elderly woman showing swelling and deformity of hands and large subcutaneous nodules near the elbows

Laboratory Findings —Secondary anemia sometimes of fairly severe grade is present in the majority of patients with rheumatoid arthritis

A moderate leukocytosis is found in a considerable number of rheumatoid patients

and the *Schilling hemogram frequently* shows increase of the immature cells, particularly in active cases

The sedimentation rate of the red blood cells is considerably increased in most cases In active cases it may be three or four times the normal rate

In 70 per cent of well established cases the patient s serum will give a positive agglutination reaction to the hemolytic streptococcus The albumin globulin ratio is increased in the great majority of cases

The urine shows no characteristic changes

Diagnosis —The diagnosis of a typical case of *rheumatoid arthritis* presents very little difficulty The important features in diagnosis are

1 Its tendency to occur in young adults, though it may occur at any age

5 In severe cases which are not checked more or less deformity and ankylosis eventually take place

Differential Diagnosis —The most important differential diagnosis is that between rheumatoid arthritis and hypertrophic or so-called ' degenerative arthritis In the latter type there is an absence of inflammatory swelling The disease does not spread but remains localized in a few joints In rheumatoid arthritis, there is a loss of calcium in the bone *which shows up in the x ray* the bone being much more transparent than normal In hypertrophic arthritis there is an increased amount of calcium deposit particularly around the joint which in the x ray appears as a condensation of the bone adjacent to the articular surface, and an actual new formation of bone around the margins of the joint The distinction between infectious arthritis and hypertrophic arthritis is very important as the line of treatment to be instituted is quite different *for the two groups*

DIFFERENTIAL DIAGNOSIS OF RHEUMATOID ARTHRITIS

	Rheumatoid Arthritis	Degenerative Arthritis
Average age of onset	Third and fourth decades	Fifth and sixth decades
Weight	Normal or underweight	Usually overweight
Condition of bones	Rarefaction	Condensation of articular margins
Joints involved	Any joint in body	Chiefly knees spine and fingers
Type	Migratory	Not migratory
Appearance of joints	Periarticular swelling	No swelling
Special signs	Fusiform finger joints	Heberden s nodes
Subcutaneous nodules	Present in 10 per cent of cases	Never present
Roentgen ray	Narrowing and clouding of joint space	Lipping of bony margins of joint
Streptococcal agglutinins	Usually present	Never present
Blood count	Secondary anemia and slight leukocytosis	Normal blood count
Sedimentation of R.B C	Considerably accelerated	Normal or slightly accelerated
Course	*Usually progressive*	*Stationary or slightly progressive*
Termination	*Ankylosis and deformity*	*No ankylosis usually no deformity*

2 The migratory character of the joint *symptoms is characteristic particularly in* the early stages Later on, the changes in the joints become chronic and persisting and tend to a *symmetrical distribution*

3 The affected joints usually are swollen and tender In mild cases there may be an entire absence of swelling but as a rule some degree of infiltration is present and one should hesitate to make a diagnosis of rheumatoid arthritis if no swollen joints are demonstrable

4 Rheumatoid arthritis is very prone to attack the metacarpophalangeal and proximal phalangeal joints with the production of fusiform fingers The tendency toward symmetrical distribution of the fusiform swelling of the fingers is quite characteristic

It must not be forgotten that in the case of a middle aged individual rheumatoid ar*thritis may be superimposed* on a degenerative arthritis and that both processes may attack the same joint

It is very easy to mistake gonococcal arthritis for rheumatoid arthritis especially in women who have no vaginal discharge *Gonorrheal arthritis is* polyarticular and the swollen painful joints may bear a close resemblance to those of rheumatoid arthritis *In this differentiation* the history is of great importance as well as the examination

of the genito urinary tract The gonococcus complement fixation test when properly performed is a valuable laboratory procedure and can usually be depended on especially when a strongly positive reaction is reported The agglutination reaction with the *Streptococcus haemolyticus* is also reliable in differentiating these two forms of arthritis The sedimentation rate is increased in both diseases

Rheumatoid arthritis must be differentiated from subacute rheumatic fever a distinction which is not always easy to make In both conditions the patient may give a history of a preceding tonsillitis followed by an acute arthritis with fever and swelling of the joints In rheumatic fever however the temperature is higher the sweating is more profuse and cardiac complications are quite frequent The therapeutic test is valuable Treatment with sodium salicylate or aspirin usually gives instant and permanent relief in rheumatic fever In rheumatoid arthritis these drugs produce only a temporary improvement

Luetic arthritis particularly that form associated with secondary lues might possibly be confused with infectious arthritis Careful examination however usually reveals other signs of syphilis

Tuberculous arthritis possibly might be mistaken for rheumatoid arthritis The former however is nearly always monarticular, the latter is usually polyarticular X ray examination will be of great assistance in making the distinction but in some cases it may be necessary to resort to exploration and animal inoculation A tuberculous or luetic joint is much more apt to present fluctuation than the joint of rheumatoid arthritis

Arthritis Associated with Focal Infections—Certain cases of infectional arthritis are definitely associated with local infection and are promptly relieved when the focus is removed Indeed these cases tend to recover completely whether or not the focus is removed Some writers believe that this type of arthritis should be classified as rheumatic fever or rheumatoid arthritis However there are certain differences which are worth mentioning Onset and exacerbations are closely associated with flare ups of the focus of infection Usually several of the large joints are affected There is considerable pain and some fever and leukocytosis

In differentiating rheumatoid arthritis from other chronic joint conditions the writer has obtained much help from some of the blood tests mentioned under laboratory findings The sedimentation rate and the Schilling count are both good indices of infection and are of assistance in separating infectious arthritis from the noninfectious forms The streptococcal agglutinin test with the patient s serum helps to distinguish infectious arthritis of the rheumatoid type from joint infections due to other bacteria

Fig 180—Radiograph of spine of a young man with advanced ankylosing spondylitis (Marie Strümpell spine) Notice how the bodies of the vertebrae are fused together by membrane of calcifying fibrous tissue The sacro-iliac joint markings have been obliterated

Other Forms of Rheumatoid Arthritis—*Still s Disease*—In 1897 Still described a form of polyarthritis in children and reported twelve cases of the disease Since then numerous additional cases have been observed The whole picture is that of a chronic infection, and most students of arthritis are disposed to look upon it as rheumatoid arthritis modified somewhat clinically by the age of the patient

So far as the morbid anatomy of the disease is concerned the findings in the joints are similar to those of rheumatoid arthritis In the later stages ankylosis and deformity

occur with marked atrophy of the muscles Lipping and spurring of the articular surfaces almost never occur, but considerable rarefaction of the bone is shown by x rays In addition to the changes in the joints hyperplasia of the lymph nodes and enlargement of the liver and spleen frequently occur Amyloid degeneration has been noted in the liver, spleen, lymph nodes and kidneys

Ankylosing Spondylitis —Most patients with rheumatoid arthritis sooner or later develop symptoms in some part of the spine particularly the cervical portion However there is a special form of infectional arthritis in which the entire spine may become implicated This may exist without involvement of other joints, and is then usually referred to as ankylosing or Marie Strumpell spondylitis (poker spine) Many students believe that this disease is entirely distinct from rheumatoid arthritis Certainly it differs fundamentally in one respect from rheumatoid arthritis in being a disease of men, mostly young men Typical Marie-Strumpell spines are rarely encountered in the female

Ankylosing spondylitis usually makes its first appearance in the lower back affecting first the sacro iliac and the lumbosacral joints The small articulations of the apophyseal and costovertebral joints are often affected The pathologic changes are similar to those which occur in the joints of patients with rheumatoid arthritis but in addition, the longitudinal ligaments show a marked tendency to become calcified As the disease progresses upward more and more of the vertebrae are involved until in advanced cases, complete ankylosis of the entire spine takes place

These young men present a very characteristic appearance The lumbar curve is flattened and the dorsal curve exaggerated The chest is flat and rigid and there is spasm of the deep back muscles The patient flexes the body at the hips the entire spine being held rigid and chest expansion is markedly curtailed These patients are usually very poorly nourished and there is marked atrophy of the trunk muscles In advanced cases the spinal column becomes fused into one piece which admits of no motion in any direction, and there is a tendency for the disease to extend into the shoulder and hip joints with eventual ankylosis in these joints also

Radiographs are very characteristic and establish the diagnosis Early cases may show no changes but in advanced cases there is demineralization of the bone obliteration of the small intervertebral articulations and calcification of the intervertebral ligaments (bamboo spine) The sacro iliac joints are affected in 90 per cent of the cases

Remarkable progress has been made in the treatment of ankylosing spondylitis since the discovery that this form of joint disease responds amazingly well particularly in the early stages to deep x ray therapy Cases so treated often make a complete and permanent recovery In the more advanced cases a certain amount of ankylosis persists but the pain disappears and as time goes on often the stiffness becomes less marked

Psoriatic Arthritis —Psoriatic arthritis or *psoriasis arthropathica* is frequently referred to in the literature on arthritis and is considered by some clinicians as a separate disease entity However the majority of these patients present the characteristic picture of rheumatoid arthritis According to Dawson 2 5 per cent of patients with rheumatoid arthritis are also the victims of psoriasis Psoriasis usually precedes the arthritis but the reverse may be true It is also interesting to note that remissions and exacerbations of arthritis are usually accompanied by remissions and exacerbations of the psoriasis

Prognosis —The prognosis in rheumatoid arthritis is dependent on many factors Perhaps the most important of these is the application of rational treatment early in the disease The prognosis is affected by the morale of the patient and by his constitutional make up Robust well developed individuals respond to treatment more readily than those with inferior physiques The actual number of patients who make a complete and permanent recovery is not accurately known So often the disease becomes arrested or quiescent only to flare up again later on when for some reason the patient's resistance has been lowered Patients who are running an acute febrile course appear to respond more quickly to

treatment than those who present a chronic indolent type of arthritis In the opinion of the writer the prognosis in early rheumatoid arthritis has definitely improved since the introduction of gold therapy

Rheumatoid arthritis alone is never a menace to life In advanced cases however where the patient s general health has undergone marked deterioration the danger of death from some intercurrent infection is quite real

The sedimentation rate of the red blood cells can be used with great advantage in following the rheumatoid patient to determine from time to time the activity of his infection We have also found that as the rheumatoid patient improves the amount of specific streptococcal agglutinin decreases in the blood and if recovery occurs the agglutinins disappear entirely

Prophylaxis —As long as the etiology of rheumatoid arthritis remains in doubt the prophylaxis of the disease will continue to present a difficult problem Obvious foci of infection should of course be removed but it is doubtful if this measure alone would prevent rheumatoid arthritis

One of the most striking features of rheumatoid arthritis is its tendency to relapse Many patients recover completely from the first attack of the disease and remain free from symptoms for several years The second attack is nearly always more stubborn in its course and often goes on into the chronic progressive form In view of this characteristic of the disease every effort should be made to prevent the second attack The patient s life and personal hygiene must be carefully regulated to a point well within his capacity to function without fatigue

Treatment —Rheumatoid arthritis is usually a chronic progressive disease similar in many respects to tuberculosis and syphilis Success in treatment therefore depends on the promptness and vigor with which it is instituted Unfortunately there is no specific therapy for rheumatoid arthritis The treatment resolves itself into efforts to increase the patient s resistance and to put him in the best possible health In addition to these general measures especial attention must be devoted to the inflamed joints to prevent ankylosis and deformity

Active incipient cases with fever can often be greatly benefited by four to six weeks intensive treatment in a hospital This will rarely be sufficient to produce a cure but the patient comes out feeling better and stronger and often afebrile He can then be treated at home or at the physician s office as seems desirable Even those patients with more advanced arthritis will often benefit considerably from a few weeks of hospital care A well equipped hospital not only provides complete rest and good nursing but offers facilities for fever therapy, physical therapy orthopedic treatment etc which are difficult to obtain at home Hospital care also offers opportunity for the investigation and removal of any possible source of infection

Rest —All students of rheumatoid arthritis are agreed that complete and prolonged rest is the keynote to successful treatment of this disease In many ambulant cases complete rest is a difficult form of therapy to enforce chiefly because the patient is anxious to keep up his daily duties However if these patients in the early stages of rheumatoid arthritis could be persuaded to give up work and take a rest cure for six months or a year a much higher percentage of them would make a complete and permanent recovery As it is and chiefly for economic reasons the physician must compromise on the rest issue and the patient is advised to take from one to two hours rest in bed every day after lunch If a real rest cure can be taken it is far preferable because the patient gets a mental and emotional rest as well as a physical one In well established cases rest in bed for a considerable part of the day is absolutely essential There should also be long sleeping hours at night induced by some mild hypnotic if necessary

Dietary and Vitamin Regime —No special diet is indicated in the treatment of rheumatoid arthritis Most rheumatoid patients are undernourished and underweight and one of the duties of the physician is to try to restore the lost weight by means of a nutritious well balanced diet In order to achieve this a high calory high vitamin diet rich in vegetables and fruits is indicated Pemberton and others have advocated a low calory diet for this disease but

at the present time medical opinion is turning away from such a point of view There may be occasional instances of overweight patients who need a low calory diet, but these are exceptions to the rule

The use of vitamins in the treatment of arthritis is purely empiric However a good many patients feel better while taking vitamins and therefore their use is recommended

Some such schedule as the following may be advised

Cod liver oil and viosterol one capsule twice a day (vitamins A and D) The highly concentrated preparations of vitamin D (Ertron and others) which have been hailed by some writers as a cure for rheumatoid arthritis have no advantage over the less concentrated preparations

Orange juice and tomato juice one glass of each a day (vitamin C)

Wheat germ or brewer s yeast once or twice a day (vitamin B)

Concentrated vitamins in the form of thiamine chloride and cevitamic acid may be administered hypodermically or by mouth if it seems desirable Some writers prefer to give cod liver oil in the unconcentrated form The chief objection to the unconcentrated product is its tendency to upset the stomach

Vaccine and Protein Therapy —Streptococcus vaccine has been used for years in the treatment of rheumatoid arthritis and is still popular with many physicians Autogenous vaccines however are not used so much now as formerly Both the subcutaneous and intravenous methods of administration have been employed A certain number of patients show benefit by both methods of injection but the intravenous method appears to yield better results

In using streptococcus vaccine, caution must be taken against overdosage When an amount of streptococcus vaccine greater than the patient can tolerate is injected into the vein a sharp exacerbation of joint symptoms often results and in some instances a definite relapse may occur

Foreign protein therapy has been advocated as a method of treating arthritis but is not very popular at the present time Various substances such as milk horse serum peptone and proteoses and typhoid vaccine have been injected intramuscularly or intravenously with the idea of mobilizing the patient's immune bodies or producing a sharp febrile reaction Of the various agents employed typhoid vaccine is the most popular

Fever Therapy —In the writer's opinion fever therapy has a definite though limited place in the treatment of rheumatoid arthritis It is not recommended, however, for the chronic well established cases In the initial stages of the disease particularly in acute febrile cases fever therapy will sometimes bring about a rapid and complete cessation of symptoms Unfortunately a considerable number of these patients who are relieved by fever therapy will suffer a relapse after a few weeks or months of comfort

There are two methods of inducing fever (1) *typhoid vaccine intravenously* (2) artificial hyperthermia by some form of hot box

TYPHOID VACCINE administered intravenously is the simplest and in the author s opinion the safer method of employing fever therapy At the New York Hospital we have used it on many arthritic patients without any untoward effects It has been found particularly helpful in the active febrile type of case The first dose should be 25 000 000 to 50 000 000 with gradual increase in subsequent doses so as to obtain a good chill and febrile reaction with each injection Typhoid vaccine therapy is contraindicated in patients with chronic cardiac disease in elderly patients and in individuals who give a history of tuberculosis

ARTIFICIAL HYPERTHERMIA —In recent years the artificial production of fever in patients by the use of electricity or the hot box has come into vogue for the treatment of various conditions and some writers have advocated its use in the treatment of rheumatoid arthritis Artificial fever is produced by several methods (1) the *hot bath,* (2) high frequency diathermy currents (3) *radiothermy* (4) *electrically* heated cabinets In the writer s opinion hyperthermia by induced heat has more disadvantages than typhoid vaccine The production of heat by radiant energy seems to be the preferable method because of its cheapness simplicity and freedom from danger A number of articles have recently appeared in

which it is pointed out that artificial fever therapy in the treatment of rheumatoid arthritis usually gives only temporary relief This point of view coincides with the author s experience

Drugs—Drugs play a comparatively minor part in the treatment of rheumatoid arthritis The few that are used however are important

Iron in the form of ferrous sulfate 3 grains (0 2 Gm) four times a day, or reduced iron 10 grains (0 6 Gm) three times a day is useful in combating the secondary anemia which is so common with this disease though too often the results are disappointing

Salicylates—For the control of pain there is no drug that stands up as well month after month as acetylsalicylic acid The dose should be 10 grains (0 6 Gm) 3 to 4 times a day and in some patients even larger doses are well tolerated There is less danger of gastric disturbance if the drug is combined with sodium carbonate or taken with food or a glass of milk In severe cases the writer sometimes combines aspirin with aminopyrine and phenacetin in a formula such as the following

Acetylsalicylic acid	gr v	(0.3 Gm)
Aminopyrine	gr iss	(0 1 Gm)
Phenacetin	gr iss	(0 1 Gm)

When the pain is not controlled by these drugs codeine ½ grain (0 03 Gm) may be necessary Codeine seems to work particularly well in combination with aspirin

The analgesic effect of alcohol should not be forgotten A small drink of whiskey or some other alcoholic beverage will do much to brighten the end of the day for the arthritic and usually gives definite relief from pain Many physicians are in the habit of prohibiting alcoholic beverages for patients with arthritis The writer however has rarely seen any ill effects from the moderate use of alcohol

Sulfur therapy has been quite extensively used in clinics but we have never been able to discover any beneficial properties in it Freyberg s careful metabolic studies on the use of sulfur in rheumatoid arthritis would seem to dispose of any theoretical basis for the use of sulfur therapy

Gold Salts—During the last decade various salts of gold have been tried with considerable success in the treatment of rheumatoid arthritis This form of therapy was originally introduced by Forestier, and has received enthusiastic support from various clinics in England and America The mechanism by which gold acts in rheumatoid arthritis is not understood It has been shown however that gold salts possess chemotherapeutic properties against hemolytic streptococci and certain other pathogenic bacteria Sabin and Warren have studied the effect of gold compounds on experimental arthritis in mice which they produced by intravenous injections of pleuropneumonia like organisms Various gold salts were found to exert a definitely curative effect on this disease and the earlier the treatment was begun the more complete and rapid was the therapeutic response Other investigators have shown that gold salts have an inhibitive effect on experimental hemolytic streptococcal arthritis in mice and rats

In recent years some interesting and important studies have appeared on the metabolism of gold when injected into the human body Freyberg and his co workers have studied the rate of absorption and excretion of various gold salts when injected into human subjects These writers found that about 75 per cent of gold is retained in the body during a course of gold therapy while the other 25 per cent is excreted for the most part through the urine and a small part through the feces The gold salt continues to be excreted for weeks even months after the injections have been concluded This slow excretion of gold products probably explains the toxic effects which are sometimes produced

The most popular forms of gold now in use are sodium gold thiosulfate the aurothiomalate of sodium (Myochrysine) and aurothioglucose (Solganal B) The sodium gold thiosulfate is usually administered intravenously while Myochrysine and Solganal B are injected deep into the gluteal muscles The dosage of gold salts has been a matter of considerable controversy In the beginning of gold therapy the dosage varied from 100 to 500 mg It was soon discovered however that such doses were extremely dangerous Freyberg has shown that a dose

of even 100 mg is unnecessarily large and that smaller doses will produce almost equally good clinical results At the present time the doses which are advocated by most authorities in America are as follows

First dose	*10 mg* intramuscularly
Second dose	*25 mg* intramuscularly
Third and succeeding doses	*50 mg* intramuscularly

The interval between doses is one week *Some writers* advise one repetition each of the small doses before proceeding to the maximum dose The total amount administered in the course should be 750 to 1000 mg It is customary to administer gold therapy in several series or courses with intervals of four to eight weeks between The reason for these intervals is to permit the body to excrete some of the accumulated gold The writer and his co workers at the Cornell Arthritis Clinic have now treated over 500 cases of rheumatoid arthritis with gold salts The first 245 cases so treated were recently analyzed with the following results

RESULTS WITH GOLD THERAPY IN 235 CASES OF RHEUMATOID ARTHRITIS

Result	Cases	Per Cent
Remission	62	31
Greatly Improved	68	35
Moderately Improved	39	20
No Improvement	28	14
Total	197	
Insufficient Treatment	38	
Total	235	

* 10 cases of ankylosing spondylitis excluded

Similar results have been reported by Dawson and Boots and other American investigators Gold therapy is now considered by many to be the most satisfactory single agent in the treatment of rheumatoid arthritis It is particularly valuable in early cases that have swelling and pain in the joints but are still free from ankylosis and deformity

Unfortunately gold therapy is attended by certain dangers which militate strongly against its general acceptance Approximately 25 per cent of the patients on gold therapy develop a rash or some other form of gold intoxication such as stomatitis or gastro enteritis Depression of the bone marrow has been observed in a number of cases with a consequent development of hemorrhagic purpura, aplastic anemia or agranulocytosis A few cases of acute nephritis have followed its use and rare instances of toxic hepatitis Because of this tendency toward gold intoxication, which is occasionally fatal patients who are subjected to gold therapy must be watched carefully for reactions A blood count and urinalysis *should be made at least once a month and* the skin carefully watched for drug rashes In spite of careful watching however, an occasional patient will develop an exceedingly unpleasant and persistent exfoliative dermatitis

Another disappointing feature of gold therapy is the comparatively high percentage of relapses, 40 per cent in the author s reported series Because of this tendency to relapse we have recently been giving our patients maintenance doses of gold salts after the regular course of treatment has been completed The maintenance dose consists of 25 mg of gold salt administered intramuscularly every two to three weeks It is too early to draw conclusions as to the value of the maintenance dose but we have obtained the impression that the percentage of relapses is considerably reduced by this procedure

Patients on gold therapy should have determination of the sedimentation rate of the red blood cells about every two to three months Patients who react well to gold therapy usually have a rapid drop in the sedimentation rate during the first course of treatment Furthermore it has been our observation that those who receive marked benefit from gold salts usually show striking improvement from the first course of gold therapy If a patient shows no improvement after two courses of gold therapy further administration of the agent is contraindicated

Sabin has recently introduced a new gold salt quite similar to Myochrysine, but with calcium substituted for sodium (calcium gold thiomalate) This salt is insoluble and is suspended in oil for intramuscular injection When the calcium salt is injected by the intramuscular route the plasma levels are considerably lower than those observed after the injection of comparable amounts of sodium gold thiomalate Furthermore

much less of the gold is excreted in the urine This salt was introduced with the hope that it would prove less toxic than the more soluble forms of gold salts However drug rashes have also been reported following the use of calcium gold thiomalate and in a limited experience at the Cornell Arthritis Clinic the therapeutic results have quite possible to do more harm than good by this method of treatment

Heat is perhaps the most important form of physical therapy and can be applied either locally to the joint or to the entire body The local application of heat to one joint is carried out by means of the ordinary electric baker or by diathermy Some

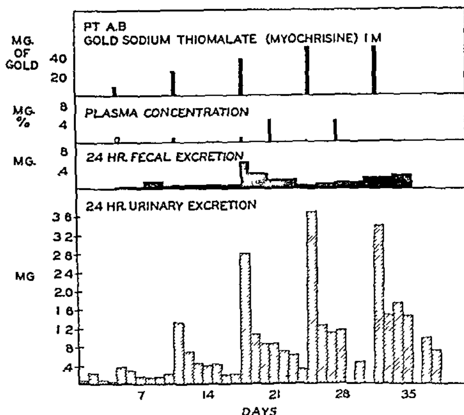

Fig 181—Graphic representation of a typical response in a patient with rheumatoid arthritis treated with increasing doses of gold sodium thiomalate (Myochrysine) injected intramuscularly The plasma gold concentration rises to reach a level of approximately 0 4 mg per cent when 50 mg of gold (100 mg of the drug) are injected Fecal excretion is irregular and increases with larger doses Urinary excretion of gold is always greater on the day of injection it is greater with larger doses Combined excretion however is small compared to the intake of gold and this graph indicates retention of approximately 75 per cent to 80 per cent of the gold injected during the period of treatment This is typical of all cases (Courtesy of Dr Richard H Freyberg)

not seemed so favorable as those achieved with Myochrysine or Solganal B

Physical Therapy—The more common types of physical therapy such as dry heat diathermy massage and exercises all have a place in the treatment of rheumatoid arthritis Their chief function is to increase circulation in the affected joints and to preserve as far as possible the tone of the skeletal muscles Physiotherapy in all forms must be skilfully applied otherwise it is prefer moist heat in the form of hot towels or submersion of the joint in hot water In the experience of the writer diathermy is usually disappointing in the treatment of rheumatoid arthritis From a theoretical standpoint diathermy should be ideal as it heats the tissues as well as the skin but practically a good many rheumatoid patients especially those in the active stage complain that diathermy actually *increases* the pain One of the simplest ways of ap

plying heat to the joint is by means of infra-red light Generalized heat is best applied by means of the hot tub bath the hot pack or the *electric light bridge* The advantage of generalized heat is that in addition to stimulating the circulation copious perspiration is induced in the patient *Hydrotherapy* has come to have an important place in the modern treatment of arthritis The rheumatism cures of Europe date back to the Roman Empire and are still very popular both on the Continent and in Great Britain The European spas which make a specialty of arthritis are Bath and Harrowgate in England Aix les Bains and Dax in France Wiesbaden and Baden Baden in Germany Bad Gastein in Austria and Piestany in Czechoslovakia Alternating hot and cold baths or contrast baths as they are usually called have the advantage of stimulating the sympathetic system as well as the local circulation in the joint

Massage complements heat in that both have more or less the same object—the improvement of blood and lymph flow through the joints Successful results in the use of massage depend on the qualifications of the masseur *and the proper selection of cases* for massage therapy Massage is contraindicated in any patient whose joints are in a highly active painful stage However in many chronic cases there is very little tenderness *on pressure over the joints and in* such cases massage can be used to great advantage not only to the joints themselves but to the adjacent muscles as well Massage is of great value in preventing and correcting the contractures that so frequently occur in rheumatoid patients at the knees and elbows Massage and passive movements preserve the elasticity of the muscles and by increasing the blood supply prevent the gradual shortening of the flexors

Exercises—The object of exercises and calisthenics is first to preserve the function *of the joint by preventing ankylosis,* second to maintain the tone of the muscles and third to prevent and overcome contractions and deformities Every arthritic should have some exercise and one of the most important factors in the treatment of arthritis is to determine just the right balance between rest and exercise in the patient s routine In the average case *with several swollen fingers* or knuckles and a certain amount of swelling and cartilaginous injury in the knees and feet ordinary calisthenics taken lying down will usually serve the purpose The reason *for the recumbent posture is to prevent* strain and fatigue The arthritic is often unable to understand why they are advised to take calisthenics and yet are forbidden to walk or stand The reason of course is that *standing and walking both introduce* a certain amount of strain and friction in the joint whereas when the patient is in the recumbent position all strain on the joint is removed The tendency of the arthritic *joint is to ankylose The tendency* of the arthritic muscle is to undergo atrophy and contraction Both of these tendencies must be overcome by regular exercises The writer instructs every patient with arthritis as to the type of exercise suitable for his particular case The rhythm of the exercise should be slow as rapid movements may induce stiffness on the following day Perhaps the most important of the exercises are those that have to do with maintaining posture In advanced arthritics passive exercises may be necessary or a combination of passive with active exercises

Colonic Irrigations—Certain patients who are suffering from profound intestinal intoxication may need a colonic irrigation once or even twice a week but the great majority *can obtain an equal* amount of benefit from the proper use of laxatives

Transfusions—Transfusions of blood have been advocated by Copeman *Holbrook* and others Holbrook treated seventy patients in this manner, and found that in the subacute or early phases of infectious arthritis with or without anemia they responded well and *in a few instances dramatically* Transfusions were of little or no help for chronic afebrile patients with advanced bony changes Transfusions are *particularly* valuable in patients who show secondary anemia 500 cc of blood is the amount usually given and it may be repeated a few days later if desirable The indirect method is *quite satisfactory and* simplifies the procedure considerably

Climatotherapy—Some rheumatoid patients respond well to a change *of* climate, particularly when they are transferred to a dry warm climate such as that of Arizona

or New Mexico Holbrook believes that the various forms of heliotherapy constitute the major portion of specific climatotherapy A physician who advises a patient to go to Arizona should stress the importance of his remaining there for at least six months or even a year Patients who for financial or other reasons cannot make the pilgrimage to the Southwest should be exposed as much as possible to sunlight and dry heat at home

Orthopedic Treatment—If every case of rheumatoid arthritis could receive prompt and efficient medical treatment comparatively few of them would need orthopedic measures Unfortunately there are a good many individuals who for one reason or another do not receive prompt medical treatment or perhaps they are lacking in resistance to the disease and advance rapidly to ankylosis and deformity For such patients orthopedic procedures of various kinds are of tremendous importance for both prophylaxis and treatment Some of these measures can be applied to ambulant cases Others can be used only in institutions The amount of rehabilitation which may be achieved even in an advanced case of rheumatoid arthritis is remarkable but such improvement requires months or even years of patient care and supervision

Surgical Treatment—Great strides have been made in recent years in the surgical treatment of advanced arthritic conditions Manipulation under an anesthetic synovectomy osteotomy arthrodesis and various reconstruction and arthroplastic operations all have an important place in modern orthopedic surgery Synovectomy is particularly useful in the correction of rheumatoid knees or elbows which have developed villous arthritis This operation involves the removal almost *en masse* of the proliferative synovial membrane A new synovial membrane may be expected to reform and a good but not complete range of motion is to be anticipated

Sympathectomy of the cervical or lumbar ganglia has been tried but rarely gives permanent benefit It has been found that this method is unavailing even temporarily unless an extreme constricting spasm of the blood vessels exists Such spasm can be demonstrated in only a comparatively few cases of rheumatoid arthritis

Psychotherapy—Most patients with rheumatoid arthritis suffer a great deal from mental depression and consequently need an abundant measure of psychotherapy On the other hand there are some individuals usually men who do not take their affliction seriously enough and the physician in all fairness to the patient should make clear to him the serious potentialities of the disease The small slender type of neurotic woman is particularly susceptible to rheumatoid arthritis and often responds poorly to treatment It is this type of patient that needs the greatest amount of moral encouragement Unless the physician makes very earnest efforts along this line, he will fail to get the full cooperation and confidence of the patient factors that mean much in the stubborn fight against the disease

DEGENERATIVE JOINT DISEASE

(*Osteo arthritis Hypertrophic or Degenerative Arthritis*)

Definition —Degenerative joint disease *or osteo arthritis as it is usually called* is a chronic arthropathy occurring usually in elderly people and characterized by hypertrophic and degenerative changes in the bone and cartilage In some cases there is considerable thickening of the synovial membrane

Degenerative arthritis occurs in both a generalized and localized form The generalized form is polyarticular and affects both the large and small joints It is a senescent process *occurring in middle aged and elderly* people and its etiology is unknown

The localized form occurs in one or several joints and may be secondary to trauma structural abnormalities or previous infection in the joint It occurs most frequently in the hips knees or lumbar spine

Morbid Anatomy —One of the first changes seen is a slight roughening and dulling of the *cartilaginous surfaces* At the edges of the surface there is more or less *lipping* and spur formation the latter consisting of spongy bone covered with cartilage As these irregularities become more prominent the cartilage is worn away and the underlying bone is finally laid bare The exposed bone becomes dense and hard and takes on a highly polished eburnated surface

Stockman points out that the characteristic change in this disease is a combination of *simultaneous bone absorption and bone production* These changes take place very gradually and irregularly and in *some cases* may lead to considerable bony deformity Chronic bony changes are seen most frequently in the hip, knee spine and finger joints Ossification may occur in the fibrous tissue about the joints and even in the ligaments the tendon insertions and the bursae The synovial membrane in the beginning is altered very little or not at all but later *on it may show thickening and hypertrophy* of the villous processes These changes in the *synovial membrane apparently* are due to trauma from the bony deformities to which they are secondary Small cartilaginous tumors sometimes form in these hypertrophied villi and when they become free in the joint cavity constitute the so-called joint mice The synovial fluid may or may not be increased in amount

In this form of arthritis the joint cavity *is never obliterated The joint may be* partially dislocated but the synovial membrane does not form adhesions and ankylosis does not occur A certain amount of locking may be present due to a new growth of bone about the edges of the joint

Etiology —Degenerative arthritis is sometimes called senescent arthritis as it occurs almost exclusively in middle aged and elderly people *It is particularly common* in women at the time of menopause As the *years advance* the wearing quality of the joint is diminished depending possibly upon some disturbance in the local circulation Just as the teeth wear down in many old people so the joints particularly the weight bearing joints are prone to wear out in the middle aged and elderly

It is generally agreed that degenerative arthritis has no specific etiology It is more *prevalent in some families* than in others so no doubt heredity is a factor

Perhaps the most important single etiologic factor is trauma The trauma may be in the nature of a mild and long-continued irritation or an acute *rather violent* form, such as might result from an accident or *fracture The trauma* to the weight bearing joints which results from overweight is one of the most frequent causes of degenerative

arthritis In such cases the knees hips and lumbar spine are the joints which suffer most

Physical defects such as curvature of the spine abnormalities of the vertebrae and flat feet predispose to hypertrophic changes in the pine of middle aged patients

Faulty posture predisposes to hyper trophic arthritis by putting an unnatural strain on the joint, or by bringing about unequal pressure on the joint surfaces In correct sitting or standing places a strain on the lower spine, and an improper gait puts an unnatural tension on the joints of the leg particularly on the knee and ankle joints Obese patients nearly all have a bad posture The lower abdomen is abnormally prominent the upper back is rounded and the shoulders pushed forward The feet are abducted producing a distinct tendency to ward knock knee This posture leads to a strain on the lumbar spine as well as on the knees and feet a condition which of course is accentuated by the overweight of the pa tient.

Occupation has an important bearing on the etiology of degenerative arthritis La borers and mechanics are affected most often Any joint which is subjected to con stant usage is apt to show symptoms in an elderly patient

Exposure is possibly a predisposing factor in degenerative arthritis though certainly to a less extent than in rheumatoid arthritis Elderly people who lead hard and exposed lives appear to be more prone to degenerative arthritis than those whose circumstances are more fortunate Persons who keep their hands in water a large part of the day are subject to degenerative arthritis in late life

Symptoms and Physical Signs—The onset of hypertrophic arthritis is insidious The patient usually middle-aged or elderly first notices a slight stiffness in the affected joint which gradually becomes more un comfortable especially during exercise The disease progresses more slowly than rheu matoid arthritis As time goes on however the symptoms become more marked and there may be constant pain in the joints involved The joints most frequently af fected are the hips knees fingers and verte-brae although under certain conditions any joint in the body may undergo hypertrophic changes

On physical examination the patient is usually middle-aged and overweight and the weight bearing joints are the ones generally affected The posture is often bad and there is usually some degree of flatfoot The af fected joints are rarely swollen and never ankylosed On movement some crepitation is usually noted Occasionally there may be an increase of fluid in the joint cavity When the affected joint is palpated it may be pos sible if the joint is superficial to feel the hypertrophied bony outgrowths around the margins of the joint

Diagnosis—The diagnosis of primary osteo arthritis can usually be made without much difficulty The age of the patient and the gradual onset of pain and stiffness in one or more joints without soft tissue swell ing are almost sufficient evidence on which to make a presumptive diagnosis The pres ence of crepitation in the joint gives addi tional support and the finding of the char acteristic bony changes in the x ray con firm the diagnosis The sedimentation rate should be normal or only slightly elevated If symptoms are limited to one joint the history of trauma should make one very suspicious of an osteo arthritis even before x rays have been examined An experienced internist will always suspect an osteo arthritis of the knees when an obese middle-aged woman limps into the consultation room[7]

Some confusion may arise in those cases which are often labeled mixed arthritis where osteo arthritis is superimposed on a preceding rheumatoid or infectious arthritis It is a fact that the two great types of chronic arthritis the rheumatoid and the degenerative can exist in the same joint one form being superimposed on the other It is also important to remember that a mild osteo arthritis can exist in a joint without causing symptoms and that in many cases of osteo arthritis of the lumbar spine the pain is due not so much to the osteo arthri tis as to bad posture developmental abnor malities spinal curvature and so on

Laboratory Findings—The sedimentation rate of the red blood cells is normal or only slightly accelerated The patient s serum re-veals no streptococcal agglutinins The blood

sugar may be elevated The basal metabolism is often below normal

X ray Examination—In hypertrophic arthritis characteristic findings can be made out in the radiographs fairly early in the disease In incipient cases these changes take the form of bony lipping and spur formation along the articular margins of the bone In the later stages the joint interval is narrowed and there is erosion of the articular bone and alteration in the shape of the articulating surfaces The surface itself however remains well defined and there is some condensation of bone immediately below the articular surface The periarticular lipping becomes more marked as the disease progresses

The *differential diagnosis* of osteo arthritis from rheumatoid arthritis has been discussed in the section on rheumatoid arthritis Osteo arthritis is occasionally confused with gout though such should rarely happen The clinical course of gout is very characteristic with its paroxysmal and intermittent attacks the presence of tophi and an elevated uric acid level in the blood should serve to identify it Secondary osteo arthritis is frequently seen in patients with chronic tophaceous gout Osteo arthritis should never be confused with a Charcot joint which develops suddenly with a large effusion and is free from pain tenderness and heat The x ray findings are quite different in the two conditions and positive Wassermann and spinal fluid reactions should identify the Charcot joint

Prognosis—There is no cure for an osteo arthritic joint that is to say the destruction of cartilage and the hypertrophic changes in the bone are permanent However the progress in osteo arthritis is usually very slow and the prognosis is much better than in rheumatoid arthritis In many cases the patient s discomfort can be completely relieved by proper treatment even though the pathologic changes in the joint persist This is particularly true in the case of the knees and back where weight reduction physiotherapy and orthopedic measures often give marked relief

Special Forms—Hypertrophic arthritis occurs in a number of well recognized clinical forms

Morbus Coxae Senilis—This form of osteo arthritis occurs in the hip It usually develops in middle age, in patients well past fifty, though occasionally it is encountered in the forties

Etiology—Osteo arthritis of the hip is nearly always referable to trauma in the form of either an actual injury or repeated small injuries such as might result from constant overuse of a joint The condition as the title indicates is usually monarticular though occasionally one sees both hips affected

Symptoms—The patient is middle-aged or elderly In the early stages the patient with osteo arthritis of the hip complains of pain in the distribution of the sciatic, obturator or anterior crural nerve At this stage it may be mistaken for neuritis In the later stages the pain is related more definitely to the hip joint and also to the knee joint indeed in some cases the symptoms in the knee joint are so pronounced that the physician is led to a mistaken diagnosis of disease in the knee joint, while the affected hip joint entirely escapes attention

The patient walks with a limp with his weight on the unaffected side On palpation of the joint in a well developed case crepitation is readily made out On passive movement of the hip joint rotation abduction and other movements may be much limited

Diagnosis—The diagnosis of degenerative monarticular arthritis usually can be made without much trouble from the symptoms and physical signs A middle aged or elderly man complains of increasing pain and stiffness in one hip He probably gives a history of a fall or some other trauma affecting the hip joint If on examination crepitation is made out the presumptive diagnosis is morbus coxae senilis As in other forms of degenerative arthritis the final diagnosis is made by x ray Radiographs disclose the characteristic lipping and spur formation with thinning of the joint space. Later on degenerative changes occur in the bone In long standing cases there may be some deformity resulting from absorption of the head and shortening of the neck of the femur

Heberden s Nodes—One of the mildest and commonest forms of osteo arthritis is the so-called Heberden s node These

nodes begin to make their appearance in middle life, particularly in the female sex and manifest themselves as bony outgrowths around the bases of the terminal phalanges They are more prone to develop in people who work hard with their hands

SYMPTOMS —The development of Heberden s nodes like that of other forms of osteo arthritis is slow and insidious and causes little inconvenience usually it does not even interfere with the normal movements of the joints Many times they are free from tenderness and pain Sometimes however particularly in the early stages they may occasion a good deal of pain and some limitation of movement At times the nodes undergo exacerbations and become a little more swollen and tender than usual The lesion may appear on only one finger but as a rule several or all of the distal phalangeal joints are involved

Menopausal Arthritis or Arthrosis —This type of arthritis occurs in two forms (1) in women who have been subject to artificial menopause by hysterectomy or deep x ray therapy In such patients the disease may appear even in the early thirties (2) cases developing during or immediately after normal menopause The age of onset in these cases is usually between forty five and fifty five

In most cases the symptoms of discomfort are most noticeable in the knees fingers and lumbar spine and x ray examination will show the usual hypertrophic changes in the bones Many students object to the term menopausal arthritis' and believe that all of these cases should be classified as degenerative arthritis However there are some cases particularly those seen in younger women in which careful examination reveals no signs of osteo arthritis For such cases the term menopausal arthrosis has been suggested

Symptoms develop insidiously the first signs of discomfort usually being in the knees A large percentage of these patients show Heberden s nodes on the distal phalangeal joints The progress of the disease is very slow and there is little tendency toward involvement of other joints

Hypertrophic Spondylitis —The vertebrae of most people past fifty years of age will show some evidence of this condition The bodies of the vertebrae undergo more or less hypertrophy and lipping at their bases and there may be some ossification of the ligaments The articular processes of the vertebrae may be enlarged eburnated and marked by bony outgrowths Actual ankylosis does not occur but there may be considerable limitation of movement due to the marked bony changes

This condition develops very slowly, usually without much pain The bony outgrowths may press on nerves however, and

Fig 182—Radiograph of the knee joint of an elderly woman showing degenerative arthritis Note thinning of the cartilage over the inner condyle and bony lipping around margins of joint (From Oxford Monograph Cecil s Diagnosis and Treatment of Arthritis courtesy of the Editor Dr Henry A Christian and Oxford University Press)

produce pain and paresthesias Other joints may show bony changes particularly the hips and knees

Treatment of Hypertrophic Arthritis —The successful treatment of osteo arthritis depends upon a correct evaluation of the etiologic factors Perhaps the most important feature of the treatment is rest for the affected joints In obese patients weight reduction is best accomplished by a low calory diet supplemented by thyroid extract for those patients whose basal metabolism is below normal Sodium iodide intravenously once or twice a week has been recommended

for this type of arthritis If oral treatment is desired, hydriodic acid, 1 drachm (4 cc) three times a day in a half glass of water can be employed Physiotherapy and other forms of heat give much relief, but care must be taken in massaging affected joints lest trauma be induced over the hypertrophied margins of bone Deep x ray therapy has been recommended by some writers but in the author's experience is rarely effective

Treatment of Special Forms—The treatment of osteo arthritis of the HIP is difficult and unsatisfactory As long as the pain is not too severe rest and other conservative measures are all that should be attempted When the pain and disability are severe surgery may become necessary In such cases, arthrodesis gives complete relief but leaves the patient with a stiff hip joint Plastic operations particularly the vitallium cup operation, are quite popular with some surgeons

Painful HEBERDEN'S NODES are often relieved by resting the hand as much as possible and by the local use of heat In this connection the paraffin bath is often helpful The method of applying paraffin is as follows

Equipment—A candy or fat thermometer
2–4 pounds parawax
1 piece of oil silk 12" x 14
1 square absorbent cotton and piece of wool

Melt parawax over slow fire then remove from stove and allow it to cool until the thermometer registers 110 to 120 F Having soaked the hand for about three minutes in hot water and while still wet dip in and out of the parawax twelve to fifteen times Quickly wrap oil silk about parawax which has accumulated on hand then around that the cotton and a piece of wool about the whole so that the heat may be retained Let hand rest quietly in the paraffin pack for about an hour Then remove the wax which may be used for the next application

MENOPAUSAL ARTHRALGIA when unaccompanied by osteo arthritic changes is often greatly relieved by estrogenic therapy, 2 000 to 10 000 rat units twice a week administered every three to five days As the patient improves oral treatment can be substituted for the parenteral injections Stilbestrol 0 5 to 1 0 mg in tablet form sometimes gives very good results It is much cheaper than the natural hormone but is more likely to cause gastro intestinal symptoms When menopausal arthralgia is accompanied by osteo arthritis, the therapeutic measures described above should be instituted in addition to the hormone therapy

The treatment of hypertrophic spondylitis should be that of osteo arthritis in general but if the discomfort persists in spite of physiotherapy and other symptomatic remedies orthopedic measures may be necessary Many of these patients become dependent on a strong back brace for the relief of pain

ARTHRITIS ASSOCIATED WITH DISTURBANCES OF METABOLISM

The arthritic manifestations associated with gout and other diseases of metabolism are discussed in the sections which deal with these diseases

ARTHRITIS OF NEUROPATHIC ORIGIN

The joint manifestations of tabes syringomyelia and peripheral nerve lesions are discussed in the sections which deal with these diseases

NEOPLASMS OF THE JOINTS

Benign or malignant new growths involving any of the structures of a joint produce symptoms which may simulate arthritis

Benign soft tissue tumors, such as lipoma hemangioma or cystic degeneration of the external semilunar cartilage of the knee excite mechanical disorders such as limitation of motion locking and synovial effusion Single or multiple xanthomata arising in the synovium (usually in the knee) produce symptoms similar to any low grade synovitis The synovial fluid which is often yellowish brown is sterile The blood cholesterol is usually elevated Synovioma is a similar but definitely malignant tumor

Bone tumors occurring near joints such as giant-cell tumors, multiple or single bone cysts osteogenetic sarcoma and metastatic carcinoma cause stiffness, swelling pain limitation of motion and even deformity if destruction of bone has been sufficient to produce a pathologic fracture

Although the disability may be great, there is usually very little local heat or redness With malignant tumors the general condition of the patient rapidly deteriorates

The treatment of joint neoplasms is surgical and orthopedic

RUSSELL L CECIL

MECHANICAL DERANGEMENTS OF JOINTS

Traumatic Arthritis —Any injury to the cartilage bone or ligaments of a joint is apt to produce persistent or transient pain swelling and limitation of motion When the joint is badly sprained temporary effusion of fluid may take place in the joint cavity Traumatic arthritis is often an important predisposing factor in the development of a localized osteo arthritis

The *treatment* of traumatic arthritis consists of rest physiotherapy and orthopedic measures if necessary

Joint Disturbances Secondary to Abnormal Postural Strain —Pronation of the feet poor posture and congenital or acquired deformities produce undue strain on the weight bearing joints and if not corrected may in the course of time lead to the development of secondary osteo arthritis Deformities such as congenitally flat feet knock knees and spinal scoliosis are particularly important predisposing factors Obesity is another common cause of joint disturbance secondary to postural strain

The *treatment* consists of correction of the postural strain

RUSSELL L CECIL

MISCELLANEOUS FORMS OF ARTHRITIS

Arthritis of Serum Sickness —This form of arthritis is described in detail in the section on serum sickness page 486

Arthritis of Hemophilia —The arthritis of hemophilia is discussed in the section on hemophilia page 984

Intermittent Hydrarthrosis —This is a rare and peculiar condition of the joints characterized by acute regularly recurring effusions of fluid into the joint cavity The etiology of this disease is still obscure There is some evidence to support the theory that it is of an infectious nature but from recent studies it appears more than likely that the disease is an allergic manifestation Schlesinger has pointed out the similarity between intermittent hydrarthrosis and angioneurotic edema Feré and Garrod have each reported a case of intermittent hydrarthrosis in which the disease was associated with generalized urticaria and Burchard refers to a case where hydrops occurred in an asthmatic

The striking features of intermittent hydrops are its periodic recurrence and its tendency to affect the knee joint The exact regularity of the recurrences is the most interesting feature the usual interval being ten or eleven days Sometimes the interval of exact periodicity changes as in one of the reported cases where the interval after having been twelve days changed to six When several joints are involved the swelling may appear in all simultaneously or in one earlier than in the others The average duration of each attack is from four to five days During the attack the joint is distended with fluid and the patient is rarely able to use the extremity because of the resulting pain In the interval between attacks the joint in most cases is practically normal although in some patients there may be a residual stiffness between the acute attacks A slight rise in temperature and a leukocytosis have been reported in some cases According to Miller and Lewin one or both knees have been involved in every case reported in the literature Occasionally additional joints are

implicated, such as the wrist or hip, and some cases progress into typical rheumatoid arthritis

The *diagnosis* is comparatively easy and is based on the following criteria

1 Acute attacks of effusion of fluid into the joint (usually a knee) occur at regular intervals of ten to eleven days

2 After a period of four to five days, fluid disappears from the joint almost as rapidly as it forms leaving the joint practically normal

3 Puncture of the joint reveals clear and practically normal joint fluid

The *treatment* of intermittent hydrops is rather unsatisfactory Fortunately a certain number of cases recover spontaneously During the acute attack the patient should rest in bed or in an easy chair Local discomfort may be relieved by hot applications and acetylsalicylic acid three times a day Miller and Lusk obtained excellent results by intravenous injections of typhoid vaccine but in the writer s experience the relief obtained has been only temporary Krida has reported complete and permanent cure by synovectomy, and favorable results have been obtained by others

Pulmonary Osteoarthropathy —The arthritic manifestations of pulmonary osteoarthropathy are discussed in the section on this disease p 1322

Hysterical Joints —Joint symptoms can occur without any organic basis Partial or complete fixation of a knee in full extension or a foot in equinus varus may be a purely hysterical phenomenon Other patients especially compensation cases may present many of the features of arthritis of the spine or those of an internal derangement of the knee Subjective complaints overshadow physical findings Swelling and local heat are absent Tenderness is often too acute to be genuine Typically hysterical conditions such as paralysis or paresthesias may occur in the same patient

The *treatment* is that for hysteria

Other Joint Disturbances —There are various other disturbances which are not classifiable as arthritis but which cause more or less pain in the affected joints Among such should be mentioned aseptic necrosis of the bone, loose bodies in the joint osteochondritis dissecans osteochondromatosis, and others For discussion of these topics the reader is referred to any standard textbook of orthopedics

DISEASES OF THE BONES

OSTEOMALACIA

Definition —Osteomalacia is a calcium phosphorus deficiency disease characterized by distinct metabolic and histologic changes which are readily restored to normal if adequate therapy is administered Histologists are agreed that in rickets and osteomalacia the essential abnormality is the same namely, a deficient calcification of all osteoid tissue The term, osteomalacia should never be employed to designate any of the other skeletal diseases characterized by generalized decalcification

Incidence.—Osteomalacia is endemic over wide areas in northern India, northern China and Japan and sporadically in certain parts of Europe. It is rare in the United States of America, most of the cases being associated with chronic steatorrhea It is primarily a disease of women and is apt to occur earlier and with greater severity in each succeeding pregnancy The *hunger osteopathy* observed in Germany and in Poland between 1917 and 1919 probably represented varying grades of osteomalacia The histologic findings and the response to vitamin D therapy support this interpretation

Etiology —Before it was known that osteomalacia was a deficiency disease various etiologic theories were proposed Hyperactivity of the ovaries, leading to hyperemia of the bones and a resulting decalcification was long accepted as a cause of osteomalacia. This theory was not based on accurate

experiment nor was there any evidence that the ovaries were abnormal Nevertheless oophorectomy was for a time the routine treatment for osteomalacia The treatment of osteomalacia with adrenalin likewise was based on fallacious reasoning Today it is agreed that osteomalacia and rickets are the same disease Osteomalacia is frequently referred to as *adult rickets* Resorption and formation of bone continue but calcification of the newly formed osteoid tissue fails to take place because of insufficient absorption of calcium and phosphorus from the gastro intestinal tract. The impaired absorption may be due to (1) privation (2) marked alterations of the calcium to phosphorus dietary ratio (3) increased intestinal rate, (4) decreased acidity of the gastro intestinal tract (5) steatorrhea and (6) vitamin D deficiency Rarely is the disease due to one cause Vitamin D deficiency is operative in all cases Privation alone does not cause the disease In this country most cases are associated with chronic steatorrhea As a result of the faulty digestion and absorption of fats insoluble calcium soaps are formed and the fat soluble vitamin D is excreted in the excess fat. That vitamin D lack is the chief cause of the calcium phosphorus deficiency is well demonstrated by the dramatic clinical and metabolic improvement which follows its administration in adequate amounts The osteomalacia of northern China and India is the result of a diet deficient in calcium phosphorus and vitamin D isolation from the sun because of environment and customs and the calcium drain of oft repeated pregnancies and long continued lactation That this type of osteomalacia is due chiefly to a lack of vitamin D was adequately demonstrated by Maxwell who noted both clinical and metabolic improvement when cod liver oil was given even though the dietary remained inadequate in respect to calcium and phosphorus

In normal individuals a minimal amount of calcium and phosphorus is excreted daily irrespective of the intake of such salts In the states of pregnancy and lactation the loss of calcium and phosphorus is further increased In osteomalacia because of deficient absorption the entrance of these salts into the body is less than the loss there from and in consequence a negative calcium and phosphorus balance results. Metabolic studies reveal an increased excretion of calcium and phosphorus in the feces and decreased urinary excretions This failure to absorb sufficient calcium and phosphorus results in a deficiency of these salts in the body fluids and an inadequate deposition of calcium and phosphorus in the newly formed osteoid tissue In severe osteomalacia a negative calcium and phosphorus balance may persist despite a high intake of calcium and phosphorus In such instances the serum calcium and phosphorus are decreased and the serum phosphatase elevated In the milder cases the serum calcium may be normal or only slightly reduced the serum phosphorus lowered and the serum phosphatase only slightly increased

Morbid Anatomy—The gross skeletal deformities encountered in osteomalacia vary with the severity of the disease and its duration and are not present in the milder cases. In the severe types the pelvis thorax spine and long bones may be deformed in a haphazard manner In such cases a severe kyphoscoliosis may reduce the height by several inches and cause the head and neck to sink downward and forward upon the chest The bones are soft and flexible rather than fragile so that bending is more common than spontaneous fractures although both may occur The bony cortex is thin and often shell like the trabeculae are greatly reduced in number or absent and the marrow spaces are enlarged

Microscopically the striking feature is the deficient calcification as shown by the wide osteoid seams Normal physiologic resorption continues Osteoclasts are normal in number but osteoblasts are very abundant The wide osteoid seams the numerous osteoblasts the absence of considerable fibrous tissue and the infrequency of osteoclasts should serve to distinguish osteomalacia from hyperparathyroidism or osteitis deformans

Symptoms—The symptoms of osteomalacia are directly proportional to the severity of the disease In the mild form the patients may complain only of weakness pains in the bones of the legs or the lower part of the back on standing and walking A patient with severe osteomalacia may seek medical

and because of the distressing *symptoms* of severe tetany (see p 1247) Another patient may suffer from a crushed vertebra *from* moderate *lifting* or a minor fall In the advanced *cases* severe backache is a common symptom The bone pain is aching in character oftentimes generalized and worse in the winter when lack of vitamin D is greatest Muscular weakness is often marked, a waddling gait is not uncommon and the bones are often sensitive to light pressure The skeletal deformities previously mentioned may be present

Roentgenologically one finds generalized decalcification thinning of the cortices bowing, fractures and deformities of the type mentioned

Diagnosis—Tetany occurring in association with chronic diarrhea should always suggest osteomalacia Any skeletal disease characterized by generalized decalcification may be mistaken for osteomalacia the osteoporotic form of hyperparathyroidism senile, idiopathic or postmenopausal osteoporosis the osteoporosis of hyperthyroidism, Cushing's disease, occasionally multiple myeloma metastatic malignant lesions rheumatoid arthritis of the spine and the osteoporosis of disuse

Osteoporotic Form of Hyperparathyroidism—This form of hyperparathyroidism may be indistinguishable from osteomalacia except by means of chemical or pathologic examination. A high serum calcium a low serum phosphorus and an elevated serum phosphatase are diagnostic of hyperparathyroidism If the disease is complicated by the presence of one of the other forms of osteoporosis the osseous changes will be out of proportion to the degree and the duration of the hyperparathyroidism and the phosphatase level will be unexpectedly low for the degree of decalcification In the occasional case of this latter type metabolic studies and histologic examination of a bone biopsy specimen may be indicated

Senile Idiopathic and Postmenopausal Osteoporosis—The diagnosis of this type of osteoporosis is discussed under the section entitled Senile Osteoporosis

Osteoporosis of Hyperthyroidism—An increased excretion of calcium and phosphorus far in excess of that resulting from acidosis or hyperparathyroidism has been observed in severe hyperthyroidism These increased excretions are via the gastro intestinal tract as well as the kidneys If the thyrotoxicosis persists for a period of years the continued loss of calcium and phosphorus will result in generalized osteoporosis Such bone resorption is generalized and homogeneous and results from widespread lacunar resorption The serum calcium, phosphorus and phosphatase are usually normal although the latter may occasionally be slightly elevated There is no relationship between the duration of the disease, the degree of osteoporosis and the slight elevation of the serum phosphatase.

Cushing's Disease (Basophilic Adenoma of the Pituitary and Adrenocortical Syndromes)—This affliction is characterized by osteoporosis most marked in the spine It has many of the clinical characteristics of postmenopausal osteoporosis In Cushing's disease, however, there is a decrease or an absence of the formation of estrogen and in addition an increase in urinary androgens The serum calcium, phosphorus and phosphatase values are normal The associated obesity hirsutism atrophy of the skin and hair purplish atrophic striae amenorrhea and hypertension should serve to differentiate it from osteomalacia

Multiple Myeloma—Rarely is the decalcification of multiple myeloma generalized or homogeneous Decalcification of the spine when present may give rise to ballooned intervertebral disks and collapsed vertebrae Usually, however localized evidence of destruction of bone is seen in the ribs the pelvis and most clearly of all in the skull The pain is more severe than that observed in osteomalacia and persists when the patient is in the recumbent position Hypercalcemia and hyperphosphatemia are often present The serum phosphatase is usually normal These features of the disease the hyperproteinemia and Bence Jones proteinuria should serve to avoid confusion with osteomalacia

Metastatic Malignant Lesions—An osteoclastic type of metastatic malignant lesion may give rise to an extensive osteoporosis of the spine The diagnosis is readily made roentgenologically by the presence of localized areas of destruction invasion of the

pedicles of the vertebrae or regions of destruction in the flat bones

Rheumatoid Arthritis of the Spine—Extensive spinal osteoporosis is frequently seen in individuals suffering from rheumatoid arthritis of the spine In addition to the osteoporosis there is evidence of destructive changes in the sacro iliac joints and the intervertebral facets Calcification of the spinal ligaments may or may not be present These roentgenologic lesions plus the characteristic history and physical findings should serve to differentiate this disease from osteomalacia

Osteoporosis of Disuse—Generalized osteoporosis may be encountered in bed ridden patients whose activities have been markedly restricted by ankylosing arthritis infantile paralysis or prolonged immobilization from other causes. In such cases the stresses and strains of normal activity responsible for normal osteoblastic activity are greatly reduced The ensuing decreased osteoblastic activity results in a decreased formation of osseous matrix and in consequence failure of calcium deposition and osteoporosis Associated with this form of osteoporosis one finds, except in very exceptional instances a normal serum calcium phosphorus and phosphatase However hypercalcinuria may occur in the early stages of immobilization and may lead to renal complications and the formation of urinary calculi In these cases the cause of the decalcification should be obvious

Prognosis.—Osteomalacia responds to adequate therapy The time required for correcting the existing abnormalities depends upon the duration of the disease and its severity

Treatment—The clinical and metabolic response to treatment is usually very prompt and often dramatic This is accomplished by administering a high calcium high phosphorus diet and adequate amounts of vitamin D Such a diet should contain liberal amounts of milk cheese nuts and eggs If the patient s dietary whims prevent such a diet the administration of 3 to 6 drachms (11 6–23.2 Gm) of calcium glycerophosphate will provide a sufficiently high calcium and phosphorus intake The daily administration of 10 000 to 50 000 units of vitamin D in the form of cod liver oil or one of the potent vitamin D preparations will usually suffice Occasionally, the administration of large amounts of cod liver oil has been ineffectual In such instances excellent results are obtained when large amounts of a potent vitamin D concentrate are administered.

HEREDITARY DEFORMING CHONDRODYSPLASIA

(Multiple Cartilaginous Exostoses Dyschondroplasia Diaphyseal Aclasis)

Definition.—Hereditary deforming chondrodysplasia is a developmental disorder of growth the chief features of which are multiple exostoses and irregularities in growth of the epiphyses The arrested development in the affected bone leads to secondary deformity

Incidence—The disease is frequently encountered Ehrenfried having collected 600 published cases by 1916 Males are more frequently affected than females The disease is often hereditary transmission taking place through the male

Etiology—The exostoses are thought to be due to a proliferation of cartilage cells arising from the epiphyseal plate This proliferation is unchecked by the periosteal sleeve and consequently the calcifying cartilage at the tip of the disk projects outward from the shaft The disease affects only those bones arising from cartilage the membranous bones being exempt

Morbid Anatomy—The exostoses usually appear on the diaphyses of long bones near the epiphyseal lines at the site of muscle insertions The outgrowth of compact bone is continuous with that of the diaphysis This merges into a mass of compact bone the surface of which is covered by cartilage which in turn is enveloped by a connective tissue membrane The exostoses are extremely irregular in shape vary greatly in size, and may be exceedingly numerous

Microscopic examination of an exostosis reveals normal hyaline cartilage the deeper layers of which are undergoing ossification The adjoining cancellous bone usually contains fatty bone marrow The base of the exostosis consists of compact bone similar to that of the cortical bone from which it arises True enchondromata are sometimes seen In addition to the exostoses changes in the shafts of the long bones or in their epiphyses may or may not be present Such deformities occur more commonly in the femur, tibia fibula ulna, and radius The ends of the bones may be wider than normal the cancellous bone rarefied and the interstices filled with myxomatous tissue The retarded and irregular growth of the epiphyses may be the cause of mild to moderate dwarfism and deformities, especially of the genu valgum and genu varum types

Symptoms—While the objective signs are striking primary symptoms are lacking because the exostoses are painless unless they are in an area where they are apt to be injured either by normal use or accident Joint symptoms may arise in consequence of articular distortions and mechanical limitations The development of malignant osteochondromata fracture erosion of a blood vessel with resulting aneurysm pressure on nerve trunks with resulting neuralgia neuritis and paralysis and signs of cord compression have been reported The exostoses appear in childhood but grow most rapidly during the adolescent period when new exostoses may appear

The roentgenographic appearance is quite characteristic Bone deformities such as described above are seen Their density and structure are extremely varied The shaft of the affected bone more often shows decreased density with a longitudinal pencilling of areas of increased rarefaction

Prognosis—The general health is unimpaired and the rare complications seldom affect the length of life Growth of the exostoses eventually ceases and the deformities become fixed at the time of skeletal maturity

Diagnosis—Apart from the superficial resemblance to mild cases of achondroplasia a typical case can hardly be confused with any other disease

Treatment—When the tumors cause unsightly deformities pressure symptoms, or suggest malignancy, they should be removed Excision of the tumor with complete removal of the base will prevent its recurrence

HYPERTROPHIC PULMONARY OSTEO ARTHROPATHY

(*Secondary Hypertrophic Osteo Arthropathy Bamberger Marie's Disease Hippocratic or Clubbed Fingers Osteo Arthropathie Hypertrophiante Pneumique Acropachy*)

Definition—In the disease hypertrophic pulmonary osteo arthropathy there occurs general and symmetric clubbing of the fingers and toes often associated with hyper

trophy of the long bones of the hands and feet and less frequently with painful en largement of the long bones of the forearms and legs These changes are associated with a variety of diseases especially chronic af fections of the lungs and heart Because of this association with diseases of the lungs and mediastinum, it seems appropriate to retain the term hypertrophic pulmonary osteo arthropathy

Incidence —The disease is probably al ways *secondary, although a few cases have* been reported without evidence of ante cedent or associated disease. Of the one hun dred and forty four cases reported by Locke one hundred and twelve were associated with pulmonary disease six disease of the circu latory system thirteen disease of the gas tro intestinal tract and thirteen unknown or miscellaneous diseases The majority oc curred with *bronchiectasis pulmonary tu* berculosis empyema lung abscess malig nant disease of the lung and mediastinum emphysema valvular and congenital heart diseases subacute bacterial endocarditis biliary cirrhosis congenital syphilis and chronic enteritis No age group is exempt Males are affected more frequently than females

Etiology.—*The exact cause of such bony* changes is unknown Many theories have been proposed. Both Bamberger and Marie believe the bone changes were caused by a bacterial toxin Such an explanation would not account for the occurrence of this type of osteo arthropathy in congenital heart dis ease Others have suggested that the disease was due to prolonged venous congestion They reasoned that compression of the lung capillaries occurs in various pulmonary dis eases and that the resulting peripheral hyperemia was responsible for the bony changes This theory likewise fails to ex plain many cases Campbell believes that edema is the primary factor in every case of clubbing and postulates that such edema is the result of a chronic low grade anoxemia in tissues (fingers and toes) where the cir culation is slower This theory may well ex plain all cases of hypertrophic pulmonary osteo arthropathy and is worthy of further consideration

Morbid Anatomy —The most striking feature of the disease is the bulbous enlarge ment of the terminal phalanges of the fingers and toes, due largely to proliferation of the soft tissues The nail first becomes curved in both directions, the watch-crystal type of nail Its color and texture may be altered The parrot beak nail results because of in creased thickening and curving downward over the tip of the finger The tissues about the nail bed are puffed, smooth, reddened and the nail is felt to float The end of the finger, especially the nail bed is apt to be *cyanotic Rarely, the entire hand is enlarged* and pawlike Enlargement of the ungual phalanx is often seen in the roentgenograms

The process may become generalized, in volving the long bones of both extremities and occasionally the flat bones. Proliferation of the inner layer of the periosteum occurs early The proliferating tissue is readily cal cified and appears as an irregular layer of *new bone underneath the periosteum Most* commonly it affects the distal third of the diaphysis, although the entire shaft may be involved Roentgenologically, the bone appears to be surrounded by a shell Early in the disease it is readily differentiated from the original bone because of its poor lime content. Later it becomes so dense and so closely united that no line of de *marcation is demonstrable Occasionally* the entire bone may undergo a rarefying in flammation very similar to that of osteitis deformans although bowing never occurs and bone lengthening is rare Late in the disease the epiphyses may be similarly af fected Suppuration never occurs

The wrists knees ankles elbows and small joints of the hands and feet may be involved in the severe cases A low grade synovitis with an associated effusion can occur Actual ankylosis is rare

Symptoms —The *onset* is insidious In its simplest form clubbed fingers there are no symptoms Pain is invariably present when involvement of the long bones occurs It varies from a mild discomfort to a most distressing deep seated ache over the fore arms and legs It is often intermittent and may occur only at night or after long stand ing In most instances the bones are sen sitive to pressure Thickening of the soft tissues may ensue giving the distal half of the *forearm and leg a clumsy cylindric* appearance In well advanced cases the

joints are stiff and painful and at times swollen Enlargement of regional lymph nodes may be seen Kyphosis and rigidity have been observed The other associated symptoms and findings are usually manifestations of the primary disease

The *clinical course* is extremely variable but usually follows that of the primary disease. It has been known to appear and disappear rapidly (weeks) Exacerbations and remissions have been reported Repeated roentgenologic examinations show that absorption of the newly formed bone does take place The clinical course may be protracted lasting several years

Diagnosis —The clinical features of the disease are so distinctive that its recognition is rarely difficult.

Treatment—The therapy of hypertrophic pulmonary osteo arthropathy is essentially the treatment of the primary disease Symptomatic treatment of the skeletal and joint pains is often indicated and necessary

ACHONDROPLASIA

(*Chondrodystrophia Foetalis*)

Definition—Achondroplasia a disease of the skeleton which begins in fetal life has the following characteristics a normal trunk a disproportionately large head pug nose dwarfed and curved extremities with trident shaped hands It is usually confined to bones which develop from cartilage although membranous bones may be affected directly or indirectly The various types described by Kaufman are probably variations of the same disease process

Incidence—The disease may or may not be hereditary Several achondroplastic dwarfs have been observed in one generation and the disease has been known to appear in successive generations In the case of *twins one may* be achondroplastic and the other normal It may be transmitted by either parent Males and females are affected with equal regularity

Etiology—Achondroplasia is the result of faulty development of the anlage for bone producing intermediary cartilage Ancon sheep Talemark and Dexter Kerry cows and the creeper fowl are excellent examples of achondroplasia, fixed by inheritance although *the mode* of transmission is *different* in each case Authorities are agreed that achondroplasia results because of anomalies in the germ plasm These anomalies are described as 'mutations by some and as chromosomal deficiencies or abnormalities by others

Morbid Anatomy—The general deformities are unique The fetus is a dwarf with *an average length of 30 to 40 cm* as contrasted with the normal 50 cm The head is relatively large (brachycephalic type), with pug nose appearance, prominent lower jaw thick lips and thick protruding tongue The circumference of *the head may* equal or exceed the body length The trunk is well developed but the extremities are short, although usually well formed (micromelia) In consequence the central point of the body is at the xiphoid instead *of the* symphysis pubis as normally The hands are small and pudgy All of the fingers are tapering of nearly equal length and spread like the spokes of a wheel (main en trident) A striking peculiarity is the general thickening of the skin over the whole body and a folding especially over the joints

Of the individual bones those usually affected in order of frequency are the femur humerus tibia fibula radius ulna *pelvis* base of the skull bones of the hands and feet vertebrae and ribs The long bones appear short thick and hard The natural curves are exaggerated The cortex is often thick because of excessive periosteal proliferation The epiphyses may be of normal size or enormously hypertrophied giving the ends of the bones a mushroom like appearance In achondroplasia periosteal ossification may

be normal or increased whereas endochondral ossification is defective The most characteristic microscopic finding is aplasia or dysplasia of the proliferative zone of cartilage As a result of the absent or defective endochondral ossification and the normal or increased periosteal ossification bone growth and bone structures are grossly altered Synostoses in the skull pelvis and other bones are common

Symptoms.—The symptoms are largely objective and have already been described A vast majority of the infants with this disease are stillborn death occurring from the seventh to the ninth month of uterine life. The few who survive are subjects of this peculiar and characteristic type of micromelic dwarfism which does not interfere with either mental or sexual activity or longevity The fetal abnormalities of the skeleton are never altered A peculiar feature of the disease is the abnormal development of the skeletal muscles which gives the subject a strength relatively much greater than that of a normal individual Mentally the achondroplastic dwarf is rarely subnormal The sexual organs in both sexes show a normal or exaggerated growth. Sexual precocity is not uncommon, and sexual desire is said to be excessive

The roentgenologic findings are very striking The long bones are short, stubby wide at their ends and much more dense than normal The excessive periosteal ossification may encroach upon the medullary space The ridges where muscles attach are considerably increased. A peculiarly characteristic deformity of the affected bones is the abrupt expansion of the epiphyseal end where ossification is irregular and defective Localized bowing especially in the tibia and femur is usual The ribs may show various thickenings deformities and at times enlargement of the costochondral junctions The vertebrae may be wedge-shaped or irregularly developed The time of appearance of the ossification centers varies greatly as does the time of union of the epiphysis and diaphysis.

Diagnosis—The unique features of achondroplasia mentioned above should serve to differentiate it from other types of skeletal disease

Prognosis—The majority of achondroplastics die in utero Those who survive the first year may reach extreme old age They rarely exceed 140 cm in height.

Treatment—No known treatment affects the disease Deformities when present can be corrected by surgical procedures

OXYCEPHALY

(Acrocephaly Tower Skull Steeple Head Scaphocephaly Keel- or Boat-Shaped Head)

Definition—Oxycephaly is a constitutional anomaly associated with premature closure of the cranial sutures and resulting deformity of the head The tower shaped head with associated exophthalmos adenoid facies partial or complete blindness represents one of the results of such premature synostosis. The scaphocephalic head with bulging frontal and occipital regions is however the most frequent expression of this constitutional anomaly

Incidence.—The exact incidence of premature synostoses has never been established The disease begins in fetal life more commonly affects males and rarely occurs in more than one member of a family The hereditary nature of the disease has been clearly demonstrated in rabbit breeding experiments In such animals the synostoses appear in the third week of uterine life

Etiology—Most workers agree that the interstitial mesenchymal tissues are primarily at fault in producing premature synostosis The misplaced centers of ossification and hypoplasia of the base of the skull are considered secondary changes

Morbid Anatomy—The pathologic changes are limited to the skull except in the occasional case with associated congenital defects The most striking features are the absence of the frontal and occipital bossae with displacement of their centers of ossification into the synostosed sutures The coronal suture may be completely synostosed or only the lateral thirds may be involved The sphenoid bones are broader than normal The orbital openings are enlarged but the orbital cavities are reduced in size Occasionally the optic foramina are narrowed The maxillae are hypoplastic The sinuses are small, rudimentary or absent. The base of the skull is hypoplastic, the fossae being shorter and deeper than normal The sella turcica is usually unchanged The bones are thin, the diploe small and the inner table may be absent Hyperostosis is seen occasionally The brain is of normal volume but tower shaped The convolutions are usually flattened Although optic neuritis and atrophy are invariably present the other cranial nerves are normal Bilateral and symmetric syndactylism usually of the upper extremities may be present Polydactylism anomalies of the elbow and malformation of the ears are seen In scaphocephaly synostosis of the sagittal suture occurs The head although less deformed is keel or boat shaped

Symptoms—The oxycephalic head is most unique in appearance The high flat forehead slopes gradually upward to the vertex with ill defined superciliary ridges and glabella The shortness of the head is as characteristic as its height being due chiefly to the reduction of the occiput which may be even with the neck The hairy scalp may be raised above the normal level appearing as though it were perched on top and as a result the ears appear lower The characteristic mouth breathing gives the patient a weird vacant stupid expression The exophthalmos is a constant feature The degree of protrusion varies greatly actual dislocation having been noted Lacrimation conjunctivitis and divergent squint are common Nystagmus is seen occasionally Marked visual defects, increasing with age are frequent A postneuritic type of optic atrophy is seen in one third of the cases and is almost always present in the adult It may occasionally be unilateral Blindness occurs in 10 per cent of these patients Malocclusion of the teeth with a high, narrow hard palate is seen frequently Partial cleft palates are encountered occasionally The senses of smell and taste are preserved A mild to moderate degree of increased intracranial pressure is often present Headaches are common, often severe in nature Convulsions may occur Mental retardation is noted in about 20 per cent of these patients Some retardation of growth and development may or may not be present The disease has no effect on the duration of life

Treatment.—Little can be done for this disease Cranial decompression may aid in arresting the visual defects and in combating the symptoms of increased intracranial pressure The associated malformations may require surgical treatment for functional or cosmetic reasons

LEONTIASIS OSSEA

(Hyperostosis of the Skull Megalocephaly Fibromatosis Osteoplastica Ossium Hyperostose des Os de la Tete)

Leontiasis ossea is a rare disease first described by Malpighi in 1697 It was not called *leontiasis ossea* until 1864 when Virchow published a more complete description of the disease This name was chosen because the bony overgrowth corresponded with the overgrowth of connective tissue seen in molluscum fibrosum with leonine *facies* The chief feature of the disease is hyperostosis of the bones of the skull The process *may* be limited to one bone or involve all of them In advanced cases marked *facial deformities*

may result but not of the type suggested by the name. Skulls weighing more than 4000 Gm with the thickness of the calvarium measuring 2 inches or more have been reported A few cases have been reported with involvement of some of the long bones

Etiology—The cause of the disease is unknown The data presented in favor of the various infectious, traumatic metabolic and endocrine theories are wholly inadequate Because the pathologic process may resemble that of Paget's disease, some have considered it to be a localized form of osteitis deformans The occasional case of leontiasis ossea with long bone involvement would favor such a view The disease begins in childhood or early adolescence Females are more commonly afflicted

Morbid Anatomy—The process may involve one or all of the bones of the skull Knaggs describes both the creeping periostitis and the diffuse osteitis type The histologic changes are the same in both except for the large deposits of subperiosteal bone in the periosteal type Early in the disease one notes disappearance of the usual bony structures The outer layers are less compact and areas of bone dissolution appear filled with vascular and fibrous connective tissue which may subsequently become fibrosed New bone may be laid down in irregular fashion in such fibrous areas although neither the laminations nor the haversian systems of normal bone are formed Small cysts may remain In the later stages the bone loses its normal contour and is greatly thickened and porous When suppuration is present it is the result of secondary infection Isolated bone sections may resemble either Paget's disease or osteitis fibrosa cystica except that the fibrosis is more marked in leontiasis ossea

Symptoms.—The symptoms are dependent on the size and shape of the bones involved If limited to one bone the facial appearance may be grotesque The symptoms are subjective and the direct result of pressure Headache may be an early and at times a severe symptom Exophthalmos is nearly always present Visual and hearing defects neuralgia paralysis and dilatation of veins are frequent. Obstruction of the nares and lacrimal duct may be observed Insomnia, mental dulness and convulsions may appear The course of leontiasis ossea is usually from twenty to forty years Death may occur suddenly with a convulsion More commonly it is due to cachexia.

Roentgenologically one observes a marked increase in the bone density Later the process may appear more translucent or fluffy The long bones should always be x rayed in order to be certain that Paget's disease has been ruled out

Diagnosis—Except in the early cases diagnosis is rarely difficult The facial deformity is more like that encountered in Paget's disease involving the facial bones however the patient is usually a child or adolescent.

Treatment—This is restricted to surgical procedures to relieve pressure

FRAGILITAS OSSIUM

(Osteogenesis Imperfecta Osteopsathyrosis Brittle Bones and Blue Sclerae Lobstein's Disease Hereditary Hypoplasia of the Mesenchyme)

Definition—Fragilitas ossium is a rare congenital disease of the skeleton characterized by frequent fractures of bones dwarfism deformities of the head chest and extremities The disease begins in fetal life but rarely manifests itself before infancy childhood or early adolescence Blue sclerae relaxation of ligaments dislocation of joints and otosclerosis (after the age of twenty) are commonly encountered in the hereditary type The nonhereditary type may or may not have associated blue sclerae

Etiology.—Most workers are agreed that the disease is the result of a hereditary hypoplasia of the mesenchyme the exact cause of which is unknown The disease more commonly affects females and the female is the more potent transmitter The inheri

tance factor follows the mendelian law and appears as a dominant characteristic De spite the renewed interest in the thymus, no one has demonstrated that dysfunction of this gland occurs in fragilitas ossium Failure to demonstrate any abnormality of the serum calcium and phosphorus and of the calcium excretion excludes the parathyroid gland from playing an etiologic role in this disease Slight inconstant unexplained elevations of the serum phosphatase have been observed

Morbid Anatomy—The bone deformities are directly proportional to the severity of the disease and to the frequency of fractures In extreme cases the calvarium is soft, with only islets of calcified tissue, and the long bones are grossly deformed in consequence of numerous fractures In the milder cases without fractures, the long bones are unusu ally slender but approximately normal in contour The fractures heal readily and may be found in all stages of repair The cortices are thin and usually, only a few fragmentary trabeculae are seen Osteoclasts appear nor mal in number but osteoblasts are greatly reduced The haversian canals are unusually wide The epiphyseal cartilage is usually nor mal Rarely the zone of provisional calci fication shows retarded activity The connec tive tissues throughout the body may be more delicate and friable the tendons being small the blood vessels and periosteum quite friable and the sclerae thin and translucent The thin, translucent sclerae allow the un derlying choroid vessels to shine through im parting the characteristic blue appearance

Symptoms—Individuals affected with fragilitas ossium tend to be shorter than normal Constitutional symptoms are absent The shape of the head is often a striking feature Protuberances of the occipital and frontal regions are common features A bitemporal protuberance so marked as to turn the ears outward has frequently been described The sclerae tend to have an ab normally blue color varying from a robin s egg to a deep slaty blue The disease is usually not suspected until fractures have occurred Marked fragility of the bones and the deformities caused by numerous frac tures constitute the chief features of the disease They usually appear in early child hood following slight violence Their fre quency is directly related to the severity of the disease and the activity of the patient

The congenital type is the most commonly encountered and severest type Such cases develop fractures and deformities in utero They are usually stillborn or die soon after birth If they survive they are helpless crippled dwarfs The patients affected with the infantile type appear normal at birth and experience their first fracture when they begin to stand and walk Greenstick frac tures without pain are common The degree of deformity present depends on the num ber of fractures their appropriate treatment and prevention The tarda type manifests itself in childhood or early adolescence frac tures occurring at the slightest provocation Otosclerosis never appears before the third decade

The roentgenographic features are marked generalized osteoporosis and slender, long bones of reduced diameter with thin cortices The bony structure may be unusually prom inent with trabeculae readily seen The epiphyses although smaller than normal appear expanded because of the narrow diaphyses The calvarium is unusually thin Islets of calcification may be demonstrable

Prognosis—The congenital type is born dead or dies shortly thereafter Those who survive are handicapped all their lives In the infantile and tarda types fractures be come less frequent with increasing age. Those patients who are carried through adolescence with little or no deformity can be expected to lead a fairly active life They should be told that the disease is transmitted as a dominant characteristic, and that if they have children approximately one half of them may be expected to develop the dis ease

Diagnosis—A typical case of fragilitas ossium rarely presents any serious diagnostic problems Because of short extremities an occasional case may be momentarily con fused with achondroplasia The large head pug nose short extremities and trident hands of the achondroplastic are of them selves diagnostic The roentgenologic dif ferences are striking Rarely a case of rickets occurring at one year of age with curvatures and fractures might be confused with frag ilitas ossium The absence of other signs and the dietary history should serve to dif

ferentiate the two Rarely should it be necessary to resort to chemical and x ray studies

Treatment —There is no known specific therapy Vitamins lime salts and various endocrine preparations have been administered without effect Elementary phosphorus has been employed with resulting sclerosis of the growing ends but without effect on the cortices where calcification is most needed Stramonium lactate followed by tricalcium phosphate and vitamin D has been employed without benefit Estrogenic therapy has caused an increased retention of calcium and phosphorus in several carefully studied cases Whether the effect of such therapy is sufficient to make its administration of practical clinical value it is as yet too soon to say It is obvious that every precaution should be taken to avoid fractures and that when they do occur they should be treated promptly if deformities are to be prevented The eyes never require treatment There is no treatment for otosclerosis.

OSTEITIS DEFORMANS

(Paget s Disease)

Definition.—Osteitis deformans is a chronic disease of the adult skeleton characterized by hypertrophy and bowing of the long bones and irregular deformation of the flat bones Our knowledge of the clinical aspects of the well advanced classic form of osteitis deformans has not increased greatly since the masterly description written by Sir James Paget in 1876 The introduction of roentgenologic and biochemical examinations into clinical medicine has contributed to our understanding of the disease in its early stages particularly the monostotic and localized forms

Incidence —Osteitis deformans is one of the more common affections of bones in adult life, occurring most frequently in the fourth fifth and sixth decades of life Schmorl reported a postmortem incidence of approximately 3 per cent in persons more than forty years of age It is rarely seen under thirty years of age In fact no authentic case under twenty five years of age has been recognized Males and females are about equally affected In Gutman's series of one hundred sixteen cases the sex incidence was the same Occasionally Paget s disease occurs in more than one member of a family A family in which three siblings and their mother were so afflicted has been reported

Etiology —The disease has been considered a clinical entity since Paget s classic description appeared and in consequence the disease bears his name He concluded that it was 'a form of chronic inflammation of the bones" The preponderance of clinical biologic and pathologic data does not favor its being a generalized systemic disease of either infectious or endocrine origin The prevailing opinion appears to be that Paget s disease is the result of some local disturbance in bone metabolism the exact nature of which is unknown

Morbid Anatomy —In osteitis deformans the changes may be confined to a portion of one bone and as Schmorl pointed out though often polyostotic it is rarely generalized The pelvis skull femur humerus lumbosacral spine tibia and dorsal spine are most commonly involved No bone is exempt The characteristic changes of the long bones are increased thickness sometimes of considerable degree varying grades of bowing and lengthening Their general contour may be irregular and their surfaces uneven Similar changes are seen more frequently in the skull than in the other flat bones The bones may be sufficiently soft to be cut with a knife On section they vary greatly in appearance As a result of new bone formation internally and on the surface the cortex increases in diameter while

the marrow cavity becomes narrowed or obliterated In some regions the bone may appear coarsely trabeculated and spongy, with evidence of an increased blood supply In other regions the bone is dense and ivory like Small bone cysts may be seen The extent and severity of the disease are not necessarily related to its duration Extensive arteriosclerosis is almost always present but is not the cause of the bone changes

Microscopically one sees an obviously disordered bone architecture There seemingly exists an imbalance between the factors which normally control bone formation and bone resorption both of which are accelerated In most instances bone formation is in excess of bone resorption although occasionally one finds regions where the first manifestation is an increased osteoclastic activity Hyperplastic vascular connective tissue may completely fill such areas Subsequently new bone is formed in an abnormal pattern The new bone may be laid down on old, partly eroded trabeculae or may enter into the formation of new ones which run in all directions The altered bone of Paget s disease takes on a distinguishing mosaic appearance because of the irregular configuration of the trabeculae and the numerous, thick uneven dark staining cement lines

Symptoms—The symptoms of osteitis deformans vary greatly In approximately 25 per cent of the cases no symptoms or signs are complained of at the time the diagnosis is made In such instances the disease is usually discovered accidentally during the course of a roentgenologic examination A large proportion of such patients have fairly extensive Paget s disease even though the disease was not suspected by the patient or the examining physician The localized and the monostotic forms are often discovered accidentally The sites most commonly affected by this form are the end of one shaft (the remainder being normal) the ischium, pubis ilium sacrum or a vertebra

In those patients complaining of symptoms, the onset is usually so insidious that it is impossible to determine when the disease began Many such patients do not seek medical aid until years later General and constitutional symptoms are rarely encountered Weakness and fatigability may be complained of by patients with deformities of the lower extremities Pain is the most common and usually the first subjective symptom varying in character from a dull soreness to the most intense paroxysmal type It may be worse after walking or standing and is relieved by rest It may occur at night It is usually in the region of the bone involvement but may be generalized The pain may disappear spontaneously The tissues overlying some of the involved bones may exhibit redness and increased temperature on palpation Pressure over such areas may result in exquisite pain Joint pain and stiffness are sometimes present Intense muscle pain and spasm are common accompaniments of the deformities Muscle atrophy ultimately develops Spontaneous fractures occur and may be the first cause for complaint. Pain in the head varying from a dull ache to severe neuralgia is complained of by some, yet others with obvious involvement of the skull have no such complaints Impairment of hearing is a common complication, impaired vision is much less frequent Sarcomatous degeneration has been reported to occur in as high as 10 to 15 per cent of the cases in one large series (one hundred sixteen cases) none was seen Renal calculi are occasionally encountered

The disease may begin in any bone The skull and the tibiae are frequently the site of onset However bowing of the tibiae as the first sign of Paget's disease has been greatly overemphasized In well developed cases the picture is a very striking one The whole calvarium is much enlarged the head is carried forward with the chin almost resting on the chest and the movements of the head are greatly restricted The spine is bent markedly forward and is rigid the bones of the shoulder girdle are massive the thorax is compressed laterally, the pelvis is very broad and massive, the legs are bowed forward and outward The arms may likewise be bowed the upper arm forward and the forearm outward and forward A marked flexion of the trunk on the legs compensates for their bowing and permits maintenance of equilibrium As a result of the deformities there is a considerable reduction in stature often as much as 6 inches On stand

ing, the feet are markedly everted one being a considerable distance in front of the other The gait is labored and waddling

The most characteristic roentgenographic features of osteitis deformans are increased bone density and loss of normal architecture The roentgenologic appearance varies with the stage of the disease Early the bone may be much less dense than normal Some of these areas of decreased density appear spotty or cystic in character and the neighboring bone is of increased density Such areas, which may involve only a portion of a shaft or the skull subsequently take on the characteristic of well advanced Paget s disease. In this stage of the disease the cortices are greatly thickened and the marrow cavity is narrowed or obliterated The bone, although dense tends to appear mottled or shows the characteristic coarse trabeculations The margins of the bones particularly those of the skull, appear fuzzy and indistinct. In consequence of the marked bowing numerous incomplete fractures of the convex aspect are often present The uninvolved bones are *normal.*

The course of Paget's disease is most variable The more severe and extensive cases may result in complete crippling in twenty to thirty years The disease may become arrested or quiescent This is true of all types but more so of the localized and monostotic forms

The changes in the calcium and phosphorus metabolism observed in osteitis deformans are not of the type observed in hyperparathyroidism. The serum calcium is normal and the serum phosphorus only slightly increased or normal The serum phosphatase is always increased being much higher in osteitis deformans than in hyperparathyroidism with a comparable degree of bone involvement The phosphatase values vary with the activity and severity of the disease the slightest elevations being associated with the localized forms In some cases the excretion of calcium and phosphorus is increased but such increases are not confined solely to the urine as they are in hyperparathyroidism

Diagnosis.—The roentgenologic appearance of even the early localized forms of Paget s disease is so characteristic that there is rarely any question as to diagnosis

Osteoblastic skeletal metastases secondary to carcinoma of the prostate may be impossible to distinguish, roentgenologically, from Paget s disease The serum phosphatase in such cases may be as high as in extensive Paget s disease Careful urologic study will usually enable one to make the correct diagnosis

Hyperparathyroidism.—Rarely should Paget s disease be confused with or mistaken for hyperparathyroidism, particularly in the advanced stages Consideration of the previously mentioned clinical, biochemical roentgenologic and pathologic differences should make the diagnosis relatively easy in the questionable case A few cases of hyperparathyroidism simulating or complicated by osteitis deformans have been observed

Leontiasis ossea begins in childhood is confined to the skull and rarely involves any other portion of the skeleton The serum calcium phosphorus and phosphatase values are normal

Bowing of the legs under forty years of age is rarely due to osteitis deformans. The development of such deformities in later life should always suggest the disease

Rarely if ever should multiple myeloma osteomalacia senile osteoporosis and other skeletal diseases associated with decalcification be confused with osteitis deformans Their diagnosis is discussed under Osteomalacia page 1318

Tertiary syphilis of the bone luetic periostitis osteopetrosis melorheostosis hyperostotic meningiomas neurofibromatosis yaws of the bone sclerosing osteomyelitis osteogenic sarcoma and acromegaly rarely simulate osteitis deformans other than superficially and their differentiation from Paget s disease should never be difficult In any doubtful case the diagnosis can be established by roentgenologic examination or by examination of a biopsy specimen.

Treatment.—There is no specific treatment for osteitis deformans Parathyroidectomy should never be performed Schmorl was unable to demonstrate any significant histologic changes in the parathyroid glands of one hundred thirty eight cases The administration of parathyroid extracts and acid salts is contraindicated Suprarenal extracts are without effect. Roentgen ray

therapy to the affected bones may relieve pain although often temporarily The best results are obtained when the disease is confined to the nonweight bearing bones Slitting of the periosteum relieves the tension of the periosteum and in most instances the pain We routinely administer a high calcium, high vitamin diet with added calcium glycerophosphate (doses of 3 to 6 drachms per day) 10 000 to 20 000 units of vitamin D and 50 to 100 mg of cevitamic acid in the hope that new bone formation can be kept greatly in excess of bone absorption

Orthopedic measures such as exercises for muscle atrophy and built up shoes in the case of leg shortening are often necessary Fractures should be treated as if the bones were not diseased They heal in a normal manner except that calcification of the callus may be delayed If a sarcoma should develop it should be treated radically with the hope that metastases may be prevented Hearing appliances are often necessary

SENILE OSTEOPOROSIS

(*Idiopathic Osteoporosis Postmenopausal Osteoporosis*)

Definition —Osteoporosis occurs in every aging and senile person hence the derivation of the term senile osteoporosis This designation has never been satisfactory because many individuals exhibiting osteoporosis without obvious cause are neither aged nor senile nor did the introduction of the term idiopathic osteoporosis frequently used in referring to this latter group enlighten us The recently coined name postmenopausal osteoporosis,' is most appropriate because the disease generally affects women after the menopause and estrogen therapy induces calcium and phosphorus retention in the subjects so afflicted

Incidence —From the foregoing it is apparent that all elderly people, particularly women are most frequently affected The average age in three reported series has been fifty seven sixty two and sixty six. However if the menopause is artificially produced the disease may appear at a much earlier age in one instance the first symptoms were experienced at the age of forty two The sex incidence is striking forty of the forty two patients studied by Albright and one hundred sixty seven of the two hundred eight cases reported by Black were women

Pathogenesis —The etiology of senile osteoporosis cannot be discussed without first describing its pathogenesis and depicting this necessitates defining the term 'osteoporosis' Adult bone is composed of an organic matrix in which is embedded a calcium phosphate carbonate complex Normally the two surfaces of the trabeculae are continuously subjected to two processes the one by resorption the other by formation The former is a function of the osteoclasts the latter is governed by osteoblasts Bone may be deficient because resorption is too great or because deposition is impaired Resorption is the result of increased osteoclastic activity which if continuous leads to osteitis fibrosa generalisata The formation of too little bone may be due to either failure of the osteoblasts to lay down sufficient osseous matrix or because the matrix once laid down is not calcified The former condition is osteoporosis the latter osteomalacia or rickets Accordingly it is emphasized that osteoporosis is primarily a disorder of tissue metabolism failure of the osteoblasts to lay down sufficient matrix and only secondarily a disease of calcium and phosphorus metabolism It is this abnormality with which we are concerned

Etiology —The extremely high incidence of osteoporosis in women, its constant tendency to appear after the menopause and the striking retention of calcium and phosphorus which ensues in this condition when estrogenic material is administered led Albright and his co workers to conclude that the postmenopausal state is the commonest etiologic factor in most cases of senile and idiopathic osteoporosis Whether the male climacteric results in the same sequence of events remains to be proved If it does the resulting osteoporosis proceeds more slowly Atrophy of disuse may be a contributing factor especially in those individuals who lead sedentary lives or are immobilized for a time because of vertebral fractures or other causes That faulty diet plays a role has not been established It is conceivable that if calcium and phosphorus are readily available the resorption of bone might be lessened This latter hypothesis would explain the beneficial effects observed in the treatment of patients with osteoporosis by means of high calcium high phosphorus diets and large amounts of vitamin D Albright suggests that a diet deficient in protein may play a more important etiologic role than one low in calcium and phosphorus because the former might result in a negative nitrogen balance and thereby make it difficult or impossible for the osteoblasts to lay down the necessary osseous matrix the prerequisite to bone formation That senescence plays a role cannot be denied

The serum calcium phosphorus and phosphatase levels are normal This is as it should be if osteoporosis is a disorder of tissue metabolism and not a primary disease of calcium and phosphorus metabolism However the urinary calcium and phosphorus excretion may be increased early in the disease This is not surprising because normally some of the calcium and phosphorus set free by the process of resorption is deposited in the newly formed osseous matrix. In osteoporosis this calcium and phosphorus are excreted because bone formation is impaired However once the decalcification is marked less calcium and phosphorus are derived from resorption and the urinary excretion is again normal or may be reduced

Morbid Anatomy.—The conditions operating to produce senile osteoporosis are those related to the production of the general involutionary process of aging Pommer was the first to demonstrate that normal bone formation was decreased while normal resorption continued with the result that progressive thinning of the bones occurred Therefore, late in the disease certain gross skeletal changes such as dorsal kyphosis and fractures of the vertebrae and the neck of the femur are frequently seen Grossly *one observes thinning of the cortices thinning* and absence of the trabeculae and fatty atrophy of the marrow Microscopically, the osteoid borders are not demonstrable or barely so, osteoblasts are diminished in number or hypoplastic and osteoclastic activity is unaltered

Symptoms.—The symptoms of osteoporosis are directly proportional to the severity of the disease the latter being governed by the rapidity with which the involutionary changes occur and the presence or absence of other factors As might be expected some of these patients are symptom free In such instances the disease is accidentally discovered during the course of x ray examinations made because of some other malady The average period of onset of symptoms following the menopause is between nine and fifteen years being later in women whose menopause has been induced artificially

The usual history is a woman in her fifties eight to fifteen years after the menopause experiences a sudden snap or pain in the back as a result of a jolt fall lifting or bending If an x ray examination is made at this time the disease is apparent Crushed or fractured vertebrae frequently result from such minor accidents The back pain persists and any sudden movement tends to cause sharp darting pains often radicular in character There is usually a previous history of weakness fatigue and various skeletal aches and pains Urinary calculi may occur in consequence of the initial hypercalcinuria and hyperphosphaturia These patients tend to show atrophy of skin and other tissues and dorsal kyphosis may be present

Roentgenograms disclose that postmeno*pausal osteoporosis has a predilection for the* spine and pelvis However the long bones

are involved in the more severe forms of the disease The skull is rarely affected, an important point in differentiating this type of osteoporosis from that due to other causes particularly, hyperparathyroidism The x ray films of the spine reveal decalcified vertebrae of the so called fish vertebrae type particularly in the lower thoracic and lum bar regions The additional pathologic lesions seen consist of crushed or fractured vertebrae herniation of the nucleus pulposus through the end plates of the vertebrae (Schmorl s nodes or Knoetchen) and frac tures of the neck of the femur

Diagnosis—This should rarely present *any difficulty* The patient *usually* a woman some ten years after the menopause first *notes the previously mentioned symptomat* ology Clinical studies reveal an osteoporotic *spine and pelvis with little or no evidence* of decalcification elsewhere normal serum calcium phosphorus and phosphatase levels and normal or slightly increased urinary calcium and phosphorus excretions Any of the skeletal diseases characterized by gen eralized decalcification may be confused with postmenopausal osteoporosis Their diagnostic features are discussed under osteomalacia (p 1318)

Treatment—To date the treatment of osteoporosis has been most unsatisfactory despite claims to the contrary Whether the previously mentioned effect of estrin on the calcium and phosphorus balance is sufficient to make its *administration of practical clin ical* value remains to be seen Daily intra *muscular injections* of 1 66 mg of estradiol benzoate for a period of ten days cause a marked retention of calcium and phos phorus However restoration of the normal calcium content of an osteoporotic skeleton would require years of therapy If estrin is administered it should not be given continu ously In order to take advantage of the possibility of lessening bone resorption by having calcium and phosphorus available in increased amounts a high calcium high phosphorus diet and large amounts of vita min D are advised Such a diet should con tain at least 1 Gm of calcium per day This is readily furnished by partaking of generous amounts of milk cheese and eggs Ten to fifty thousand units of vitamin D per day in the form of cod liver oil or one of the potent vitamin D concentrates will suffice The relief of pain is best obtained by assum ing the recumbent position increasing the tone of the musculature of the back by means of exercises and supporting it when necessary with a light brace Heat and mas sage are effective in combating the pain and muscle spasms accompanying *the acute* episodes Prolonged immobilization should *be avoided whenever possible in order to* prevent the osteoporosis of disuse from caus *ing further demineralization*

DISEASES OF THE NERVOUS SYSTEM

INTRODUCTION—METHODS OF EXAMINATION

It is impossible to understand nervous diseases without comprehension of general medicine and general pathology The number of primary diseases of the nervous system is rather small and degenerations due to defective hereditary endowment or vital lack are unpromising material for treatment Infections such as the acute exanthemata poliomyelitis, syphilis or tuberculosis however may exert their most serious effect on the brain or spinal cord and vascular degeneration is the cause of such simple and common brain lesions as apoplexy and cerebral thrombosis. Even central softening of the cord may be produced by sclerosis of spinal arteries if it be so severe as to impair nutrition of spinal nervous elements The accurate appraisal of the powers of a failing heart muscle or the discovery of a starch indigestion may be the clue to the cause of senile epilepsy and a high nonprotein nitrogen content in the blood may throw light on obscure conditions such as recurring convulsions The presence of hematoporphyrin in the urine may be evidence that an apparent nervous breakdown' in an overworked middle aged banker is really a chronic acetanilid poisoning from bromo seltzer potation and a high sugar content in the blood although the urine is normal may reveal the diabetic character of certain multiple neuritic and radicular pains which were previously unidentified and therefore irremediable Neuritis of the brachial plexus is more often due to toxic absorption from a periapical dental abscess than to exposure to cold Absence of free hydrochloric acid in the gastric contents gives a lead to the correct therapy of pernicious anemia and combined system disease of the spinal cord in the fourth and fifth decades of life The physician bent on correct neurologic application must therefore like St Peter on the roof top call nothing common or unclean in his search for prime causes and if he cannot culture the stool himself must be aware of cultural possibilities and their significance Just as a student must master a technic in order to diagnose a chest condition must understand how to inspect to percuss, to auscultate and to weigh the positive and negative signs thus discerned, so he must know a simple method of approaching a neurologic problem an irreducible minimum of examination to be systematically pursued which is based as all examinations must be on accurate anatomic and physiologic knowledge.

It is not necessary to elaborate here the details of these fundamental sciences, but a plan of clinical approach may be outlined with such application of our knowledge of structure and function as may be needed for illumination

Summary
Tentative diagnosis

History—The general character of the complaint should first be determined so that the examiner may be oriented to some degree, as to the nature of his problem then a more careful history of the beginning and progress of the symptoms which has led up to the final condition This must be obtained as far as possible in chronologic sequence and should be as fully elaborated as the patient will permit Some cross examination is usually needed and leading questions may be delicately suggested, for example transient attacks of diplopia or of inadequacy of the bladder sphincter, remote in point of time, usually must be sought after and similar direct questions often have to be made depending on how the trend of the history stimulates the diagnostic ideas of the examiner The *position* of a lesion of the central nervous system is often determined by clinical examination which reveals precisely the nature and degree of the loss of physiologic function but its *nature* frequently can only be surmised by careful consideration of the manner in which such functions are interfered with Four patients for example suffering respectively from luetic spinal thrombosis, extradural fibroma Pott's disease (tuberculosis) and spinal fracture dislocation, all of which have involved to a severe degree the tenth dorsal segment of the cord, should have practically identical clinical manifestations and disabilities, spastic paraplegia (paralysis of both legs with increase in muscle tone), complete sensory loss below the level of the affected spinal segment and sphincter paralysis These can be readily differentiated by the variations in anamnestic detail Complete paraplegia in the first instance would occur painlessly as an acute or subacute process lasting but perhaps half an hour In the second probably one lower extremity would have symptoms sensory and motor for months before the other was involved and even then complete paraplegia would probably take place slowly and be accompanied possibly by radicular pains confined to the skin area supplied by the tenth dorsal roots In the third case severe localized and shooting root pains would preface for a long time the rapid onset of signs of paraplegia These pains are ameliorated by rest and increased by movement during the months in which the disease is confined to the bone and before the collection of inflammatory exudate so compresses the cord as to forbid transmission of impulses The history of injury in the last instance would of course almost certainly reveal the cause of the paralysis

Examination—After the previous personal and family history have been taken, the above scheme should be followed in the further conduct of the examination but

with discrimination for one naturally does not examine visual acuity and the sense of smell before determining the picture in broader outline by appraising the proper functioning of the more important cranial nerves and the motor reflex and sensory systems It is usually wise to leave the ex amination of sensation to the last because the condition of the other systems capable of more rapid investigation may indicate the probable character of the sensory derange ment.

During the entire examination facts are gradually revealed which guide the physician toward this diagnosis or that Consequently it is possible to stress some parts of the pro cedure more than others, to discover the futile lines of investigation and to make the examination more forceful in other direc tions Proper incidence in examination can only be learned by experience, and the student would do well at first to master the routine method already set forth

The *mental functions* can be roughly judged by the taking of the history The power of attention and concentration may be more precisely gauged by some such test as Bourdon s in which the patient is asked to mark on a printed page a certain letter or letters. Should a suspicion arise of the patient s mental endowment Ziehen s tests may be employed Simple problems such as explaining the difference between a river and a lake water and ice an error and a false hood or further the Binet Simon or Terman scale may be employed with wisdom

Nervous System.—The *first* and *second cranial nerves* are really parts of the brain and not peripheral nerves but it is conveni ent for clinical purposes to regard them as such Visual acuity is tested roughly by asking the patient to count fingers with each eye separately Accurate tests are made with Snellen s types and pictures Changes in the size of the fields of vision can be determined roughly by seeing if the patient has as large a field of vision as that of the examiner for accurate measurement a perimeter is necessary

By *hemianopia* is meant blindness of half the visual field due to a lesion at the optic chiasma or behind it in one of the optic tracts *If the lesion be in front of the* chiasma *e g* in the optic nerve itself no hemianopia occurs because *the decussation* of the optic fibers has already taken place Ipsolateral blindness results with optic atrophy expressed by an optic disk white as tissue paper when seen with the ophthal moscope Such lesions of the optic nerve may be due to glioma of the nerve or to *pressure on the nerve* by a subfrontal tumor or abscess or by inflammatory exudate from sinusitis. Lesions of the chiasma itself are most often the result of tumor of the pituitary body which by its position at the *chiasma itself frequently gives rise to a bi*temporal hemianopia and whitened pap illae

Papilledema choked disk often im properly called optic neuritis is the conse quence of a rise of intracranial pressure whereby cerebrospinal fluid is forced down the sheath space of the nerve and appears at the nerve head or papilla This only indi rectly affects the nerve and for a long time is compatible with perfect vision but even tually the fluid becomes organized the nerve fibers are compressed and secondary optic atrophy occurs Primary optic atrophy may come from tabes or from poisoning with methyl alcohol The constant use of the ophthalmoscope is essential in neurologic medicine and almost essential in all branches of medicine This instrument is more indis pensable than a stethoscope.

Slight *irregularity in the shape of the pupils* always suggests that lues may have produced changes in the ciliary ganglion or in the ciliary nerves Changes in the nuclei of the third nerve or in the ciliary ganglia may produce the classic *Argyll Robertson pupil* This is ingravescent by the following stages

1 A pupil contracting sluggishly to light and briskly on convergence

2 One fixed to light and brisk on con vergence

3 One fixed to light and sluggish on con vergence.

4 Fixed to light and fixed on convergence

These phenomena are most often due to lues but may be seen as a result of epidemic encephalitis of acute alcoholism or even of tumor provided that the paths of the pupil reflexes be so slightly involved as to damage one set of fibers and not the other The opposite of an Argyll Roberston pupil *i e*

retention of the power of contraction to light and the loss of that on convergence is characteristic of diphtheritic nervous infection but may also be occasionally due to periaqueductal lesions such as encephalitis

The patient must be made to turn the eyes at different speeds in all directions, to reveal any strabismus loss of ocular movement nystagmus or diplopia *Strabismus* may depend on a long-standing refractive error but if recently acquired is most probably due to paralysis of one of the extrinsic ocular muscles and overaction of the unimpaired antagonist For instance, a lesion of the third nerve may produce paralysis of the pupil ptosis of the lid and eversion of the eyeball from uncontrolled action of the unscathed external rectus muscle supplied by the intact sixth nerve A slight paresis (weakness) of an ocular movement permits light to fall from a seen object on different parts of the two retinae, this produces diplopia or double vision The smaller the muscular error the more distressing the diplopia seems to the patient because with slight failure of parallelism in the eyeballs the sensitive macular region of the retina and the but slightly less sensitive perimacular region are in operation so that the true image is very little more distinct than the false

Loss of *conjugate movement* of the eyeballs may be discovered at this time due to some lesion of the quadrigeminal plate such as a pineal tumor or encephalitis or even a midbrain luetic meningitis This is occasionally seen also in myasthenia gravis *Nystagmus* is an involuntary rhythmic ataxia or incoordination of the eyeballs usually bilateral and more often found on conjugate movement than when the eyeballs are stationary In its true form it depends on a lesion of the cerebellum or its tracts in the pons medulla and midbrain Lesions of these structures give rise to decomposition of rhythmic movements so that motor ataxia of the arms and legs results This so called 'intention tremor of the hands is a manifestation of pure cerebellar disease and is strictly analogous to the nystagmus of the eyeballs, caused by similar structural defects Nystagmus may come from labyrinthine disease through the connections of the vestibular nerve with the cerebellar system by Deiter's nucleus, and it is occasionally present in somewhat different form in high myopes and albinos

The *fifth nerve* has both a motor and sensory division, the former has its nucleus in the midbrain, the latter in the long descending nucleus in the medulla and first two segments of the cervical cord On the course of the sensory division lies the gasserian ganglion, below which passes the motor root Total palsy of the sensory fifth destroys all superficial sensation on the same side of the face including the cornea, but excluding the skin over the jaw angle which is supplied by the great auricular nerve The mucous membranes of the affected side are included in this anesthesia with the exception of the posterior third of the tongue which receives its supply from the glossopharyngeal nerve Taste is affected in that area of the tongue in which sensation is gone The motor branch supplies the muscles of mastication and when it is paralyzed the masseter and temporal muscles atrophy on the affected side, and the lower jaw when opened deviates to the side of the lesion by reason of the inaction of the ipsolateral external pterygoid muscle

If the *seventh nerve* be affected in the pons there is usually also a lesion of the ipsolateral sixth nerve, due to the proximity of the sixth nucleus to the intrapontine seventh nerve Paralysis of the nerve produces motor palsy of the same side of the face and the forehead cannot be wrinkled the eyelid properly closed, nor can the orbicular mouth muscles be used for laughing, whistling, or emotional expression This paralysis renders eating and drinking arduous Liquids are apt to be spilled owing to the difficulty in closing the lips If the chorda tympani be involved as when the lesion is in the fallopian aqueduct, the sense of taste is affected in the anterior two thirds of the same side of the tongue

The *eighth nerve* consists of two sets of fibers having different functions the cochlear branch from the organ of Corti the nerve of hearing and the vestibular branch from Scarpa s ganglion in the vestibular apparatus the nerve ' as it were by which movement and posture are appreciated The cochlear function is examined by a ticking

watch and by seeing if a vibrating tuning fork is better heard by air or bone conduction. In deafness of middle ear origin, the former is lost and the latter retained If the cochlear nerve be destroyed (so called nerve deafness') both conductions are blocked

Tests for the functional integrity of the vestibule consist in syringing the tympanum with hot and cold water to see if nystagmus and vertigo be produced. Rapid rotation of the individual is also often valuable in this determination

The functions of the *remaining three cranial nerves* are examined by making the patient protrude the tongue and by looking carefully for such signs of muscular atrophy therein as tremor of fine fibrillary' character, undue furrowing especially unilateral or deviation from the middle line of the teeth, by examining the movements of the palate on deep inspiration and phonation (the uvula in the presence of unilateral palatal palsy is lifted toward the sound side), by inspecting the vocal cords and determining if an abductor palsy be present due to involvement of the recurrent laryngeal nerve The patient must be made to shrug his shoulders and rotate the head against resistance to discover a possible spinal accessory lesion giving rise to paralysis of the sternomastoid and upper third of the trapezius muscle

The Motor System.—Inspection and palpation reveal loss of power in a muscle or group of muscles, and any changes in tone The movements at each joint should be tested against resistance The patient should extend the hands abduct the arms raise them above the head grasp the observer s hands firmly and show his power for pulling and pushing movements at the elbows With the arms folded across the chest he should try to rise from the bed then all movements at the hip should be executed and appraised in power likewise at the knee and ankle

By palpation it is possible to estimate the nutrition of muscles if it be diminished the muscle is said to be *atrophic* if increased *hypertrophic* Occasionally in certain muscular diseases (so called myopathies) the apparent muscle volume is increased while its power is greatly lessened (pseudohypertrophy)

The *distribution of paralysis or paresis* is determined by the site of the lesion Thus injury to one internal capsule produces hemiplegia or paralysis of the face arm, or leg of the opposite side, injury to say, the pons extensive enough to include both pyramidal tracts produces diplegia or double hemiplegia, a spinal cord injury is apt to cause paralysis of both legs or paraplegia and if it be in the cervical region a tetraplegia in which all four limbs are included

The tone of muscles weakened by a lesion of the corticospinal motor tract (upper neuron palsy) is usually increased (spastic) and decreased (*flaccid*) when the lesion is in the motor system between the anterior horn cells and the motor end plate (lower neuron palsy) The characteristics of these two great types of paralysis may be further tabulated as shown below

Upper Neuron Palsy Supranuclear Type

Movements" are paralyzed rather than single muscles or groups of muscles
Spasticity or increase of muscle tone
No atrophy
Reaction of muscles to electricity normal.
Deep reflexes increased Arm jerks knee and ankle jerks
Plantar reflex of Babinski type extension of great toe on stimulation of the sole of the foot.

Lower Neuron Palsy Nuclear and Infra-nuclear Type

Single muscles or groups of muscles affected if due to spinal lesion in spinal segmental distribution
Flaccidity or decrease of muscle tone
Atrophy the rule.
Electric reactions those "of degeneration " No reactions to faradism and an abnormally slow vermiform contraction to galvanism.
Deep reflexes decreased or lost.
Plantar reflex may be lost, but if present is of flexor type

Tone and posture are influenced also by brain lesions not of the pyramidal or corticospinal system but of the extrapyramidal or striatospinal system This mechanism phylogenetically older than the other dominating instrument controls attitude tonus and automatic associated movements The disease most characteristic of this lesion is paralysis agitans in which attitude or posture of the body and limbs is altered tonus is greatly increased so that the limbs when passively moved convey to the examiner a feeling of cogwheel rigidity automatic associated movements (such as swinging the arms when walking) are decreased or lost,

and tremor superadded by reason of interference with the rubrospinal tracts

It has been stated above that the position of the lesion and the structures it affects determines the type of paralysis produced Many combinations, of course, are possible, and while multiple lesions may occur in the brain and give rise to strange medleys of defective function it is always wise for the beginner to determine shrewdly whether one lesion correctly placed could produce the *existing condition Thus a hemorrhage* in the *crus cerebri* produces paralysis of the contralateral face, arm, and leg and almost certainly by its incidence on the third nerve an ipsolateral ptosis of the eyelid and defective movements of the pupil of that eye and of the superior, inferior and internal rectus muscles If the hemorrhage be large enough to implicate the red nucleus the weakened arm and leg are ataxic and the seat of tremor In similar fashion a unilateral pontine lesion may produce contralateral hemiplegia and ipsolateral palsy of the fifth sixth seventh, and eighth nerves *Bulbar lesions* naturally interfere with the functions of the cranial nerves therein so that there is trouble in swallowing in articulating or in phonation

A lesion for example of the *seventh cervical segment* of the cord produces spinal level signs of lower motor neuron type, with interference with the functions of the seventh segment *e g* paralysis of the intrinsic hand muscles with retention of movements at the shoulder (supplied through the fifth and sixth segments) and pyramidal tract paralysis (upper motor neuron type) below the lesion level, that is to say spastic paraplegia with sensory paralysis below the distribution of the seventh segment diminished arm jerks, and increased deep reflexes in the legs Sphincter paralysis also occurs

A *middorsal lesion* gives rise to spastic paraplegia also the arms are not implicated but owing to the longer innervation of the recti abdominalis muscles from the dorsal cord the upper recti remain intact while the lower are paralyzed The attachment of the umbilicus to the sheath of the rectus muscle determines then in this situation that on attempts to contract the recti muscles (as in rising from the recumbent position) the umbilicus will not remain stationary as it does normally but will be pulled upward 1 or 2 inches by the unantagonized superior recti muscles

A lesion of the *cauda equina* produces a picture determined by the functions of the nerve roots contained in the lowest part of the spinal dura mater sheath The motor loss is of *lower neuron type, characterized* by atrophy of the affected muscle group *with electric reaction of degeneration* and loss of the deep reflexes subserved by the roots affected If the sacral roots be involved there is usually sphincter paralysis and, in any case, if the posterior spinal roots be included in the damaged area there are characteristic shooting root pains Such loss of sensation as may be present is found in the skin areas sensorily served by the affected roots

The paralysis consequent to inflammation or injury of any nerve or plexus of nerves is of course, of lower neuron type, and is confined to the muscles supplied by the affected nerves

Multiple neuritis due to some general constitutional intoxication (alcohol, lead diphtheritic toxin diabetes lack of vitamin B) is a symmetric disease which produces dropped hands and dropped feet and is due to the especial incidence of the poison on *the extensors of the fingers* and hands and the anterior tibial and peroneal muscle groups The palsy is flaccid and atrophic with loss of reflexes and is usually associated with pain *in the affected muscles and loss* of sensation following 'a glove and stocking' distribution due to the failure of function in the terminal twigs of the mixed peripheral nerves

During the examination of the motor system, myopathies must be looked for These are primary muscular diseases which occur in predisposed stocks *The cause is unknown* the peculiar distribution of the muscular weaknesses, the absence of changes in reflexes (other than from mechanical reasons due to extreme muscle atrophy) and of sensory changes combined with the presence of pseudohypertrophy *in certain muscles* especially those of the calves and the infraspinati due to the *fatty changes* in the degenerating muscle, usually give the clue to correct diagnosis.

Ataxia or *incoordination* of the arms is

sought for by asking the patient to bring his fingertips together with the arms extended before him to touch his nose or his ear with each index finger, and to follow with his hands the movements made by the observer's finger The first two tests are carried out with the eyes open and shut Ataxia of gait is tested by asking the patient to walk along a straight line and to stand still with the feet together and the eyes shut This is known as Romberg's test Ataxia may depend on loss of sensation from the affected limb especially on loss of the sense of position, such as occurs typically in disease of the posterior columns like tabes dorsalis The patient is able to guide the limb by the eyes but in the dark or if the eyes be shut he loses' the limb does not know exactly its position and brings it, smoothly enough to the wrong place. This form of ataxia thus arises *from a purely* sensory defect whereby inadequate information is received

The other great class of ataxias is entirely motor in origin and is due to a defect in the cerebellum or its tracts The function roughly speaking of this organ is to compose to make smooth cortical impulses When this function has been impaired the movement of the limb is broken up into its component parts and becomes jerky The patient is always aware of the position of the limb in space but he lacks the controlling mechanism to bring it smoothly and with properly graduated forces to its objective This *failure to synchronize* muscular action is known as asynergia and results not only in the jerky movements described but in dysmetria which consists in overshooting the objective because of failure to control nicely the strength required for the task. Dysmetria may occur though with a different aspect in ataxia of sensory origin In this the *spatial relationship* between the limb and the objective is poorly estimated and the wrong movement is well performed

The gait of a 'sensory ataxic is stamping in character The tabetic is constantly in the position of a normal person who on going up a flight of stairs in the dark thinks there are eight steps when there are but seven He miscalculates the distance between his foot and the ground in a way the tabetic does all the time A cerebellar gait is more reeling or drunken." If only one cerebellar lobe be affected the ataxia is on the same side as the lesion, and the patient tends to fall to that side This ipsolaterality of cerebellar ataxia depends on the fact that each cerebellar lobe controls impulses coming from the opposite cerebrum which in turn sends impulses to the opposite side of the body through the decussation of the pyramids

Under the heading *involuntary movements* are classified chorea the jerky non purposive character of which has a definite cerebellar quality athetosis, slow vermiform movements which occur in a hemiplegic limb in the producing lesion of which a thalamic component has occurred, fibrillary twitching fine rippling movements of parts of the muscular bellies which occur typically in amyotrophic lateral sclerosis but which are indicative of all acute degeneration and impending or progressive muscle atrophy myoclonus in which an entire muscle or muscle group is twitched often rhythmically and violently seen in both acute and chronic epidemic encephalitis as a release phenomenon from the basal ganglia of the same general pathologic pattern as athetosis and tremors fine such as are seen in exophthalmic goiter or coarse from lesions of the tegmentum of the pons or crus with changes in the rubrospinal tracts

Reflexes—The reflexes are divided into the superficial the deep and the 'organic types

Superficial Reflexes—In the first group the corneal has already been considered The *pharyngeal* and *palatal reflexes* consist of contraction of the pharynx and elevation of the palate when either is touched and depend for their production on integrity of the glossopharyngeal nerve and the bulb They *may be entirely absent in hysteria and in* the absence of organic disease

The *abdominal reflexes* are obtained by stroking with some hard instrument (a pencil or key) parallel with the ribs and also with the inguinal folds Their spinal level runs from the eighth to the twelfth dorsal segments They are very rarely absent in healthy young or middle aged persons whose abdominal walls are not obese If bilaterally absent in young persons a suspicion of early

multiple sclerosis may be entertained In *cerebral hemiplegia* the abdominal wall (transversalis rectus abdominis, and internal oblique muscle) usually does not contract on stimulation of the paralyzed side, and reduction of the force of this reflex on one side is often early intimation of a slight or ingravescent lesion of the motor tract supplying that side Efforts should be made to see whether the abdominal reflexes on one or both sides are fatigable, repeat stimulation if necessary for five minutes Recently this procedure indicated to the writer the correct side of a brain tumor in a child

The *cremasteric reflex* elevation of the testicle on stroking the inner side of the thigh is less dependable than the abdominal reflex It may be retained in the presence of a complete hemiplegia, but is more probably reduced or lost Its segmental level is the first and second lumbar

The most important superficial reflex is the *plantar* To evoke this the blunt instrument is stroked with some force along the outer side of the sole from behind forward Normally this is followed by a flexor movement of the great toe and a contraction of the tensor fasciae femoris Care must be taken not to overstimulate as this produces a defensive withdrawal and dorsiflexion of the foot If the motor tract or the leg center in the cortex be injured, this normal flexor type of plantar reflex is replaced by a slow extensor movement of the great toe, a fanning' spread of the other toes, and a contraction of the hamstring muscles This extensor reflex is the so called Babinski sign' It is always pathologic, being a more primitive type of spinal reflex than the flexor response and is normally controlled by the cortex It is physiologically present in infants unable to walk It may occur for a few minutes to an hour after an epileptic convulsion sufficiently severe temporarily to exhaust the cortex

The writer has observed that the first indication of a pyramidal tract having come as it were under fire is a change in the posture of the affected leg and foot when the patient is lying relaxed in bed There occurs an eversion of the leg and foot in contrast with the other limb The position resembles or approaches that occasioned by a fracture of the neck of the femur This sign is valuable and delicate and most often can be found before the development of Babinski's reflex It might be called pyramidal eversion of the leg and foot.

The *bulbocavernosum reflex* is elicited by placing the finger on the urethra behind the scrotum and at the same time stimulating by pin prick the glans, normally the urethra is felt to contract sharply This phenomenon is lost early in tabes dorsalis and is abolished by any lesion of the caudal roots of the third and fourth sacral segments

The Deep Reflexes—The *biceps triceps* and *supinator jerks* depend on the integrity of the reflex arc through the fifth cervical to the first dorsal segment. They are obtained by tapping the biceps tendon the styloid process of the radius and the triceps tendon

The *knee* and *ankle jerks* obtained by tapping the patellar and Achilles tendons when the supporting muscles are entirely relaxed, have segmental levels of third and fourth lumbar and first and second sacral respectively If feeble they can be increased by making the patient lock his hands together and pull one against the other They are abolished by any break in the arc, by multiple neuritis where the break occurs low down in the peripheral nerves, by tabes dorsalis, Friedreich's ataxia or subacute combined sclerosis of the cord, the lesion here being in the posterior roots or columns of the cord by disease of the motor anterior horn cells of the cord as in acute poliomyelitis and amyotrophic lateral sclerosis, or occasionally by cavity formation in the cord (syringomyelia) As has been said, myopathies may abolish the reflexes by destroying the muscular mechanism needed for their production These reflexes are exaggerated in the presence of pyramidal tract disease in which case the normal cortical control of the cord is withdrawn so that the cord is allowed independent action.

Increased deep reflexes unless unilateral are not so valuable a sign of organic disease as is their loss When these reflexes are increased one must look for *ankle clonus* a rhythmic contraction of the soleus muscle obtained by continued passive stretching of the Achilles tendon *The organic motor reflexes* depend on the vegetative nervous sys

tem and cause contraction for the most part of nonstriated involuntary muscles The most important are the ciliospinal whereby the pupil dilates on scratching the skin of the neck and the oculocardiac whereby the heart is slowed some ten beats a minute by compression of the eyeballs in their sockets This is especially marked in vagotonic persons and may be abolished in tabes

later by the establishment of a reflex automatic bladder action whereby the bladder content is discharged periodically by the production of a primitive mass reflex in response to stimulation of the sole or the inner side of the thigh

Sensation—It would be well here to recollect in outline the paths in the central nervous system of the various forms of sen

Fig 183—Chief sensory pathways ascending from the spinal cord (Villiger s Anatomy of the Nervous System)

The reflex centers of the vesical rectal uterine and genital automatic actions are in the lumbar and sacral segments of the cord and also in the hypogastric and hemorrhoidal plexuses of the vegetative nervous system. Periodic reflex bladder incontinence is normal in infancy after total transverse spinal cord lesion there is an initial period of urinary retention followed in a week or two by overflow dribbling and a week or two

sation These pass upward from the periphery to the posterior roots of the cord thence they pass into the cord and are distributed as follows the fibers bringing sensation from the muscles and joints together with a few of those for touch pass upward uncrossed in posterior columns to the gracile and cuneate nuclei on the same side of the medulla as they entered the cord Thence they continue upward and cross the middle line in the

internal arcuate fibers forming the sensory decussation of the fillet The fibers continue through the crus cerebri to the optic thalamus, where redistribution again takes place some ending in the thalamus, others continuing to the rolandic area of the cortex

The remainder of the tactile fibers and those conveying temperature and superficial

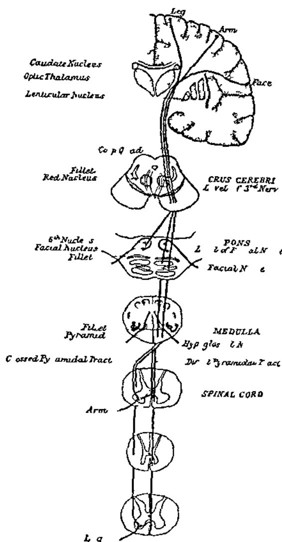

Fig 184—Diagram of the pyramidal tract (the chief motor pathway of the nervous system) (Purves-Stewart s Diagnosis of Nervous Diseases)

pain sensations entering by the posterior roots cross the spinal cord almost immediately and go up the opposite side of the cord from which they entered in the spino thalamic tract of the lateral column When they reach the thalamus the same redistribution takes place, as has been mentioned Some impulses pass on to the discriminating centers of the postrolandic and supramarginal gyri others end in the nuclei of the thalamus, which in this manner is a terminus for various types of undiscriminating sensation of an emotional character (pleasure pain, and some visceral sensations)

To recapitulate, the sensations of deep pressure pain (such as that produced by squeezing the calf muscles) of vibration (ability to appreciate the vibration of a tuning fork placed on bone), of sense of position of joints (whether they be flexed or extended) and some touch sensations ascend the same side of the cord as they enter on to relay stations in the posterior column nuclei in the medulla From there they cross to the opposite side in the fillet to the optic thalamus, and either end or are relayed to the sensory cortex

Sensations of temperature (distinguishing between hot and cold), of superficial pain (pin prick), and the majority of superficial touch sensations enter the cord as do the others by the posterior roots cross the cord immediately and ascend to the thalamus in the lateral ground bundle or lateral column, where they are dealt with as already described

These sensations do not reach the cortex as pain temperature touch etc, at this highest level judgment and selection of sensation occurs whereby spatial relations and differentiation of objects (stereognosis) and discrimination of intensity take place

It is well here to set down, if only as a method of remembering the functional anatomy of the cord the symptom complex known as *Brown Sequard s paralysis* produced by a lesion destroying one lateral half of the cord On the side of the lesion from section of the descending pyramidal tract there will be upper motor neuron paralysis of the leg with increased deep reflexes and an extensor type of plantar reflex From section of the posterior columns and interruption of the uncrossed fibers from the posterior roots below the lesion there results on the side of the lesion loss of sense of position of the limb loss of vibration sense and loss of deep pressure pain sensations At the level of the lesion there is an ipsolateral zone of loss of touch temperature and superficial pain due to interruption of the local fibers of the posterior roots

On the body opposite to and below the

lesion there is loss of sensation for temperature and superficial pain and some depression of touch appreciation due to the cutting of the spinally crossed fibers for these functions coming from the opposite side of the cord. There will be no motor paralysis on this side

The beginner would do well to avoid complicated instruments for sensory examination a pin a wisp of cotton a tuning fork and two test tubes of hot and cold water

The examination of the trophic functions or as they are still called the trophoneuroses' is best understood from the chapter on those conditions The same is true of the examination of the cerebrospinal fluid, of aphasia and convulsions The vegetative nervous system is dealt with, as far as our clinical knowledge of its functions is concerned in the section on endocrinologic conditions.

FOSTER KENNEDY

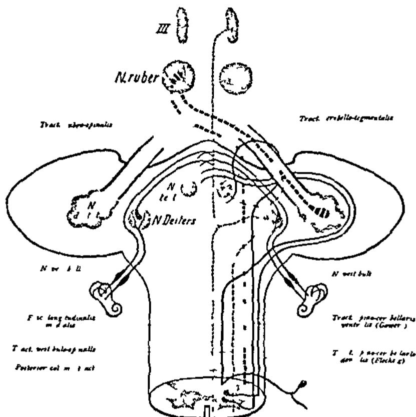

Fig 18.—Important pathways to and from the cerebellum (Villiger's Anatomy of the Nervous System)

added to intelligence and patience are adequate equipment Knowledge of the types of sensory loss must be added to this armament the skin areas served by the plexuses and the peripheral nerves the spinal root areas and familiarity with the phenomenon of dissociated sensation which has just been described as occurring in Brown Sequard palsy and is also seen in syringomyelia (central lesion of the cord involving pain and temperature fibers at the point of their spinal decussation but sparing the other sensory fibers less centrally placed)

THE DIAGNOSTIC SIGNIFICANCE OF THE CEREBROSPINAL FLUID

History.—The study of the cerebrospinal fluid which now embraces physical histologic chemical bacteriologic biologic and immunologic methods had its beginnings in 1891 when Quincke demonstrated the

method of lumbar puncture The first punctures were performed for therapeutic purposes, to reduce pressure in hydrocephalus and in tuberculous meningitis Soon afterward fluid was also withdrawn in acute meningitis

Following closely on the diagnostic and therapeutic application of lumbar puncture in meningitis, the procedure was employed on patients with syphilis of the nervous system so that the fluid might be examined But in the first decade of this century the only criteria of value were the cell count, differential cell picture and globulin reaction In this pioneer work the French workers Ravaut Sicard, and others led the way In 1910 Mestrezat published his epoch making book which emphasized the chemical aspect and laid the foundation for much subsequent work At this time the Wassermann reaction took its place with chemistry, cytology, and bacteriology and the diagnosis of neurosyphilis became clarified by the demonstration of the 'four reactions of Nonne' namely a lymphocytosis, an increase in the globulin content and a positive Wassermann reaction in the blood and in the spinal fluid

Colloidal chemistry entered the field in 1913 with the publication of Lange s gold chloride test The gold sol test attracted immediate attention and as it now seems, assumed unwarranted importance it certainly led to neglect of the previously known fundamental tests

Little attention had been paid to pressure although Quincke in his original work used a manometer Since Queckenstedt s article on hydrodynamic tests appeared in 1916 however, pressure studies at the bedside have been added to the tests carried out in the laboratory

Later attention was called to 'fractional examinations of the spinal fluid that is, examination of the first and last portions of fluid obtained on lumbar puncture This method was designed to give evidence of the chief locus of pathology whether cerebral spinal or diffuse This method was promptly superseded by methods of multiple punctures cisternal, ventricular and even puncture of the thoracic and cervical subarachnoid space

The present advance in our knowledge of the cerebrospinal fluid as indication of disease appears to be *largely in* the field of chemistry, with close correlation of blood and fluid by means of *micro chemical tests*

Anatomy and Physiology —The cerebrospinal fluid is found in the ventricles of the brain the subarachnoid spaces of the brain and spinal cord and, according to some observers in the perivascular spaces The normal amount is approximately 150 cc, under abnormal physiologic and pathologic states this amount may be very considerably increased While the whole fluid system is intercommunicable the fact that the composition of the ventricular fluid differs considerably from that of the subarachnoid space is evidence that admixture is not prompt or complete

According to Weed, there appears to be a dual source of the fluid although whether it is a secretion a filtrate or a dialysate is not certain Most of the fluid appears to come from the choroid plexus of the lateral ventricles whence it passes through the third ventricle and aqueduct of Sylvius into the fourth ventricle and then by way of the foramina of Magendie and Luschka into the cisterna magna to mix with a smaller amount of fluid which seeps into the cerebral subarachnoid space by way of the perivascular spaces The exact point of *origin* of this latter fluid is in doubt From the cisterna magna which Dandy *describes* as the distributing center the cerebrospinal fluid passes forward along the *base of* the brain and upward over *the convexities* where it is absorbed into the venous sinuses by means of the arachnoid villi *There* is also a downward course into the spinal subarachnoid space whence it is in *part* absorbed by the arachnoid projections which cover the spinal nerves

Movement of the *fluid* must not be thought of as a stream or a flow but as admixture and diffusion *affected* by variations of pressure caused by pulse, respiration etc Normally slow *movements* of fluid from one *locus to another* may be *rendered* quite rapid under artificial conditions of pressure and drainage *although* they are always more rapid when in the direction of the normal trend

Only one function of the cerebrospinal fluid is known the mechanical protection of

the brain and spinal cord That it also serves metabolic functions is likely, but what these are and how they are performed is not known

Loci at Which the Cerebrospinal Fluid May Be Obtained—Long before fluid was obtained by design occasional opportunities were offered for its examination in cases of rhinorrhea following fracture of the cribriform plate This accident is rare and examination of the fluid of little value except as it indicates the large potential output (approximately 1 liter a day) Since 1891 fluid has been obtained for diagnosis primarily by lumbar puncture The needle enters the caudal end of the subarachnoid space below the conus which lies opposite the first lumbar vertebra in this space occupied only by the roots of cauda equina nerves cannot be injured for it is impossible to prick a nerve floating in fluid There are five interspaces at which lumbar puncture may safely be made the most convenient of which may be used in any given case Other places at which cerebrospinal fluid may be obtained should be mentioned The lateral ventricles are accessible in babies through the open anterior fontanel and in adults through trephine openings the cisterna magna is readily reached by suboccipital puncture by the experienced operator and puncture of the *cervical and thoracic subarachnoid* space rarely indicated, is quite possible Cisternal puncture has been advocated as a substitute for lumbar puncture to avoid postpuncture headache a point of view with which the writer is not in sympathy

Tests—Among the many tests which have been recommended in studying the cerebrospinal fluid a few stand out as of proved value With 10 cc of fluid or even less all of the most important may be performed and fortunately several of the most *significant* can be *carried out literally at the* bedside. A number of special examinations are also of value in certain investigations but it is the writer's opinion that the results of the following group of tests when carefully analyzed and correlated with the clinical findings give reliable and valuable information

Physical Characteristics—The fluid which is normally crystal clear may be turbid from bacteria or cells or actually purulent The formation of a clot on standing indicates that fibrin is present and is always pathologic Purulent fluid may be yellow green white, or muddy, according to the bacteria *present A clear yellow coloration is pro*duced by pigment from the blood and may indicate antecedent hemorrhage or venous stasis characteristically due to compression *of the spinal cord* Whether disease or technic is responsible for blood tinged or bloody fluid must be determined at the time of puncture If it is due to faulty technic the blood will rapidly diminish in amount as fluid is withdrawn, as shown in successive tubes This method of fractional examination' especially useful in determining the site of bleeding can be used for other purposes for occasionally more cells or greater protein are found in the last tube of fluid taken than in the first suggesting that a focus of pathology has been opened up by withdrawal of fluid

Pressure and Dynamic Studies—Normal pressure with the patient in the lateral position and completely relaxed is usually between 100 and 150 mm in the aqueous manometer For clinical purposes this may be measured with sufficient accuracy by allowing the fluid to run into a glass tube with a 2 mm bore A pressure above 200 mm is suspiciously high and above 300 mm almost *always denotes increased intracranial pres*sure The significance of low pressures is less certain The manometer demonstrates pulse oscillations and respiratory excursions the former usually 1 to 2 mm the latter 4 to 6 mm in extent

With the manometer in place and oscillations visible an assistant presses gently on each side of the larynx separately and then together until the carotid pulse is palpable By this maneuver which compresses the jugular veins venous stasis is immedi*ately produced in the* cranium this results in increased intracranial pressure which under normal conditions is transmitted promptly throughout the cerebrospinal fluid and is registered by a marked and prompt rise in the lumbar manometer This test is useful in the diagnosis of a number of conditions leading to spinal subarachnoid block tumors of the cerebellar fossa and lateral sinus thrombosis Rarely a drop in pressure occurs while carrying out this test and it

will be found that an irritable carotid sinus has been stimulated

Cytology—One of the earliest tests employed and still one of the most important *examinations* is that of the cell content of the fluid Normally no cells are present, or only a rare arachnoid cell Some observers maintain that as many as ten lymphocytes per cubic centimeter of fluid is normal but the writer thinks that the presence of ten lymphocytes or even five is pathologic and requires explanation

A count of more than ten lymphocytes is almost universally admitted to be pathologic, and to be evidence of an inflammatory process somewhere within the cerebral or spinal subarachnoid spaces A certain differential value is attributable to high and low counts as will appear in later sections *The count should be carefully obtained from* well mixed freshly drawn fluid in the regular blood counting chamber under the high power objective This permits identification of the cells

Differential counting of cells is simple in acute exudative fluids by means of ordinary stained films but in fluids containing few cells it is difficult because the cells are readily lost in the process of making the film and often stain poorly on account of distortion due to prolonged immersion in the fluid At least three types of cells should however be recognized even in the counting chamber—the lymphocyte, the polymorphonuclear leukocyte and the large arachnoid mononuclear cell With special care, plasma cells and eosinophils may be identified and tumor cells have occasionally been reported present. The significance of cell types as well as of cell numbers is obviously great Tumor cells from meningeal emplacement have rarely been reported as also large cell counts in leukemia

Chemistry—PROTEIN DETERMINATION in the cerebrospinal fluid is of fundamental importance Normally very slight (20–40 mg *per* 100 cc.), the protein content may increase pathologically (up to 4 Gm per 100 cc) until it approaches that of blood serum This must be looked upon as a non specific reaction of exudative or transudative origin Rough examination with the naked eye is of value when once the examiner has learned the normal turbidity The nitric acid trichloracetic acid and other tests demonstrate the presence of coagulable protein but perhaps the most simple of all is the mixture of three parts of 95 per cent alcohol with one part of spinal fluid These tests normally produce a faint protein flocculation easily recognizable from gross pathologic amounts So great is the importance of even a slight protein increase that a quantitative estimation is desirable, for this purpose the sulfosalicylic acid method of Denis is recommended

Unquestionably, *quantitative estimation of the globulin and albumin contents* separately will be of value when reliable micro *chemical tests have been perfected* At the present time the globulin ring test of Ross Jones (saturated solution of ammonium sulfate underlying an equal amount of spinal *fluid) gives* a rough *index of the amount of* globulin present Normally no cloud is seen at the junction of fluid and reagent but in neurosyphilis in particular a well defined cloud indicates a marked globulin increase even when the total protein content (*i e* albumins and globulins) shows no great increase by the sulfosalicylic acid method

SUGAR—Normally the lumbar fluid contains about 0 065 per cent sugar It is now well determined that a diminution or even a loss of sugar occurs regularly in acute meningitis and tuberculous meningitis High sugar content usually reflects a high blood sugar reading, under experimental conditions an intravenous injection of glucose is reflected in the cerebrospinal fluid in about two hours Quantitative tests for sugar when these diseases must be considered in *diagnosis* are therefore necessary A rough macroscopic method is here of little value although failure of Benedict s solution to *reduce* with three drops of fluid suggests a diminution in the sugar content

CHLORIDES—The chloride content is regularly low in bacterial meningitis

NONPROTEIN NITROGEN UREA URIC ACID AND CREATININE.—Tests for nonprotein nitrogen urea uric *acid and creatinine are* occasionally made for example in uremia but are not recommended as of routine value

COLLOIDAL TESTS—Three colloidal tests have been widely recommended the original test of Lange using *gold chloride* the gum

mastic test of Emanuel and the *benzoin test* of Guillain

The mechanism of precipitation by these tests is not understood but certain changes occur with different dilutions of spinal fluid which are more or less characteristic of a number of diseases The earlier workers unquestionably assigned to these tests particularly the gold sol test altogether too much value One type of curve in the gold sol test has however retained its importance the misnamed paretic curve now usually spoken of as first zone reaction This type of reaction represented by discoloration of the gold chloride reagent by the stronger dilutions of spinal fluid and by complete precipitation of the benzoin and mastic test reagents is certainly characteristic of paresis although it is not pathognomonic Like others colloidal tests have a distinct place in the complete analysis of the spinal fluid Alone they are of little value

Biologic Test —This is the Wassermann test.

Bacteriologic Tests —These are the same as in the study of other fluids and exudates by means of films and cultures Guinea pig inoculations for tuberculosis rabbit inoculations for *Treponema pallidum* the monkey inoculations for poliomyelitis must be considered as exceptional or research procedures and not applicable to routine examination of the fluid The use of *dyes* to demonstrate permeabilities *air* and *opaque substances* for the purpose of x ray localization are obviously not the part of a routine examination of the fluid Nor is the use of drugs designed to test permeability of the encephalic barrier upon a sound routine basis

Summary.—When diagnosis is doubtful and the spinal fluid is to be examined the routine procedure should be to perform lumbar puncture with the patient in a lateral horizontal position take the initial pressure reading with an aqueous manometer observe the increase of pressure during compression of the jugular veins separately and combined and the rapidity and degree of fall after release of the jugular veins and observe the pressure after withdrawal of 10 cc of the spinal fluid so that the difference between the initial and final readings may give some indication of the total quantity of fluid in the cerebrospinal spaces In the laboratory the cell count and differential cell count should be determined the protein content ascertained by the quantitative method if possible the globulin ring colloidal (preferably gold sol or benzoin) and Wassermann tests made, and the sugar content determined quantitatively if the fluid has not stood too long Bacteriologic studies are desirable if there is turbidity or if meningeal infection is strongly suspected

Clinical Application of Tests.—Let us now consider the diseases and pathologic conditions which evoke positive changes in the spinal fluid Because of striking similarity in fluid pathology these may most easily be compared in groups irrespective of their etiology This method also emphasizes any contrasts within a given group

The Acute Meningitides.—By the time that *acute meningitis* is suspected clinically the spinal fluid has usually undergone characteristic changes *i e* increase in pressure increase in the number of cells (polymorphonuclear leukocytes predominating) increase in the protein content and invasion by the infecting organism demonstrable both on film and culture The fluid at first merely cloudy rapidly becomes more turbid and purulent contains increasing numbers of organisms and cells and an increasing quantity of protein and fibrin either preformed or forming in the test tube. Sugar estimation is of great significance in all forms of acute meningitis Sugar is reduced early and rapidly falls a condition unknown in other diseases It should be emphasized that this test must be performed immediately after aspiration of the fluid because the sugar disappears *in vitro*

While the infecting organism is usually found with ease particularly the pneumococcus and streptococcus the meningococcus and *H influenzae* frequently cannot be recovered in the early stages of the disease even in the centrifugalized sediment. In such cases a number of procedures are recommended the spinal canal may be drained to permit recovery of the organism in the last portion of the fluid the neck may be rotated to loosen the exudate which tends to accumulate about the foramen magnum puncture of the cisterna magna may be employed and finally puncture of a lateral

ventricle All of these methods have been employed successfully for recovering the organism and for administering serum

In acute meningitis which has entered into a *subacute stage* there is a tendency for mucofibrinous masses to accumulate in different loci of the spinal and cerebral subarachnoid spaces especially in the lumbar sac and in the upper cervical canal Under such conditions the fluid is thick purulent, and scanty The organisms may be numerous or absent In such instances of meningitic block puncture at a higher level frequently yields plenty of fluid and organisms

Since the introduction of sulfonamides in the treatment of meningitis less frequent examination of the spinal fluid is indicated A preliminary examination however is necessary to determine the type of organism and in cases not doing well puncture at different loci is still indicated to determine the presence of exudative loculation The determination of sulfa drug level in the fluid may be advantageous but as it follows the blood level so closely it is usually not necessary

Numerous organisms attack the meninges but by far the most common are the streptococcus pneumococcus and meningococcus In epidemics the last assumes first place in frequency Other bacteria less frequently recovered are *Staphylococcus aureus* and *albus Bacillus pyocyaneus Hemophilus influenzae B typhosus B coli* and *Micrococcus catarrhalis* *As a rule the meningitis* caused by these less frequent organisms is of a less severe type but variations in the virulence of different strains make such a statement of only general significance

Aseptic Meningitis —Under certain conditions *aseptic meningitis* develops The fluid is usually turbid but colorless and not purulent although showing a polymorphonuclear cytology Most important is the absence of organisms and a normal sugar titer Aseptic meningitis develops in certain fevers such as pneumonia and is thought to result from the action of a toxin which passes into the cerebrospinal spaces A sterile cloudy fluid with 1000 or more cells is frequently seen in aural infections and usually signifies an epidural or subdural abscess It occurs regularly after injection of foreign substances into the subarachnoid space and is therefore a sequela of intraspinal injection of serum Lipiodol used for radiographic localization of tumors of the spinal cord causes a well marked transitory aseptic meningitis with symptoms of meningeal irritation as does air used for the same purpose and novocain injected for anesthetization Even salt solutions, not properly balanced, cause a reaction which may be classified as aseptic meningitis Severe meningeal and myelitic reactions have been caused by injection of various antiseptics

Tuberculous meningitis as a rule runs a fairly definite clinical course likewise the spinal fluid findings vary little with different patients The first fluid examination made early in the illness is usually characteristic of the disease, even though the clinical picture be doubtful, if not at first a comparison of fluid changes on successive punctures in the next few days yields findings which are almost conclusive

Early in the illness the fluid will be found abnormal pressure moderately elevated (200–300 mm) fluid clear or very slightly turbid a clot forming after standing If a sample of fluid is placed on ice a veil like clot appears suspended from the surface (so called pellicle) There will be numerous cells 50 to 100, both polynuclears and mononuclears in about equal proportion protein is markedly increased twice or three times normal Most significant of all the *sugar content is already low* As the disease progresses *the fluid* becomes more and more turbid the cells increase in number the protein also increases but the sugar diminishes

Tubercle bacilli may be found at any stage best obtained by staining the clot but without the bacterial evidence the progressive changes noted in the fluid are highly characteristic Guinea pig inoculation will seldom fail to give positive results but the long incubation period robs this method of diagnostic importance

Acute poliomyelitis acute encephalitis brain abscess and acute lymphocytic meningitis yield fluids which are similar Examination of the fluid alone does not differentiate these diseases and even a succession of examinations over a period of many *days often* fails to do so All have the following in common the pressure is high normal or moderately elevated dynamic tests *normal* the fluid clear or very slightly turbid but color

less The cell count in all is slightly elevated but more frequently less than 100 even the differential cell count is not fixed for while a mononuclear formula is the rule a few to many polynuclears are often present In epidemic encephalitis however polynuclears are rare and in poliomyelitis they are seldom seen after the first day or two of illness The protein tests show slight increase in all and in all the sugar remains normal throughout the illness. Colloidal tests are abnormal but variable in type and not helpful the Wassermann negative

Syphilis of the Central Nervous System — Since the fluid varies with the type of neurosyphilis and the stage and activity of the pathologic process it is necessary to consider separately the typical changes of the different clinical types of this protean disease in order to obtain a clean cut conception

Late Primary and Secondary Syphilis —In late primary and secondary syphilis the fluid frequently contains a moderately increased number of lymphocytes (20–50) a slightly increased quantity of protein and reacts positively to the Wassermann test Since it occurs in so many patients during the efflorescent stage most of whom never develop neurosyphilis it is likely that the reaction often represents an aseptic meningitis comparable with that described above. Still some of the patients presenting this picture early continue to show positive fluid findings and do develop neurosyphilis so that it is reasonable to consider these findings as consistent with incipient syphilis of the nervous system

Acute Meningitic Syphilis —During the first year usually about six months after infection acute meningitic symptoms may occasionally supervene The condition of the fluid in such acute syphilitic meningitis is quite characteristic the pressure is increased (250–350 mm) the cell count is high (500–1000 cells) lymphocytes predominate and polymorphonuclear leukocytes are numerous, the Wassermann reaction is strongly positive and collodal tests are positive but variable in type Fluid taken from patients with this acute meningitis has been shown when inoculated into the testicle of a rabbit to contain the *Treponema pallidum*.

Late Neurosyphilis Active Stage.—While late neurosyphilis may be separated into the tabetic meningovascular and general paretic types clinically it is impossible to do this by examination of the cerebrospinal fluid although one specimen may show a strong and another a weak syphilitic reaction (see Table 1) The strong reaction is found almost without fail in general paresis but is not pathognomonic in that it occurs frequently in less severe manifestations of neurosyphilis Both series of tests unmistakably denote active neurosyphilis but correlation with clinical experience suggests that the stronger reactions indicate more resistant infection and are associated with severe parenchymatous involvement Such reactions are characteristic of general paresis and in this disease are so constantly strong that in their absence a diagnosis of general paresis is questionable Strongly positive reactions may also occur in fluid from patients with tabes and syphilitic optic atrophy The weaker tests are characteristic of tabes and meningovascular syphilis when the process is active and advancing In by far the larger number of progressive cases of late neurosyphilis the reactions are of this character

Late Neurosyphilis. Inactive Stage —Many patients with obvious signs of neurosyphilis will be found to have normal or nearly normal spinal fluid There may be a slight increase in the protein content and a

Table I.—Two Types of Fluid Characteristic of Late Active Neurosyphilis

	Strong" reaction	"Weak" reaction
Cytology	10 to 40 mononuclears Plasma cells present.	20 to 80 mononuclears Plasma cells rare or absent
Total protein	80 to 125 mg per 100 cc	50 to 100 mg per 100 cc.
Globulin ring test	Strongly positive	Weakly positive.
Gold-sol	5 54321000	1123321000
Colloidal benzoin	Strong	Weak
Wassermann	Strongly positive.	Weak, moderate, or strongly positive.
Blood Wassermann	Strongly positive.	Positive or negative

weak gold sol reaction but not increase in the cell count and a negative Wassermann reaction Such conditions are characteristic of an inactive stage of the disease and usually indicate that the process is stationary whatever the extent of degeneration It is however well known that normal or relatively normal spinal fluid may be obtained in clinically active neurosyphilis as is proved by obtaining abnormal fluid from another locus or as evidenced postmortem

Under successful antisyphilitic therapy a return of the fluid reactions to normal is to be expected a drop in the cell count usually being the first sign of improvement and followed by reduction of protein content and a change in the Wassermann reaction The pathologic gold sol curve is often the most resistant abnormality The fluid frequently does not become completely normal even in patients who show persistent clinical improvement Under treatment the fluids of some patients remain fixed" and sometimes react more strongly than before treatment Experience shows that irrespective of apparent clinical improvement such unaltered reactions indicate progress of the disease and therefore a poor prognosis The relation between the clinical and serologic course of neurosyphilis is still debatable and cannot be further considered here

Spinal Subarachnoid Block—Normally the spinal subarachnoid space contains fluid which is freely interchangeable within the spinal canal and subject throughout its length to variations in pressure If at any point this space is constricted two independent fluid chambers are formed Change of pressure on one side of this block is not therefore transmitted to the other side (hydrodynamic evidence of block) and the composition of the fluid below the block also changes The most conspicuous alteration is a marked increase in the protein content presumably due to venous transudation (hydrostatic evidence of block) The most satisfactory although not the only method of demonstrating the hydrodynamic evidence of block is the artificial elevation of intracranial pressure by compression of the internal jugular veins of the neck Normally the pressure rises promptly in the lumbar manometer if block be present anywhere above the point of puncture however, no elevation of pressure occurs The hydrostatic evidence of block is *readily* seen in the marked increase in *protein content* which below the block sometimes approaches that of blood serum

Two *types of fluid* have been described as characteristic of block the *one yellow* which clots on standing (Froin syndrome of *coagulation massive et de xanthochromie*) the other clear and colorless which contains excess protein (Nonne syndrome) Neither type of fluid contains cells except in unusual cases when the block is associated with meningeal inflammation It is quite probable that both represent different degrees of the same process With both types of fluid block may be demonstrated by hydrodynamic tests

Spinal subarachnoid block is caused by a considerable number of pathologic processes which may be classified according to location (1) affections of the spine tumors abscesses pyogenic and tuberculous dislocations (2) intraspinal but extradural epidural abscess tumors (3) subdural tumors of the meninges acute fibrinopurulent exudate chronic adhesions cysts (4) intramedullary tumors gumma syringomyelia rarely

COMPLETE BLOCK—Experience shows that for the most part yellow fluids containing a large amount of protein and showing evidence of block (the Froin syndrome) occur especially in patients with pronounced transverse myelitic symptoms in whom the level of block is well determined by clinical examination

INCOMPLETE BLOCK—There are however numerous patients from whom a colorless fluid is obtained in which there is only moderate increase in protein content and no increase of the cell count (the cyto albuminous dissociation of the French) In them a *partial block* may be demonstrated in a number of ways by a slow rise in the manometric pressure following jugular compression by the existence of a latent period before the rise following jugular compression and by maintenance of a high pressure below the block after jugular release or most commonly by a combination of these three methods In such patients the diagnosis of block is less certain Combined cisternal and lumbar puncture is advisable to permit comparison of the fluids above and below the

block which provides much more conclusive hydrostatic and hydrodynamic evidence than lumbar puncture alone. These tests of the permeability of the spinal subarachnoid space have been of very great service in the early differentiation of obstructive and compressive lesions of the spinal cord from spinal cord affections which are primarily degenerative and do not produce block

The location of a spinal block may be visualized by the use of *iodized oil* In this country lipiodol (Lafay) as advocated by Sicard and Forestier is chiefly used Two cc of oil injected into the cisterna magna will fall when the patient is sitting to the top of spinal block and can there be seen by x ray film or fluoroscope If injected by the lumbar route and the patient placed in the Trendelenburg position the oil may be seen to stop at the lower pole of the blocked area The experienced observer may obtain from the character of the shadow not only help as to localization but also as to etiology

Cauda Equina Lesions—Tumors of the cauda equina not infrequently will give fluids similar to those of cord tumors just described with subarachnoid block and greatly increased protein as the significant findings *provided that lumbar puncture is made below the tumor* But as this is often difficult or impossible we must rely upon what evidence is obtained from puncture directly above the tumor and here we find a high protein fluid which is frequently yellow The further above the tumor the less abnormal is the fluid a fact readily demonstrated by multiple punctures The fluid above a cauda tumor is therefore similar to that from below but always less abnormal and most significant of all shows *no evidence of block*

Occasionally soft vascular tumors fill the lumbosacral canal as evidenced by persistently bloody fluid on puncture In such a case we must be on guard to distinguish between blood obtained from a tumor and bloody fluid from faulty technic (see later)

Of all the causes of low back pain and sciatica *herniation of an intervertebral disk* —usually L 4/5—has been found a frequent cause The majority of such herniations are accompanied by slight or moderate increase in the protein content of the fluid The fluid in most other conditions causing the same symptoms is normal except in cauda tumor in which case the protein increase is usually much greater than in ruptured disk. The herniation may be visualized by x ray following air injection or more satisfactorily by lipiodol both of which methods demonstrate a filling defect due to the hernia As the favorite site of a ruptured disc is low in the lumbar spine every endeavor should be made to puncture the sac below the suspected level as the fluid below this usually shows elevated protein whereas above it may be normal Hence it is often wise to perform a double lumbar puncture in order to obtain fluid both from above and from below the supposed hernia normally the protein from these two loci will vary little but in the presence of herniated disc there will usually be a considerable difference Occasionally a puncture below a herniated disc shows block and very high protein This occurs only when the disc cartilage has protruded so far as to be almost free and is so large that it stimulates an extradural tumor in causing transverse caudal symptomatology

Lateral Sinus Thrombosis—A modification of the Queckenstedt test is applicable to the diagnosis of lateral sinus thrombosis In such a condition compression of the jugular vein on the side of the lesion fails to elevate the fluid in the spinal manometer whereas compression on the unaffected side causes an excessive elevation equivalent to that normally seen when both veins are compressed The fluid findings are otherwise not characteristic although they usually show evidence of mild aseptic meningitis In the case of a mural thrombus this test is of course less striking The test has been found more *reliable in sinus thrombosis of the right side* than of the left as would seem reasonable from the anatomic finding that the torcula most frequently turns to the right and appears to discharge more blood to the right lateral sinus

Chronic Degenerative Diseases of the Central Nervous System—In such diseases as progressive muscular atrophy amyotrophic lateral sclerosis and *syringomyelia* combined system disease no distinctive alterations of the spinal fluid have been found As a rule a slight to moderate increase in the protein content and the presence of an

occasional lymphocyte and granular phagocyte give the impression that a destructive process is present but the changes which we are able to demonstrate today are in no way pathognomonic

In *active progressive multiple sclerosis* a combination of findings is highly characteristic With considerable uniformity the pressure of the fluid is normal the dynamic conditions normal the protein content high normal or slightly increased (40–60 mg per 100 cc) a trace of globulin present the cell count slightly increased (15–30 lymphocytes) and the Wassermann reaction negative The colloidal reaction is however strong and in the gold sol test there is not infrequently a paretic zone While not pathognomonic this combination of findings occurs often in multiple sclerosis and almost never in other diseases It is therefore significant In inactive nonprogressive multiple sclerosis the fluid is normal or changed as in other degenerative diseases just described

Neuritis and Radiculitis—The spinal fluid in peripheral neuritis is normal When the neuritis involves the nerve roots however we find an increase in protein sometimes a very considerable increase Guillain s dissociation cyto albumineuse is characteristically found in radiculitis (infectious neuronitis) The same is true of diabetic neuritis

Cerebral Hemorrhage—When bloody or blood tinged fluid is obtained on lumbar puncture immediate steps must be taken to determine whether the blood is in the fluid as the result of some abnormality or as the result of faulty technic. This point may usually be determined by receiving the fluid into three or more test tubes which will be decreasingly turbid if from the technic of puncture If the fluid containing blood derived from a pathologic source be centrifugalized evidence of hemolysis will be seen in the supernatant fluid

Granting that the blood is found in equal amounts in a series of test tubes we can safely assume that the subarachnoid fluid has been previously contaminated with blood and that if no previous puncture has been performed the blood indicates hemorrhage somewhere in the neuraxis The age of the hemorrhage may be roughly estimated by noting the color as it changes from red to orange to yellow Evidence of such a hemorrhage will usually be found for two to three weeks

Hemorrhagic fluids are under increased pressure at least early and show a protein content consistent with the amount of blood present but usually more white cells than would be expected because of the meningeal reaction to blood

The pathologic significance of blood in the spinal fluid can often be estimated with considerable certainty If found in persons who have just received a head injury it may be assumed that the *bleeding is from pial vessels* with or without brain injury If found in a young person with no injury, one thinks first of *spontaneous hemorrhage from aneurysm* at the brain base in an older person with hypertension and arteriosclerosis the *hemorrhage is primarily cerebral* with rupture into ventricles or subarachnoid space

Two important types of intracranial hemorrhage may fail to show frank blood on spinal puncture namely arterial hemorrhage into the epidural space and venous hemorrhage into the subdural space Yet both may be suspected by an increase in fluid pressure In the case of *subacute and chronic subdural hematoma* however we find in half the cases a yellow tinted fluid under slight increase in pressure and containing a little elevation of protein without cells.

While it is quite certain that small vascular accidents may occur in the brain with no recognizable fluid accompaniments such lesions be they small hemorrhages thromboses or emboli are frequently suspected on finding slight elevation in pressure and protein

Communicating Hydrocephalus and Serous Meningitis—The outstanding features of communicating hydrocephalus and serous meningitis are the presence of an excessive amount of spinal fluid and a diminished concentration of the fluid The excessive amount of fluid (50–75 cc) may be estimated by measuring the amount obtainable (normally about 15–20 cc) with the patient in the lateral position An idea of the quantity may be obtained also by noting the rapidity of drop in pressure on withdrawal of known amounts Normally the pressure drops approximately 30 mm in the manometer after withdrawal of 10 cc When the quantity is

large the drop is much less perhaps 10 or 20 mm The Ayala index attempts to express this relationship in mathematical terms The lower concentration of the fluid is best demonstrated by the protein tests these may show almost no turbidity not infrequently so little that it cannot be accurately measured

Uremia Diabetes and Myxedema—In at least three diseases in which metabolism is markedly altered there are characteristic changes in the spinal fluid In uremia the nonprotein nitrogen content is elevated and in diabetes the sugar content is increased This increase is roughly in proportion to but never so great as that in the blood In nephritis and especially in uremia the pressure is likely to be high and the amount of fluid increased If vascular accidents have occurred the total protein content is also increased The fluid findings in myxedema are of interest showing moderately high pressure and increase in protein As these fluid findings are also seen in brain tumor this *similarity should be recognized*

Brain Tumor—Lumbar puncture in the presence of subtentorial tumor should be considered a dangerous procedure and should not be performed except as indicated below Lumbar puncture in patients with tumors above the tentorium is usually safe but frequently aggravates the symptoms and is therefore *not to be performed without consideration* It is probable that any physician who has had wide experience with lumbar puncture has had personal experience with or knowledge of death either immediate or within twenty four hours following withdrawal of fluid Usually the cause is a tumor in the cerebellar fossa which produces hydrostatic pressure and medullary paralysis by wedging the medulla in the foramen magnum

When it seems essential to examine the spinal fluid although a tumor may be present it is reasonably safe to tap the spine if there is no well marked elevation of the optic disks If the disks are choked however it is wiser to omit lumbar puncture entirely or perform combined ventricular lumbar punctures which provide more valuable information and are safer By this method the lateral *ventricle is tapped first* and the pressure lowered before lumbar puncture is performed Then manometers are attached and dynamic studies carried out as in the case of suspected spinal subarachnoid block With subtentorial tumor a partial ventriculo subarachnoid block is characteristic The only tumors above the tentorium likely to produce block are those obstructing the aqueduct of Sylvius *i e* tumors of the third ventricle, pontine gliomata and pineal tumors.

Pressure in the case of tumors varies greatly from high normal to the highest recorded in any disease (frequently 700–800 mm) depending on the size and situation of the tumor A pressure of 1000 mm has been reported In the early evolution of the tumor however, no general brain pressure is exerted, and therefore no increase in pressure is found in the cerebrospinal fluid so that a normal pressure must not be considered as inconsistent with the presence of brain tumor In brain tumor the fluid is usually colorless but slightly yellow fluids are occasionally obtained usually in the case of subtentorial localization Rarely a supra *tentorial glioma with cystic degeneration* will give a yellow discoloration of the spinal fluid

One type of tumor characteristically yields a high protein titer *i.e* the acoustic neuroma Not infrequently the fluid is yellow As tumors of the cerebellum do not as a rule give such a fluid we have in the fluid examination a differential point of some value The safety of lumbar puncture is the presence of any brain tumor should be questioned especially in subtentorial tumors for in such tumors the possibility of medullary herniation into the foramen magnum is especially to be feared Therefore the physician should duly consider the advantages of the fluid examination as compared with the dangers of puncture in such cases

The protein content of the fluid also varies. It is most often just above normal (50–60 mg) but may reach 100 to 200 mg per 100 cc especially with subtentorial tumors In such patients there is a sharp contrast with the low protein content of the ventricular fluid and dynamic evidence of block is of importance in localization

Often no cells are found. More frequently a few arachnoid cells and lymphocytes give evidence of local irritation or degeneration occasionally all counts comparable with

those of aseptic meningitis are encountered Rarely have tumor cells been reported

There is usually an abnormal reaction in all colloidal tests but there is certainly no distinctive zone in the benzoin mastic or gold sol reaction

The Wassermann reaction is said to be occasionally positive with tumor but it is usually negative An unrecognized, associated syphilitic process is a reasonable explanation for this rare anomaly

On the whole the evidence obtained from lumbar puncture in a brain tumor suspect is likely to be less than hoped for and with the known danger already emphasized above is not to be performed without satisfactory reason Fluid analysis has proved of considerable value in three situations (1) when a brain tumor and vascular lesion of the brain cannot be differentiated elevated pressure and protein favor tumor (2) when tumor and syphilitic meningitis are indistinguishable, the cell increase and Wassermann reaction will settle the question (3) when acoustic neuroma is suspected a high protein and often yellow fluid will give added support to this diagnosis

Significance of Normal Fluid Findings —If the cerebrospinal fluid pathways be patent it is most unlikely that an inflammatory lesion or a space constricting tumor of any size can be present without accompanying change of some sort in the spinal fluid Small lesions must be excepted in this general statement such as certain vascular lesions mentioned above Likewise we have no criteria on which to base a diagnosis of the various degenerative processes These must be studied by pneumo encephalography a subject not here considered

Even in the case of certain expanding lesions of the cranium we must not be too dogmatic in our primary statement for not infrequently a tumor of the frontal lobe a large subdural hematoma or an abscess of considerable size, has been found present where fluid pressure and all tests were considered normal Nevertheless the significances of positive and negative findings alike are so often of importance that evaluation of the spinal fluid must be considered of prime importance in the diagnosis of obscure diseases of the nervous system

JAMES B AYER

SYPHILIS OF THE CENTRAL NERVOUS SYSTEM

(Meningovascular Tabetic and Paretic Neurosyphilis Congenital Neurosyphilis)

Neurosyphilis' is a general term which includes all those disorders of the nervous structures the envelopes surrounding them and the blood vessels traversing them which are caused by the *Treponema pallidum* The organism usually invades the nervous system early in the course of syphilis although symptoms may not appear for many years. The symptoms may be of almost any variety but may logically be considered as variations of a common disease caused by a single type of organism The clinical manifestations depend on the localization of the virus and the pathologic changes which in turn depend on the inherent reaction of the tissue invaded In 1913 when the *T pallidum* was found in patients with general paresis and tabes dorsalis evidence that these syndromes are types of neurosyphilis seemed to be complete At the same time, the concept of parasyphilis lost much of its meaning and with more satisfactory methods of treatment it is no longer necessary to consider it

The brain and spinal cord are composed of neurons and neuroglia cells Both are formed from the ectodermal layer The neurons form the true parenchymatous tissue The meninges* and blood vessels are derived from the mesoderm and are in no sense true nerve tissue but because of their close anatomic relationship with the brain and spinal cord any pathologic changes in them directly influence these latter structures From the viewpoint of morbid anatomy clinical symptomatology and response to antisyphilitic therapy it is convenient to think of neurosyphilis as being predominantly meningeal vascular or parenchymatous Such is the basis of the following discussion

Etiology —The *Treponema pallidum* is the cause of all neurosyphilis While the disease is generalized (primary and early secondary period) and the entire body is being invaded by the spirochetes the central nervous system rarely escapes This is evidenced by the symptoms the serologic changes and

* Recent work of Harvey suggests that the pia-arachnoid is of ectodermal origin

the presence of the spirochete in the cerebrospinal fluid In many cases the central nervous system apparently becomes sterilized and undergoes no later change but in 30 to 40 per cent this reaction of immunity is lacking or only partial and the spirochetes remain present within the central nervous system only to produce symptoms in later months or years Why some infected patients develop active neurosyphilis and the majority escape has been explained in several ways but no explanation is scientifically proved or free from doubt For example it has been stated that the *incidence of neurosyphilis* depends on the constitution and heredity of the individual affected and studies have been made which purport to show that neurosyphilitics are of the neurotic type Bolton claims that the histologic brain pattern which permits general paresis to develop can be recognized The theory that a particular strain of spirochetes has a definite neurotropism has also been advanced by numerous observers and there are several famous instances of the development of paresis or tabes in different individuals infected from the same source Conjugal neurosyphilis is relatively frequent Experimental evidence that there is a difference in the reaction of spirochetes taken from the fresh chancre and from the brain of the paretic has been obtained by Levaditi and A Marie Their evidence however is not free from criticism Another theory is that the condition of the patient at the time of his infection and the character of his immunity responses are all of primary importance. This latter view seems to be the best at the present time if only because it leads to thorough investigation of the nervous system in every syphilitic patient regardless of the stage of the disease

Symptoms.—The symptoms characteristic of early neurosyphilis of all types are headache due usually to the meningitis vertigo blurring of vision and mild optic neuritis None is necessarily present The spinal fluid during the primary and early secondary period frequently undergoes mild changes Its lymphocytic content increases globulin is present the gold sol reaction changes and the Wassermann reaction may be positive All these abnormalities may occur together At times the Wassermann reaction of the spinal fluid is positive before that of the blood becomes positive Spirochetes which could be grown in animals have been recovered from the spinal fluid in the very earliest stages of the disease As a rule the symptoms disappear either with treatment or spontaneously in much the same manner as does the skin roseola a fact probably to be accounted for by the immunity which the patient develops

Types—*Meningovascular Neurosyphilis (Cerebral Syphilis Spinal Syphilis Cerebrospinal Syphilis Syphilitic Meningitis Cerebral Gumma* etc) —DEFINITION.—Meningovascular neurosyphilis is an involvement of the membranes and vessels of the nervous system by the *Treponema pallidum* with or without secondary involvement of the nervous parenchyma Although it is usual for both meninges and blood vessels to be involved there are many instances where one or the other is predominantly affected and not so rarely there is almost exclusive involvement of either structure

INCIDENCE.—The condition is said to develop usually within the first five or six years after infection but is not rare many years later and is associated with congenital as well as with acquired syphilis No very definite statements can be made about the incidence of the various types of meningovascular neurosyphilis but it may be stated that approximately 20 to 30 per cent of all patients with syphilis develop meningovascular symptoms

MORBID ANATOMY —In the vast majority of cases the primary pathologic changes occur in the meninges and blood vessels and are therefore similar to the syphilitic lesions in other mesenchymal tissues In the *meninges* the reaction is of an exudative nature and the tissue is invaded by inflammatory cells for the most part by small lymphocytes but also by a few large lymphocytes and endothelial cells and an occasional plasma cell. The lesion is chiefly in the pia arachnoid although at times the dura is also involved In the very acute fulminating condition which is quite rare polymorphonuclear leukocytes may make up to 50 per cent of the infiltrating cells The meningitis may be somewhat localized or so extremely diffuse as to affect all the cerebrospinal meninges In the mild type the infiltration

is only slight, but it may become extremely marked The macroscopic picture of the pia of mildly affected patients is almost normal, a slight haziness being the only visible change If the lesion is more marked the membranes may be greatly thickened, have a matted appearance and occasionally even resemble creamy pus The very large gummatous lesions which may develop are similar to the gummatous tumors seen in other parts of the body Although the most frequent site of the meningitis is the base of the brain and the thoracic portion of the spinal cord other parts of the meninges may also be involved Individual nerve fibers may be surrounded by the exudate and compressed, and when the basal meningitis is relatively severe several nerves may be affected At times the spinal meningitis is so intense that the circumference of the cord is greatly compressed with consequent degeneration of the fiber tracts

Cerebral irritation may result from meningitis of the convexity Optic neuritis sometimes follows invasion of the pia in the region of the optic chiasm In certain acute conditions the cerebral cortex is involved by extension the spirochetes invading the cortical tissue and causing an encephalitic complication

The lesions of the cerebral *blood vessels* are similar to the vascular changes in other parts of the body the perivascular sheaths being infiltrated with lymphocytes There is some question whether the process starts in the intima, media, or adventitia but it is probable that the media undergoes the first change The relation of the coats becomes altered and because the elastica splits and the intimal lining is broken thrombi frequently form This is the most common serious vascular accident of neurosyphilis although at times hemorrhages occur from the weakened vessels

The spirochetes are relatively easily obtained from the lesions of the more acute types of meningitis and meningo encephalitis, on the other hand it is impossible to recover them from those of the chronic type and from gummata

Symptoms.—The symptoms of meningovascular neurosyphilis vary greatly according to the location and extent of the lesion the relative severity of the meningeal and vascular changes and the extent of the pathologic process One should always keep in mind that meningovascular neurosyphilis may simulate any form of nervous or mental disorder and produce symptoms resembling those of any neuropsychiatric condition

Although symptoms may develop within the very earliest period of the syphilitic infection or not appear until forty years or more after the primary stage, certain manifestations have come to be associated with the different stages of the disease. In the first weeks of the syphilitic infection the symptoms of cerebrospinal involvement are usually quite mild and consist chiefly of headache (probably due to meningeal irritation), tinnitus aurium vertigo, and blurring of vision At times pains may be caused throughout the body by irritation of the spinal nerves Ophthalmoscopic examination frequently reveals papillitis During this period however there may be symptoms of a very severe cerebrospinal meningitis with intense headache rigidity of the neck Kernig s sign and complete prostration Such a syndrome requires prompt and vigorous antileutic treatment

In the period beginning six months to a year after the primary stage severe meningovascular disasters including meningo encephalitis occur with relative frequency The meningitis may be either cerebral or spinal A palsy of one or more of the cerebral nerves may develop which is fleeting and disappears within a few days or may be more permanent When it is of very short duration recurrences are frequent Headache dizziness and visual and auditory symptoms are often noted Spinal cord symptoms are less frequent, but may develop as rheumatic pains in any part of the body and occasionally as disturbances of the sphincters Very marked spinal meningitis at the dorsal level sometimes leads to compression of the cord or to so called transverse myelitis with resulting spastic paraplegia Erb considered the syphilitic spastic paraplegia which bears his names as a primary degeneration of the corticospinal tracts but it is doubtful if such an entity exists because the few cases that have been studied pathologically show compression of the cord by the meningitis Gummata are quite infrequent in the first year

The *vascular disorders* are the most dreaded complication of the early period Thrombosis of one of the large meningeal or cerebral vessels is not infrequent The sylvian and lenticulostriate arteries are particularly susceptible to this lesion this results in hemiplegia These apoplectic conditions often come on without warning or on the contrary the patient may awake after a few days of headache and dizziness to find himself paralyzed. The paralysis is the result of a destruction of brain tissue due to the shutting off of the blood supply Although this condition usually develops during the first five to seven years after infection the syphilitic patient is liable to such manifestations of meningovascular syphilis throughout life

SEROLOGY —During the primary and early secondary period of mild neurosyphilis the changes in the spinal fluid are relatively insignificant Occasionally the Wassermann reaction in positive but more frequently there is slight pleocytosis (10–25 cells per cubic millimeter) A little globulin may be present, and there may be a weak gold sol reaction The blood Wassermann is negative during the early part and positive during the latter part of the primary period In the early secondary period of very mild cases the spinal fluid is very similar to that found during the primary stage while the Wassermann reaction of the blood is usually positive

In patients with symptoms, the reactions of the spinal fluid are likely to be rather strong after a few months. In most instances the Wassermann reaction is positive with 1 cc of fluid The cell count may be quite high (20–200 cells per cubic millimeter) and when the meningitic symptoms are relatively severe may run up into the thousands The fluid nearly always contains globulin and an increased quantity of albumin The gold reaction usually follows the so called 'luetic curve At times the serologic reactions may be strongly positive and resemble those of paretic neurosyphilis

If the lesions are chiefly vascular the serologic findings may be the same as those of the meningeal form but often they approach normal

Prognosis—Although the prognosis of meningovascular neurosyphilis is better than that of any of the other types of the disease no general statement can be made because there are so many different manifestations of the condition and the changes vary so greatly in the different stages The outlook for patients with meningeal lesions, whether early or advanced is usually excellent if treatment be adequate For those with fulminating neurosyphilis it is very doubtful even with the best of treatment, and if adequate and active therapy be omitted the prognosis is hopeless Of the strictly vascular conditions there are two types one which becomes manifest at an early period and may be so arrested by suitable treatment that there are no further vascular changes and another which appears at a later stage and responds to therapy less satisfactorily because the vascular lesions are more generalized Most patients however do improve greatly after treatment

Tabetic Neurosyphilis (Tabes Dorsalis Locomotor Ataxia Syphilitic Posterior Spinal Sclerosis) — DEFINITION — Tabetic neurosyphilis is an infection characterized by visceral crises and symptoms referable to the afferent spinal nerves and the nerves of special sense The kinesthetic and pain fibers are as a rule first affected this leads to progressive loss of position sense and to lancinating pains Trophic disturbances and disorders of the cerebral nerves are also frequently associated with the condition

MORBID ANATOMY —There is a degeneration of the posterior columns of the cord of the posterior roots and to some extent of the posterior ganglia Sometimes the optic nerve degenerates and other sensory nerves may be involved Meningitis generally of a mild chronic type usually accompanies tabes dorsalis

PATHOGENESIS —There is a general belief that the pathologic changes in tabes originate in the intradural portion of the posterior root. The French school has called attention to the possibility that the lesion may start in the posterior ganglia The degeneration of the cells of these ganglia is however rarely sufficient to explain the degree of degeneration within the posterior root Much notice has also been given to the idea that a toxin circulating in the spinal fluid affects the posterior root but this theory has been rendered less acceptable by

is only slight, but it may become extremely marked The macroscopic picture of the pia of mildly affected patients is almost normal a slight haziness being the only visible change If the lesion is more marked the membranes may be greatly thickened have a matted appearance and occasionally even resemble creamy pus The very large gummatous lesions which may develop are similar to the gummatous tumors seen in other parts of the body Although the most frequent site of the meningitis is the base of the brain and the thoracic portion of the spinal cord other parts of the meninges may also be involved Individual nerve fibers may be surrounded by the exudate and compressed and when the basal meningitis is relatively severe, several nerves may be affected At times the spinal meningitis is so intense that the circumference of the cord is greatly compressed with consequent degeneration of the fiber tracts

Cerebral irritation may result from meningitis of the convexity Optic neuritis sometimes follows invasion of the pia in the region of the optic chiasm In certain acute conditions the cerebral cortex is involved by extension the spirochetes invading the cortical tissue and causing an encephalitic complication

The lesions of the cerebral *blood vessels* are similar to the vascular changes in other parts of the body the perivascular sheaths being infiltrated with lymphocytes There is some question whether the process starts in the intima media or adventitia but it is probable that the media undergoes the first change The relation of the coats becomes altered and because the elastica splits and the intimal lining is broken thrombi frequently form This is the most common serious vascular accident of neurosyphilis although at times hemorrhages occur from the weakened vessels

The spirochetes are relatively easily obtained from the lesions of the more acute types of meningitis and meningo encephalitis on the other hand it is impossible to recover them from those of the chronic type and from gummata

Symptoms —The symptoms of meningovascular neurosyphilis vary greatly according to the location and extent of the lesion the relative severity of the meningeal and vascular changes and the extent of the pathologic process One should always keep in mind that meningovascular neurosyphilis may simulate any form of nervous or mental disorder and produce symptoms resembling those of any neuropsychiatric condition

Although symptoms may develop within the very earliest period of the syphilitic infection or not appear until forty years or more after the primary stage certain manifestations have come to be associated with the different stages of the disease. In the first weeks of the syphilitic infection the symptoms of cerebrospinal involvement are usually quite mild and consist chiefly of headache (probably due to meningeal irritation), tinnitus aurium, vertigo and blurring of vision At times pains may be caused throughout the body by irritation of the spinal nerves Ophthalmoscopic examination frequently reveals papillitis During this period however there may be symptoms of a very severe cerebrospinal meningitis with intense headache rigidity of the neck Kernig s sign and complete prostration Such a syndrome requires prompt and vigorous antileutic treatment

In the period beginning six months to a year after the primary stage severe meningovascular disasters including meningo encephalitis occur with relative frequency The meningitis may be either cerebral or spinal A palsy of one or more of the cerebral nerves may develop which is fleeting and disappears within a few days or may be more permanent When it is of very short duration recurrences are frequent Headache dizziness and visual and auditory symptoms are often noted Spinal cord symptoms are less frequent but may develop as rheumatic pains in any part of the body and occasionally as disturbances of the sphincters Very marked spinal meningitis at the dorsal level sometimes leads to compression of the cord or to so called transverse myelitis with resulting spastic paraplegia Erb considered the syphilitic spastic paraplegia which bears his names as a primary degeneration of the corticospinal tracts but it is doubtful if such an entity exists because the few cases that have been studied pathologically show compression of the cord by the meningitis Gummata are quite infrequent in the first year

brought down unsteadily as if being slapped on the floor This latter condition is characteristically tabetic.

During the early stages there is little if any loss of the tactile, pain or temperature *senses* Hyperthesia and hypalgesia develop later Hyperesthesia, especially of radicular distribution is quite common Rarely, in the late stages complete anesthesia develops and is followed by disappearance of the pain which may have been very severe The loss of kinesthetic sense as shown by inability to feel passive movements of the toes or fingers may be noted quite early

The *visceral crises* are relatively common manifestations. That most frequently seen is the *gastric crisis* which is characterized by recurrent abdominal distress and vomiting often associated with considerable pain in the abdomen The attacks come on without relation to food and may persist for hours or days at a time After the crisis has passed the patient feels well and has no gastro intestinal symptoms The attack may be extremely severe and controlled only by large doses of morphine The character of the crises varies greatly Some patients have mild nausea and distress while others vomit almost continuously This manifestation is not related to the general function of the gastro intestinal tract and gastric analyses and x ray studies are entirely negative in the typical uncomplicated case Since in some patients gastric crises are accompanied by no other troublesome tabetic symptoms and the reflexes may be quite normal some authorities consider the gastric crises a separate syndrome

Crises of other organs also occur Those in the rectum are characterized by diarrhea or tenesmus, those in the larynx by local spasm

Disorders of the sphincters are at times the first symptoms Incontinence of urine usually beginning as dribbling with great difficulty in starting the stream and inability to completely empty the bladder is a very common symptom The bladder has reduced tone dependent on loss of sensation and is readily recognized on cystoscopy as a spinal cord bladder In relatively few cases there is also loss of control of the rectal sphincter Loss of sexual power is a frequent and often an early symptom

Atrophy of the Nerves of Special Sense — Mild *optic atrophy* occurs in many cases of tabes that leading to marked diminution of vision or complete blindness however develops in about 10 per cent of all tabetic patients and may be an early or almost isolated symptom Like gastric tabes it may occur without the usual cord signs and symptoms and is often designated as optic tabes. The *auditory nerve* is sometimes similarly involved but marked degeneration is less frequent Symptoms depending upon atrophy of the *other nerves of special sense* are rare

Although *trophic disturbances* usually appear during the very late stages *Charcot joints* may develop at any period occurring most often in weight bearing joints *e g* hip knee ankle and spine The lesion is to be looked upon as the result of repeated traumata to the joint surface due to lack of sufficient joint sensation and consequent deficient muscular protection. *Perforating ulcers* which were formerly seen quite frequently are now extremely rare possibly because of modern methods of treatment

The most important *neurologic signs* are (1) absence of the knee jerks and ankle jerks and less frequently of the tendon jerks of the upper extremities (2) the Romberg sign (3) ataxia of the legs and less often of the hands (4) pupillary changes irregularity inequality sluggishness and the typical Argyll Robertson condition (5) loss of control of the sphincters and sexual impotence (6) sensory disturbances such as hypesthesia and even anesthesia and (7) Charcot joints

The *tendon reflexes* are typically lost early frequently before the appearance of any symptoms Their absence is caused by interruption of the reflex arc when the fibers of the posterior roots are destroyed Those of the lower extremities often disappear while the reflexes of the upper extremities are retained although when the upper part of the cord is involved the reverse is true The ankle jerks are frequently lost before the knee jerks. In many cases of tabes the reflexes are retained especially when there is evidence of gastric crises or optic tabes The *skin reflexes* may be present or absent The *abdominal reflexes* are likely to be absent as they are in other forms of syphilis

the more modern conception that all the morbid changes of neurosyphilis are caused by the activity of the spirochetes rather than by their toxin The fact that meningitis practically always develops has evoked the suggestion that the posterior root is pinched in the inflammatory process (compare with cerebral nerve palsies due to basal meningitis) but this does not explain the relatively infrequent involvement of the anterior roots

The work of Richter seems to demonstrate that the tabetic lesion is due to the activity of the spirochete itself and that the local change consists of a specific granuloma in the posterior root Richter has apparently succeeded in his attempt to show that the meningitis is a secondary and not a primary tabetic lesion or in other words that tabes may exist without meningitis The anatomic relationship as first pointed out by Nageotte is such that there is a more acute angle made by the posterior root and the meninges than by the anterior root According to Richter this offers a recess with less fluid in circulation in which the spirochetes can locate and this accounts for the greater frequency of involvement of the posterior than of the anterior root He points out however that the latter is affected late in the disease He has been able to demonstrate the presence of spirochetes in what he describes as a definitely specific granuloma of the posterior root This theory seems to be the most satisfactory and coincides most nearly with the present concept of the parasitology of syphilis

SYMPTOMS AND SIGNS—Most of the typical signs and symptoms of tabetic neurosyphilis appear only after the disease has persisted for some time and relatively few develop during the very early stages or in atypical conditions In the early stages tabes may be of two types in one the symptoms develop before the neurologic signs in the other the signs are the first to appear In fact in one group of patients the neurologic findings may be very nearly normal while there are such typical symptoms as lancinating (rheumatic) pains gastric crises and other visceral crises The diagnosis is confirmed by the spinal fluid findings In another group Argyll Robertson pupils and the absence of the tendon reflexes may be obvious before any symptoms develop

Of the characteristic *symptoms* the most common are related to the sensory system and are apparently caused by pathologic change in the posterior roots These symptoms are of the type of painful sensations or kinesthetic abnormalities the latter of which lead to motor incoordination The cerebral nerves of special sense especially the optic are often involved with subsequent symptoms such as blindness and deafness Visceral symptoms such as gastric rectal and laryngeal crises which are common probably depend on disorders of the sympathetic and autonomic fibers Trophic changes (perforating ulcer and Charcot joint) also occur

Pain which is the most common of the early symptoms usually begins in the legs and sooner or later becomes very severe It is often described as a burning gnawing or lancinating sensation such as might be produced if a hot knife were stuck into the flesh and twisted The attacks which come on with lightning like rapidity last for hours and are followed by only a brief interval of freedom Such attacks may recur throughout many years In some instances there is a sensation of constriction about the waist or chest (girdle sensation) which follows involvement of the radicular nerves Associated with the attacks are all sorts of abnormal sensory phenomena such as paresthesia numbness and sensations of cold warmth or tingling When the pain is very severe pressure on the skin may give relief or be intolerable because of the exquisite sensitiveness Occasionally ecchymoses appear on the skin in the region where the pain is felt.

Ataxia (incoordination), the result of loss of the fibers of the posterior roots and posterior columns often appears after the onset of the pain although it may be the earliest symptom and be unassociated with any other disorder of sensation It usually involves the lower extremities but occasionally affects the hands when the cord lesions are cervical The change of gait which usually develops slowly is ordinarily first noticed when the patient is *walking in the dark* Once in a while the change comes very suddenly The abnormality varies from a slight unsteadiness in the early stages to a marked change of gait in the late stages in which the foot is thrown into the air and

Pachymeningitis haemorrhagica is occasionally present The pia arachnoid becomes more or less thickened especially over the frontal regions and is usually milky or translucent Frequently, cerebrospinal fluid accumulates between the pia and the cortex as a result of cerebral atrophy The cerebral atrophy is most prominent at the frontal poles where the lesions are most marked and is manifested by widening of the sulci and flattening of the convolutions The ventricles are usually enlarged and ependymitis or roughening of the fourth ventricle is usually visible

Microscopically, the disease is characterized by degeneration of the nerve cells especially in the frontal region and as the disease progresses or in aberrant types in any part of the cortex cerebellum or bulb The structure of the cortex is greatly disturbed All types of pyknotic changes are present Completely degenerated cells are in close proximity to well preserved cells Gliosis compensates in part for the loss of nerve elements Satellitosis and phagocytosis occur and rod cells are often present. Perivascular infiltration of the small vessels of the cortex white matter and pia with lymphoid cells is always present Most striking and most characteristic is the presence in the tissue of plasma cells which in some instances form the majority of the infiltrating cells It is usually said that new blood vessels form in the affected areas Subependymal glia proliferation occurs in the ventricular areas and is most evident in the floor of the fourth ventricle Vascular sclerosis of the larger vessels is not a part of the paretic process and is to be considered a complication Degeneration of the fibers of the projection system results from the neuronal loss so that in late cases there is often degeneration of the corticospinal tract Tabetiform lesions of the cord are common

SYMPTOMS—The symptoms of paretic neurospyhilis are protein in character and form almost any syndrome. The onset is at times insidious at other times sudden For systematic discussion the mental symptoms may be divided into three groups (1) those of the period of onset often spoken of as the medico legal state (2) those of the period of full development of the disease and (3) those of the terminal period in which the patient is bedridden Such a division is entirely arbitrary and in many cases impracticable A galloping form of the disease is described which progresses very rapidly and leads to death within a short period

1 *The Early Stage*—Any *change in the personality of an adult* should arouse suspicion of paretic neurosyphilis The first changes in character may be very slight and of brief duration, a slight change in manner for instance greater irritability carelessness about the clothes and person lack of judgment absent mindedness, inability to concentrate increased fatigability hypersuggestibility and slowness of comprehension These symptoms may develop very early and be of very little apparent significance in themselves They may, however, lead to such disasters as heavy losses in business alcoholism and loss of reputation because of various excesses Very frequently *neurasthenic symptoms* develop into mild depression or on the other hand into euphoria and elation These symptoms may become much more marked after a period of days, weeks months or even years and lead to symptoms characteristic of the well established phase of the disease

The early physical signs and symptoms include headache visual disorders and loss of weight Often there is a slight disturbance of manual dexterity *i e* tremors of the outstretched hands and inability to make coordinated movements The frequent decrease of muscle tone especially of the face results in flattening of the nasolabial folds which reduces the facial expression and markings and often makes the patient appear younger than he is Another characteristic symptom is a speech defect which causes poor enunciation of such test phases as Methodist Episcopal third riding artillery brigade etc

The *pupillary changes* of neurosyphilis appear in the paretic form as in all others The typical Argyll Robertson pupil can only infrequently be seen In the early stage the reaction of the pupils may be quite normal or the dilated pupil may respond poorly to light. Later there is no reaction to light but there is response to accommodation and finally both types of reaction are lost

probably also because of interruption of the reflex arc in the posterior roots The *cremasteric reflexes* persist except in unusual or advanced conditions

The noteworthy *Romberg sign* (inability to maintain equilibrium with eyes closed and feet placed close together) may be observed before the patient has noticed any difficulty in walking because of the reduction of the normal flow of impulses from tendons and joints which are essential for reflex standing

Pupillary Signs—As in other types of neurosyphilis irregularity and inequality of the pupils are common early signs The pupils are almost always unequal and their early sluggishness of response usually increases until they are of the typical Argyll Robertson type *i e* respond in accommodation but not to light This type of reaction is seen more commonly in tabes than in any other form of neurosyphilis The pupils may be so contracted that their diameter is less than that of a small pin head but they may also be quite large. In not a few cases they become fixed and react to neither light nor accommodation

Motor Palsies—Paralyses of the extrinsic eye muscles especially the levator palpebrae and the external or internal recti may be the first manifestation of tabetic neurosyphilis to attract the patient s attention Such palsies may occur years before any of the other characteristic symptoms of tabes They are usually temporary lasting for a few days or weeks but are sometimes permanent As a rule they are accompanied by reflex anomalies in other parts of the body which are revealed by examination Lid drop or diplopia often precedes by several years the symptoms of which a tabetic patient complains but since these conditions right themselves rather promptly they are often not seriously considered Muscle tone is generally decreased in the extremities affected because of the reduction of afferent impulses to the cord Joint capsules are relaxed and increased mobility of the joints can be demonstrated

In the late stages of the disease the intrinsic muscles of the hand or foot may become wasted and also although more rarely the larger muscles This may result from degeneration of the anterior horn cells pinching of the anterior root by the meninges or, as Richter suggests from degeneration of the anterior root caused by spirochetal action at the junction of the anterior and posterior roots

SEROLOGY—Probably in the tabetic type as well as in the other forms of neurosyphilis changes take place in the spinal fluid before either signs or symptoms of the disease become manifest The reactions of the blood and spinal fluid in tabetic neurosyphilis are very similar to those in the meningovascular type Not infrequently the spinal fluid resembles that recovered from paretic patients and occasionally it is entirely negative apparently because of spontaneous arrest a condition which leads to the concept of a burned out process

DIAGNOSIS—Serologic tests usually permit recognition of tabetic neurosyphilis before the appearance of marked symptoms and signs Consequently when laboratory methods of diagnosis are employed and modern treatment is promptly instituted fewer cases are allowed to assume the typical characteristics It is well to bear in mind that a typical case is relatively far advanced and is past the stage in which the clinician can take pride in making a diagnosis

PROGNOSIS—Without treatment the symptoms usually increase slowly for many years until the patient finally becomes bedridden Frequently however the progress is so very slow that the change from year to year is only slight On the other hand symptoms may develop very rapidly Under treatment improvement is the rule and occasionally arrest of the progress occurs spontaneously

Paretic Neurosyphilis (General Paresis General Paralysis General Paralysis of the Insane Dementia Paralytica)—DEFINITION—Paretic neurosyphilis is a chronic syphilitic meningo encephalitis characterized by progressive dementia and a diffuse generalized paralysis which terminates in death

INCIDENCE—About 3 per cent of syphilitic patients develop symptoms of paresis They occur approximately three to five times as frequently in men as in women although the incidence of luetic infection is not greatly different in the two sexes

MORBID ANATOMY—In paretic neurosyphilis there is characteristically a macroscopic thickening of the dura which is frequently adherent to the calvarium.

ated with atrophy of the anterior horn cells The clinical diagnosis depends on the neurologic signs of neurosyphilis and the changes in the spinal fluid

Syphilitic epilepsy is not a well defined syndrome and there is much discussion concerning its existence. *Three types* are described in the first though there is no pathologic or serologic evidence of neurosyphilis epileptic seizures develop some time after the syphilitic infection of an individual supposedly without hereditary epileptic taint who has never had previous convulsions the second type is supposed to be related to meningo vascular neurosyphilis and is apparently the result of irritation of the brain, in the third type there is a parenchymatous disorder of luetic origin In the two latter there is the suggestion of an etiologic connection between the convulsions and syphilis in the first, such an hypothesis has little foundation It is true that epileptiform seizures are not rare in all types of cerebral neurosyphilis but the recurrence of convulsions over a period of years is very uncommon

Syphilitic paranoia is described in the German textbooks as a condition in which the patient has the clinical evidence of paranoia in conjunction with syphilis or neurosyphilis It is even less well established than the syphilitic epilepsies.

Syphilis of the peripheral nerves may be secondary to disease of such nearby structures as bones fasciae and muscles Gummata may encroach upon and implicate the nerves The peripheral nerves may however be affected by a direct extension of the inflammatory reaction along the lymph channels and perivascular spaces Such neuritis is known to cause palsy of motor nerves or in the case of the sensory nerves neuritic pains

Congenital neurosyphilis closely simulates all the syndromes of acquired neurosyphilis. Only too frequently the nervous involvement of congenital syphilis is not recognized during the early years of the patient s life Recent studies have shown that about 20 per cent of the patients with congenital syphilis show clinical or serologic evidence of neurosyphilis Symptoms may make their appearance in the first years of life or may be delayed until adolescence when they suggest meningovascular, tabetic, or paretic neurosyphilis

Juvenile tabetic neurosyphilis is very unusual The symptoms are quite similar to those of the acquired form except that pains are perhaps less frequent.

Juvenile paresis is relatively very frequent as compared with juvenile tabes (50 1 in the author s series) The usual age of onset is between twelve and eighteen years The patient may have appeared to be quite normal before the paretic symptoms develop showing few if any stigmata of congenital syphilis The characteristic clinical manifestation is usually dementia which progresses rather rapidly Occasionally the symptoms are those of grandiosity In other instances the child fails to develop mentally and is considered feebleminded The duration of life is usually from three to five years after the onset of mental symptoms

The serology of all juvenile neurosyphilis is identical with that of the acquired form

Syphilitic feeblemindedness is described in many textbooks but the author has not recognized such an entity Unless there is definite luetic involvement of the brain the juvenile syphilitic usually has the mentality characteristic of his family

Diagnosis —As the various syndromes of neurospyhilis simulate almost any organic or functional disease of the nervous system it is necessary to consider the possibility of the disease whenever neuropsychiatric signs or symptoms develop The history of syphilis and examination of the blood and spinal fluid usually suffice for diagnosis of neurosyphilis It is unusual and rare for the serology to be negative Frequently it is only by examination of the spinal fluid that diagnosis is possible When the serology is negative the diagnosis of neurosyphilis is permissible only if the symptoms are very characteristics since experience has shown that such conditions are usually nonsyphilitic. It is nearly always advisable to confirm the clinical diagnosis by examination of the spinal fluid

Differentiation of the various forms of neurosyphilis is made by the symptoms and to some extent by the condition of the cerebrospinal fluid Even pathologically however it is not possible to distinguish all types Thus syphilitic meningitis may simu

Changes in the *tendon reflexes* are common Atrophy of the efferent or afferent pathways may be so balanced as not to alter the reflexes or may increase diminish or destroy them As a rule the changes of the tendon reflexes are relatively late manifestations although they may take place before the onset of any other recognizable symptoms The Babinski sign ankle clonus and other pathologic reflexes are to be observed in the early stage but are usually associated with atypical conditions or vascular complications late in the disease they are common In the early stages the sphincters are rarely involved and there is often increased sexual potency

Sometimes the period of onset is short and the disease attains the fully developed stage with great rapidity, in fact a seizure may occur in a person in apparently good mental and physical condition and be followed by well developed symptoms of the established stage The progress may however be so slow that a year or more elapses between the onset of mental symptoms and the development of the characteristic syndrome

2 The *stage of full development* is characterized by varied symptoms which may mimic any type of mental disease Typically there is *euphoria* and the patient is grandiose elated with delusions of wealth and great prowess and feels better than ever before This classic syndrome appears in only 10 to 20 per cent of cases Another type is that of *depression* with anxiety fear of impending danger and self accusation A third well recognized syndrome is that of a *simple dementia* in which without either excitement depression or delusion formation the mind of the patient deteriorates In a fourth form *paranoid ideas* predominate There are many other variations which need not be mentioned here

Common to all the forms and of the greatest importance is the *progressive dementia* Loss of memory especially for recent events later for past events as well difficulty in calculation and writing and defects of judgment are sooner or later apparent

Paretic seizures of either the epileptiform or apoplectiform type which are frequently accompanied by transient paralyses are characteristic of this stage The defect of speech is more marked and the disorders of the reflexes become quite prominent

3 *Terminal Stage*—In the third stage physical weakness becomes very great The patient becomes bedridden and finally reaches the condition of a vegetative organism There is emaciation bed sores develop and generalized paralysis of all the muscles of the body ensues If death is not caused by a seizure or by intercurrent disease it finally results from paralysis of the respiratory muscles

Prognosis—Paretic neurosyphilis has in the past been considered invariably fatal but at the present time the prognosis is more hopeful because of the newer forms of therapy Untreated patients who still are far more numerous than those who receive adequate treatment live on the average two and one half to three years after the onset of definite symptoms Some patients however die in a seizure at the very onset of the disease others linger for five to six years and very exceptionally a patient lives as long as nine or ten years

Spontaneous remissions are characterized by improvement of both the mentality and the physical condition of the patient This may be so great as to allow the patient to return to his former occupation These remissions usually last no longer than six months very rarely they continue for a year In a few cases they have been reported to persist for a period of years Spontaneous remissions occur in 2 to 10 per cent of patients Patients *treated in the early stages of paresis* by fever or with tryparsamide or a combination of the two have shown remissions in 30 to 40 per cent of cases Another 20 to 30 per cent are apparently arrested but with considerable deterioration The accumulated evidence now is sufficient to show that very beneficial modification is possible and that the prognosis is less serious than it was previously

Syphilitic Spinal Muscular Atrophy—A quite rare form of neurosyphilis is that in which degeneration of the anterior horn cells of the spinal cord produces the syndrome of progressive spinal muscular atrophy The lesion consists of perivascular infiltration with lymphocytes and plasma cells and meningitis similar to that of tabes associ

presents a different therapeutic problem The author is firmly convinced that no definite generalization is permissible and that the routines supposed to be applicable to many different types of cases are *illogical* and reprehensible The following outline of some very fundamental principles of treatment is based entirely upon the author's personal experience and may not agree at all with the beliefs of various authorities

Care of the *general hygiene* of the patient is one of the important features of the treatment of all types of neurosyphilis Many individuals improve when they have plenty of rest, fresh air and good food receive hydrotherapy and have their somatic defects corrected Coordination exercises are of the greatest importance at the ataxic stage of tabes and often bring marked symptomatic improvement

Fever and *tryparsamide* are the two main reliances in the treatment of the more serious types of neurosyphilis These methods have now thoroughly established themselves and over a period of approximately a score of years have been found to give rather consistent results Their value can be best considered in relation to the treatment of general paresis which previous to the introduction of these methods was almost out of the field of therapeutics. With the use of either *fever or tryparsamide it is possible to arrest* the active progress of the spirochete in at least 70 per cent of the cases Approximately 30 to 40 per cent make improvement clinically sufficient to return the patient to his former place in society and in approximately an equal number there is evidence of an arrest of the process as shown by cessation of the progress of the disease or by serologic criteria The results are very much the same with either method but fever has the advantage of working more rapidly Certainly the combination of fever and tryparsamide affords the best chance of success and the combined use is advisable both from the standpoint of doing as much as possible for the patient and because the continuing use of tryparsamide affords a greater guarantee against the relapse

There are a number of methods of involving fever for therapeutic purposes The one that has been used most extensively is *malaria* In usual practice the *Plasmodium vivax* the organism of tertian malaria, is employed as being mildest and most easily controlled In some cases where the patient is immune to this organism a quartan strain *may be preferable The only practical way* at present of transmitting the disease is from patient to patient In institutions which treat a good many such patients it is possible to keep a constant supply of infected patients as sources from which blood can be obtained for the inoculation of others As a rule eight to ten paroxysms are considered a sufficient course of malarial fever although occasionally fewer attacks will produce adequate results and at other times more paroxysms are allowed to the patient

Fever produced by *mechanical modalities* such as hot moist air boxes inductothermy warm water sprays etc is well standardized and allows for the development and maintenance of any temperature level desired The advantage of mechanically produced fever is that it is somewhat safer than malaria and can be given one day a week allowing a patient to continue his occupation on the other days This type of treatment requires an elaborate set up with experienced physician and technician Opinions differ as to the relative therapeutic value of malaria and mechanical fever

Fever may be produced by the *intravenous injection of typhoid vaccine* by certain *sulfur preparations* and other *protein shock methods* By and large these latter methods are not by any means so valuable as either the malaria or mechanically produced fevers

Following the course of fever it is the custom of many clinics to give weekly injections of tryparsamide either in courses of ten to twelve injections followed by a rest period or more or less continuously until the spinal fluid has become negative

It is logical to assume that these methods would be relatively more successful in the treatment of the less recalcitrant types of neurosyphilis than in general paresis As a matter of fact in the meningeal and meningo vascular neurosyphilis where there is not too much vascular degeneration tryparsamide aided by arsphenamine and bismuth has such a high degree of efficacy that fever is hardly ever required In fact in the relatively pure cases of meningeal syphilis the arsphenamines or bismuth are capable

late the tabetic condition in spite of a quite different course, it is then known as 'syphilitic pseudotabes' Likewise the meningovascular type may be erroneously diagnosed as paresis and *vice versa.*

Tables 1 to 4 outline the changes usually found in the spinal fluid in the different types of neurosyphilis and offer some possible aids to differentiation

TABLE 1 —SPINAL FLUID FORMULAE IN MENINGOVASCULAR AND TABETIC NEUROSYPHILIS

WASSERMANN REACTION	CELLS	TOTAL PROTEIN	GLOBULIN	GOLD SOL.
Positive in 0 05 to 1 cc 40 per cent negative with 0 2 cc Pure vascular neurosyphilis usually negative with 1 cc	Tabes 0 to 200+ Average 25 to 50	17 to 150 mgm per 100 cc Average 78	0 to ++++	0122100000 0134431000 3332100000 4443210000 5555431000
	Meningovascular and acute meningitis 200 to 2000	Average 99 mgm per 100 cc		
	Chronic 0 to 200+	Average 73 mgm per 100 cc		
	Vascular often no increase	Average 50 mgm per 100 cc		

TABLE 2 —VARIETIES OF SPINAL FLUID FORMULAE IN MENINGOVASCULAR NEUROSYPHILIS

WASSERMANN REACTION	CELLS	TOTAL PROTEIN	GLOBULIN	GOLD SOL.	REMARKS

Treatment —Each case of neurosyphilis

weakness of the lower extremities occurs as a result of the pyramidal tracts becoming involved Because of the progressive involve

Fig 186—Section of the spinal cord of the patient shown in Fig 188 with amyotrophic lateral sclerosis showing degeneration of the lateral columns and preservation of the posterior columns The anterior horn cells have disappeared

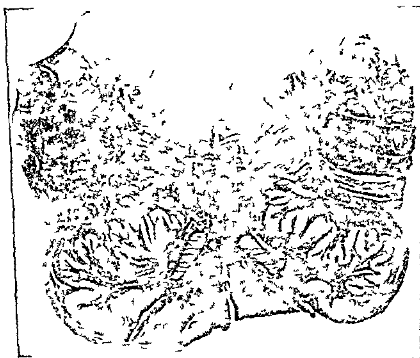

Fig 187—Section of the medulla oblongata from a case of amyotrophic lateral sclerosis shown in Fig 188 The cells of the hypoglossal nuclei are degenerated The pyramidal tracts were not completely degenerated

ment of anterior horn cells in the cervical cord there may be almost constant fibrillary tremors noted in the hand and arm muscles until wasting of these muscles is complete There is no pain no other subjective or objective sensory disturbance and the sphincters are seldom involved In the early stages of the disease the tendon reflexes in the upper extremities may be preserved or even increased but as the wasting of these muscles progresses the reflexes may be dimin

themselves of producing very good results in a substantial percentage of cases In purely vascular neurosyphilis the problem is practically identical with that of vascular syphilis elsewhere in the body and while brilliant results are not attainable the best relief can be obtained by the use of small doses of arsphenamine bismuth and iodides

In the tabetic type of neurosyphilis the problem is very similar to that in general paresis but the results by and large are not quite so satisfactory due largely to the complications that may arise and to the fact that there is often a type of damage that cannot be repaired Some of the mild cases react very satisfactorily to arsphenamine alone Others do very well with a combination of tryparsamide and arsphenamine and not a few react satisfactorily only to fever As a rule it is a matter of slow trial to find the optimum method of treating the tabetic It is in this type of neurosyphilis that the intraspinal injection of the Swift Ellis serum has its greatest place As a matter of fact however it is being used less and less because of the pain and discomfort as well as the risk and technical difficulties inherent in this method

Visceral crises are satisfactorily affected in only about half the cases by whatever method used although in recent times many claim that mechanically produced fevers will give good results in a higher percentage than this Difficulties with the sphincters when once established are only rarely benefited by any form of antiluetic treatment and usually require the care of a genito urinary specialist

Optic atrophy is especially difficult to handle There is considerable divergence of opinion as to the feasibility of handling it at all However there is some evidence that fever does favorably influence some cases especially those that have not developed too far The intracisternal injection of arsphenaminized serum is looked upon favorably by a few authorities Tryparsamide is usually contraindicated in these cases as the drug may injure the optic nerve The chief hazard of tryparsamide is its tendency to damage the optic nerve and visual disturbances occur in 3 to 5 per cent of cases in which it is used though as a rule the damage is slight It must be used however with great care and circumspection in all cases

HARRY C SOLOMON

DISEASES OF THE MOTOR TRACTS

Amyotrophic Lateral Sclerosis —This condition was first adequately described by Charcot in 1865 It is a disease of adult life in which the cervical regions of the spinal cord are first attacked with involvement of the anterior horn cells and the pyramidal tracts As a result of this the muscles of the upper extremities undergo atrophy and present the picture of a lower motor neurone paralysis while a spastic weakness an upper motor neurone syndrome occurs in the lower extremities As the disease progresses upward extension ensues with involvement of the bulbar nuclei and a true bulbar palsy with atrophy of the tongue cheeks facial and pharyngeal muscles is noted in the terminal phase

Etiology —The cause is unknown but it is the writer s opinion that the process may be initiated as a result of ischemia of the cells and tracts at the involved level At the point of the cervical cord enlargement there is a great number of cells with a high respiratory quotient and as diminution of systemic circulatory efficiency occurs these cells may undergo ischemic degeneration The syndrome has been reported in chronic lead poisoning and syphilis Trauma has also been considered a cause

Pathology —The cervical cord is usually the initial site of the lesion Here the anterior horn cells manifest various stages of degeneration and the lateral columns likewise indicate involvement As the process extends upward the cranial nerve nuclei become involved with resulting symptoms of progressive bulbar palsy being added (At post mortem the motor tracts are found degenerated up to the cortex)

Symptoms and Course —The disease usually begins after the third decade of life The first symptom is commonly symmetrical weakness and atrophy of the muscles of the hands The insidious wasting of the thenar hypothenar and interosseous muscles later extends to the shoulders and eventually

Morbid Anatomy—Degeneration of the pyramidal tracts is usually seen in the lower dorsal segments

Symptoms—Slowly progressive weakness of both lower extremities is the characteristic symptom The weakness is bilateral and of a spastic type In this disorder an extreme scissors gait' may be seen as a result of the extreme rigidity of the adductor muscles Increased tendon reflexes positive Babinski and ankle clonus are almost invariably present but sensory changes are absent The sphincters are rarely involved and the upper extremities are not affected Mills reported a case in which the disease appeared to be unilateral

Diagnosis—With evidence of a progressive bilateral pyramidal tract involvement to the state of a spastic paraplegia the disease should be suspected if there is no evidence of any involvement of other structures—especially if the spasticity seems to be greater than the degree of weakness *Multiple sclerosis posterolateral sclerosis syphilis* and *spinal cord tumor* may resemble the disease but in all of these there are symptoms of involvement of other structures

Treatment—Where an etiology can be established the treatment is logically the treatment of the basic disease In the absence of a determined etiology vitamin therapy should be initiated

Prognosis—The prognosis is poor unless the cause is discovered and successfully treated before the changes are irreversible

Progressive Bulbar Palsy (*Progressive Glosso pharyngo labial Paralysis*) —*Definition*—This is an uncommon disease of later life in which symptoms of a lower motor neurone type of paralysis involving the muscles of phonation mastication and deglutition occur with atrophy of the muscles of the tongue lips jaws larynx and pharynx

Etiology—No cause is known but it is possible that an ischemic type of cell death occurs because of inadequacy of circulation in the pons and medulla The syndrome may be added to that of amyotrophic lateral sclerosis as a terminal phase

Symptoms and Course—The disorder usually begins around fifty years of age The earliest symptoms are difficulty in articulating the lingual and labial sounds and interference with chewing because of the weakness of the tongue and muscles of mastication Atrophy of the involved muscles progresses and the presence of fibrillary tremors in the muscles of the pharynx tongue masseters and cheeks is a prominent feature and is presumably due to involvement of the cells in the cranial nerve nuclei When atrophy of a muscle becomes complete the tremors cease The disease progresses at a variable rate and sometimes may appear to be arrested As a rule however, the disease terminates fatally in from six months to three years Death usually occurs from aspiration pneumonia or from inanition The difficulty in swallowing may be slow in appearing Solid foods or liquids of low specific gravity may at first present difficulty while soft foods milk cream and thin broths may be swallowed with comparative ease No sensory disturbance occurs and in typical cases no loss of power of the extremities is seen Intelligence is likewise preserved

Diagnosis—The disease offers few diagnostic difficulties if it is kept in mind that atrophy of the facioglossopharyngolabial muscles is a distinct feature and that there are no associated disturbances of sensation or power elsewhere In *pseudobulbar palsy* similar difficulties of speech mastication and deglutition may occur but there is no muscle atrophy In *myasthenia gravis* the symptoms fluctuate are either produced or aggravated by effort and are relieved by rest In uncomplicated myasthenia there is no atrophy of the tongue or other muscles In *amyotrophic lateral sclerosis* which may produce a bulbar palsy there is evidence of cervical spinal cord and pyramidal tract disease In *tumors* and other intrinsic lesions of the brain stem sensory and other motor symptoms are present

Treatment—No successful treatment is known but sustaining life by soft diet and vitamin reinforcement is advisable If there is evidence of circulatory inadequacy circulatory stimulants and transcerebral diathermy may be helpful

Progressive Spinal Muscular Atrophy (*Aran Duchenne Progressive Muscular Atrophy Chronic Anterior Poliomyelitis*) —This is characterized by progressive muscular wasting due to degeneration of anterior horn cells of the spinal cord It usually

ished or abolished while in the legs the tendon reflexes may at first be normal but as the lesion advances they eventually become increased and pathological plantar reflexes are demonstrable Within six to eight months a complete flaccid paralysis of the arms may become established and spastic paralysis of the lower extremities results in total disability of the individual The terminal phase of the disease is ushered in with the involvement of bulbar cranial nerve nuclei, with resulting difficulty in swallowing (dysphagia), chewing and talking (dysarthria) Death may occur from deglutition death usually occurring within three to ten years of onset

Treatment —No form of treatment is uniformly successful, much benefit has been reported from the administration of large doses of vitamin B_6 (8 cc of wheat germ oil and 50 mg or more of alpha tocopheral acetate daily) by some investigators, but others, including the author have seen no beneficial results Laminectomy and decompression have advocates as has deep x ray therapy During the stage of bulbar paralysis care must be exercised to prevent choking and a soft diet must be provided

Fig 188 —Amyotrophic lateral sclerosis of three years duration showing muscular atrophy of hands and upper limbs Patient died of bulbar symptoms one month after this photograph was taken Sections of the spinal cord and medulla oblongata of this case are shown in Figs 186 and 187

pneumonia or choking The sensory tracts are not involved and intelligence remains intact but occasionally involuntary crying and laughing occur

Differential Diagnosis —The picture resembles *syringomyelia* but subjective or objective sensory involvement is absent and the course is much more rapid than in syringomyelia A tumor implicating the *cervical spinal cord* may present a similar picture but again sensory changes are nearly always present *Progressive spinal muscular atrophy* does not involve the pyramidal tracts.

Prognosis —The prognosis is grave with

Primary Lateral Sclerosis (*Spastic Spinal Sclerosis of Erb*) —The group of symptoms described under this name by Erb in 1875 is regarded as a syndrome of variable etiology The symptoms are progressive spastic paralysis of the lower extremities with the typical reflex changes of bilateral pyramidal tract involvement.

Etiology —The etiology is obscure but many cases are undoubtedly due to vitamin deficiency The writer believes that many are due to demyelinization as a result of chronic passive congestion of the cord in patients with disorders effecting an increase of intrathoraco abdominal pressure

Diagnosis.—Because of the familial tendencies and the implication of the proximal portions of the limbs the greatest difficulty may be experienced in differentiating this condition from *progressive muscular dystrophy* but the absence of hypertrophy and pseudohypertrophy and the presence of fibrillary tremors of the muscles serve to distinguish it. *Congenital myatonia* differs from it in being congenital in origin and without familial tendencies and by the proportionately greater involvement of the muscles of the trunk at a much earlier age but pathologically the two conditions cannot be separated It should not be confused with a form of *primary* or *idiopathic wasting* that occurs in very young babies because of failure of nutrition

Prognosis.—As in the adult form the disease generally ends fatally as the result of intercurrent disease Recovery is unknown

The Neural Form of Progressive Muscular Atrophy (*Charcot Marie Tooth Type Peroneal Atrophy*).—*Definition*.—This type of progressive muscular atrophy was described independently by Charcot and Marie and by Tooth in 1886 It is essentially a slowly progressive atrophy of the peroneal muscles

Etiology.—The exact cause is unknown but there is a marked heredofamilial tendency and a congenital defect is likely Isolated cases are also seen

Pathology.—The predominant lesions are found in the nerves and both the anterior and posterior roots may show degenerative changes The cord is also involved and degeneration may be noted in the posterior and lateral columns The anterior horns are seldom intensely affected but may show minor changes

Symptoms and Course.—Onset is usually in childhood or before puberty but may occur in early adult life Atrophy and pes varus and equinovarus or other deformities of the foot occur insidiously with resulting difficulty in walking Ankylosis of the ankle and of intrinsic joints of the foot may develop Slowly the atrophic changes spread to involve the muscles below the knee—only rarely do the muscles above the knee become involved Eventually the muscles of the hands and forearm become similarly affected with no involvement about the elbows It is noteworthy that the atrophy is out of proportion to the loss of power A wizened leg or hand may carry on to a surprising degree Fibrillary tremors are common and reflexes are lost in the involved muscles Sensation is usually disturbed along the same neural pattern but progresses even more slowly than the motor disturbance

Fig 189.—Progressive neural muscular atrophy (progressive muscular atrophy of the Charcot Marie-Tooth type) of about twenty years duration showing atrophy most intense in the distal portions of the extremities

Subjective sensory symptoms such as paresthesias and pain are fairly common and occasionally trophic changes of the skin occur especially in the feet

Diagnosis.—An old *peripheral neuritis* may present a picture resembling the disease but there the onset occurs with greater rapidity and is usually painful

Prognosis.—Life may be extended to old

begins with atrophy of the small muscles of the hands but the shoulder or other muscles may become involved first The disease generally shows symmetrical involvement but it may originate and remain as a unilateral process for some time

Etiology—Occasionally the symptom complex is caused by *syphilis* and may respond dramatically to antiluetic treatment but as a rule the cause cannot be determined In some instances it has followed years after an attack of acute poliomyelitis The disease like others in this group termed abiotrophies by Gowers occurs in middle life and the author thinks that the process is due to ischemia of the anterior horn cells The thought is that these large cells having a high nutrition requirement begin to degenerate when circulatory inadequacy occurs in later life

Morbid Anatomy—The characteristic lesions consist of atrophic and degenerative changes of the anterior horn cells In typical cases no inflammatory changes are noted

Symptoms—Muscular wasting and resulting weakness begin insidiously and slowly progress through the various levels of the spinal cord Usually the hands are involved first the forearms arms shoulders trunk and lower extremities later Fibrillary tremors are frequently noted in the muscles involved The disease is a slowly progressive rather than a malignant one and it may be fifteen to twenty years from the time of onset before it is a distinctly disabling one As atrophy involves a muscle its reflex may be abolished but the reflexes at uninvolved levels of the cord remain normal since the pyramidal tract is not implicated No sensory changes occur

Diagnosis—*Amyotrophic lateral sclerosis* is a more rapidly progressive disease and the pyramidal tracts are always involved *Syringomyelia* presents the typical dissociation of pain sensation as well as pyramidal tract signs

Prognosis—Life may be lived in comparative comfort for many years and death usually occurs from intercurrent disorders Remissions often take place with the disease becoming stationary

Treatment—General tonic and supportive measures with vitamin reinforcement of the diet appear to retard the progress of the disease and may effect a remission

Progressive Spinal Muscular Atrophy of Childhood of Familial or Hereditary Character (*Werdnig Hoffmann Type*)—*Definition*—Progressive spinal muscular atrophy of childhood is a condition first described by Werdnig and later by Hoffmann, which differs from the adult form of spinal atrophy in its hereditary and familial tendencies It develops in the early years of life involving first the muscles of the pelvic girdle then extending toward the ends of the limbs It is dependent on degeneration of the anterior horn cells and the peripheral motor nerve fibers and on alterations in the crossed pyramidal tracts

Etiology—The cause is unknown Several children of the same parents may be affected but isolated cases also occur The condition is most probably dependent upon a defect in the development of the nervous system (abiotrophy)

Morbid Anatomy—In Hoffmann s patients there was degeneration of the multipolar cells of the anterior horns of the spinal cord intense degeneration of the anterior roots and less marked change in the peripheral nerves together with degeneration of the crossed and direct pyramidal tracts The muscles undergo simple atrophy

Symptoms and Course—The disease begins in childhood and progresses slowly The child either never learns to walk or loses the ability to do so The condition is manifested by weakness and atrophy of the muscles of the trunk and pelvic girdle the iliopsoas quadriceps femoris and later of those of the upper limbs and neck The proximal portions of the limbs are affected first the changes then slowly extending to the hands and legs A year or more elapses before the distal portions of the limbs are involved The wasting of the muscles is generally symmetrical and so uniform is the atrophy that in the beginning it may be concealed by fatty tissue The tendon reflexes are abolished Fibrillary tremors may be present but frequently are absent. Hypertrophy never occurs Sensation is not disturbed Bulbar symptoms sometimes develop but are rare The disease is progressive and generally ends fatally before the seventh year

the cerebrospinal fluid from its point of formation in the choroid plexuses of the lateral and third ventricles to the fourth ventricle and thence to the subarachnoid space through the foramina of Magendie and Luschka When normal absorption of the fluid in the subarachnoid space is thus prevented its accumulation in the lateral and third ventricles produces *internal hydrocephalus (obstructive internal hydrocephalus)*

The *diagnostic test* for this is injection of a neutral dye (indigo carmine) which is specially prepared into one of the lateral ventricles and a few minutes later removal of some of the spinal fluid by lumbar puncture If the dye does not appear in the fluid thus obtained there is obstruction in the sylvian aqueduct or in the foramen of Monro By introducing air into the lateral ventricle (Dandy s ventriculography) the exact site of the obstruction can often be determined The *prognosis* of congenital hydrocephalus is serious although in many children the disease is arrested and physical and mental development is more or less normal Measurement of the skull at regular intervals enables the physician to determine how rapidly the condition progresses

Treatment is hazardous but recoveries have been observed in Bellevue Hospital after opening the wall of the third ventricle Removal of fluid from the ventricles is easy before the fontanels have closed but is of little if any benefit it is not without danger of sudden collapse if performed too rapidly Dandy and others have actually put sounds and later tubes through partially obstructed sylvian aqueducts with good results in a few cases This is of course a difficult and dangerous operation

Meningocele is hernia of the membranes of the brain through a cleft in the skull *encephalocele* is also protrusion of the brain substance usually in the occipital region in the median line

Spina bifida is a congenital defect of the sacral or lower lumbar vertebrae which is very often associated with protrusion of the meninges These form a lump under the skin which is soft and contains cerebrospinal fluid and at times portions of the cauda equina or of the spinal cord itself Spina bifida is apt to be associated with other developmental anomalies such as cervical rib syringomyelia or hydrocephaly Sometimes when the bony defect is slight there is no lump (meningocele) but a tuft of hair or a pad of fat lies over the lesion this condition is called *spina bifida occulta* Both *spina bifida* and *spina bifida occulta* may produce a definite syndrome The lower limbs are weak and often much atrophied below the knee There is incontinence of urine or perhaps enuresis Trophic ulcers are very prone to develop on the soles of the feet either spontaneously or as a result of slight injury to the skin (a blister for example produced by a badly fitted shoe) The ankle jerks are absent as a rule This condition may manifest itself only at puberty when the more rapid growth of the spine compared with the spinal cord and roots within causes pernicious traction on the cauda equina which results in functional disturbance of the sacral and lower lumbar motor and sensory roots

The *prognosis* depends on the extent of the hernia and what it contains The sac if large may rupture and cause death at once or later from purulent meningitis Surgical intervention has saved some patients. If the sac contains only fluid and meninges the chance of cure is greater than when it also contains nerve structures

Treatment —The best time for the operative treatment of spina bifida is usually the first few weeks of life Operation very soon after birth is indicated in some cases when the sac ruptures or threatens to rupture Penfield and Cone have recently devised a new technic for the prevention of hydrocephalus following operation on spina bifida

Defects of the Spinal Cord —Entire absence of the spinal cord (*amyelia*) is associated with anencephaly *Amyelencephaly* is absence of both brain and spinal cord *Atelomyelia* is lack of development of the cord *e g* absence of the pyramidal tracts *Asymmetry* of the cord occurs with possibly defective development of one pyramidal tract In *heterotopia* the gray portions of the cord are displaced so that patches of gray matter are scattered among the bundles of white fibers this condition is sometimes produced artificially at autopsy by rough removal of the cord *Micromyelia* the presence of an abnormally small spinal cord is

age but there is no known successful treatment that can be expected to alter the course of the disease Remissions or arrests may occur before full evolution of the disease picture

Treatment —Some successes are reported with vitamin B and E therapy but are difficult to evaluate because of the tendency for arrest to occur at various stages

HEREDITARY AND FAMILIAL DISEASES OF THE NERVOUS SYSTEM

THE nervous system like the other structures of the human body is not always complete or normal at birth Furthermore it may appear to be normal at birth and for a number of years thereafter then suddenly or gradually there develops some defect in function or structure which manifests itself as a syndrome or disease The more important of these disturbances including those which occur in more than one member of a family are briefly described here

MALFORMATIONS OF THE BRAIN MENINGES AND SPINAL CORD

At birth the brain may be entirely absent—*anencephalia*—or absent except for the cerebellum and part of the basal ganglia Such conditions are associated with *acrania* Sometimes when development is arrested the cerebrum remains single instead of separating into two hemispheres there is only one ventricle and the rudiments of the eyes unite to form one eye (*cyclopia*) When the skull is abnormally small (*microcephaly*) and the brain is also very small and defectively developed the condition is known as *micrencephaly* Greater development of one side of the brain than of the other is called *asymmetry* In *porencephalus* a cyst is connected with the ventricle and there is lack of cerebral substance In *nuclear aplasia* certain cranial nerve nuclei are absent or imperfectly developed When the oculomotor nuclei are aplastic ptosis of the upper eyelids and weakness or absence of movement in the eyeball ensue This condition may be present at birth or develop slowly and progressively in adult life producing bilateral ptosis paresis of the extra ocular muscles and later paresis of the internal muscles of the eye It is not always associated with other involvement of the central nervous system and when it occurs alone is probably due to a congenital imperfection of the nerve cells of the oculomotor nuclei which was not apparent at birth

Hydrocephaly, sometimes present at birth is characterized by abnormal enlargement of the head and dilatation of the ventricles of the brain at the expense of the brain substance which as a rule is flattened into thin sheets surrounding the ventricles It is usually internal and bilateral but occasionally the ventricular distention is restricted to one lateral ventricle as the result of either a developmental anomaly of the brain or of some lesion in the ventricular walls *External hydrocephaly* is a condition characterized by accumulation of fluid in the distended subarachnoid space over the surface of the brain and by atrophy or shrinking of the brain substance Moderate hydrocephalus is not incompatible with normal intelligence and may even be associated with brilliance Generally however it is associated with some degree of mental impairment and often also with weakness of the limbs because the pyramidal tracts are degenerated or ill developed.

The congenital form is frequently caused by total or partial obstruction of the aqueduct of Sylvius this prevents circulation of

the cerebrospinal fluid from its point of formation in the choroid plexuses of the lateral and third ventricles to the fourth ventricle and thence to the subarachnoid space through the foramina of Magendie and Luschka When normal absorption of the fluid in the subarachnoid space is thus prevented its accumulation in the lateral and third ventricles produces *internal hydrocephalus* (*obstructive internal hydrocephalus*)

The *diagnostic test* for this is injection of a neutral dye (indigo carmine) which is specially prepared into one of the lateral ventricles and a few minutes later removal of some of the spinal fluid by lumbar puncture If the dye does not appear in the fluid thus obtained there is obstruction in the sylvian aqueduct or in the foramen of Monro By introducing air into the lateral ventricle (Dandy's ventriculography) the exact site of the obstruction can often be determined The *prognosis* of congenital hydrocephalus is serious although in many children the disease is arrested and physical and mental development is more or less normal Measurement of the skull at regular intervals enables the physician to determine how rapidly the condition progresses

Treatment is hazardous but recoveries have been observed in Bellevue Hospital after opening the wall of the third ventricle Removal of fluid from the ventricles is easy before the fontanels have closed but is of little if any benefit it is not without danger of sudden collapse if performed too rapidly Dandy and others have actually put sounds and later tubes through partially obstructed sylvian aqueducts with good results in a few cases This is of course a difficult and dangerous operation

Meningocele is hernia of the membranes of the brain through a cleft in the skull *encephalocele* is also protrusion of the brain substance usually in the occipital region in the median line

Spina bifida is a congenital defect of the sacral or lower lumbar vertebrae which is very often associated with protrusion of the meninges These form a lump under the skin which is soft and contains cerebrospinal fluid and at times portions of the cauda equina or of the spinal cord itself Spina bifida is apt to be associated with other developmental anomalies such as cervical rib *syringomyelia* or *hydrocephaly* Sometimes when the bony defect is slight there is no lump (meningocele) but a tuft of hair or a pad of fat lies over the lesion this condition is called *spina bifida occulta* Both *spina bifida* and *spina bifida occulta* may produce a definite syndrome The lower limbs are weak and often much atrophied below the knee There is incontinence of urine or perhaps enuresis Trophic ulcers are very prone to develop on the soles of the feet either spontaneously or as a result of slight injury to the skin (a blister for example produced by a badly fitted shoe) The ankle jerks are absent as a rule This condition may manifest itself only at puberty when the more rapid growth of the spine compared with the spinal cord and roots within causes pernicious traction on the cauda equina which results in functional disturbance of the sacral and lower lumbar motor and sensory roots

The *prognosis* depends on the extent of the hernia and what it contains The sac if large may rupture and cause death at once or later from purulent meningitis Surgical intervention has saved some patients. If the sac contains only fluid and meninges the chance of cure is greater than when it also contains nerve structures

Treatment—The best time for the operative treatment of spina bifida is usually the first few weeks of life Operation very soon after birth is indicated in some cases when the sac ruptures or threatens to rupture Penfield and Cone have recently devised a new technic for the prevention of hydrocephalus following operation on spina bifida

Defects of the Spinal Cord—Entire absence of the spinal cord (*amyelia*) is associated with anencephaly *Amyelencephaly* is absence of both brain and spinal cord *Atelomyelia* is lack of development of the cord *e g* absence of the pyramidal tracts. *Asymmetry* of the cord occurs with possibly defective development of one pyramidal tract In *heterotopia* the gray portions of the cord are displaced so that patches of gray matter are scattered among the bundles of white fibers this condition is sometimes produced artificially at autopsy by rough removal of the cord *Micromyelia* the presence of an abnormally small spinal cord is

associated with such conditions as Friedreich's disease A spinal cord is seldom completely double (*diplomyelia*) and may be so in only a few segments The condition is due to failure of the central canal of the cord to close or contract normally This duplication of the canal is not so rare as some of the other anomalies

Types of Mental Deficiency —Mental deficiency is of many degrees and grades In some patients there are obvious organic defects of the brain (microcephaly or hydrocephaly for example) while in others the brain appears to be normal even on microscopic examination

The Profound Idiot —This is the lowest type of mental defective He is usually of small size physically abnormal and at any age more helpless than the normal infant He has apparently no mentality

The Superficial Idiot —Slightly higher in the scale but still in the idiot class is the superficial idiot Such individuals may be able to speak very imperfectly can walk and perform other muscular movements with better coordination than can the profound idiot They are often mischievous ill tempered and difficult to manage

The Idio imbecile and the Imbecile —The third grade is the idio imbecile and the fourth the imbecile which includes three grades—low middle and high Imbeciles can be trained in the various arts and trades but require a long apprenticeship and a good deal of supervision preferably in a colony

The Moral Imbecile —This type is not only mentally but morally deficient and needs constant supervision He can like other imbeciles be trained but must be carefully watched because of his tendency to do evil things

Backward Children —The very large class of backward children can be trained to fill a place in the outside world since their mental processes are normal but slower than the average Some of these individuals appear perfectly normal except during excitement illness or under other adverse conditions

Amaurotic Family Idiocy —A type of idiocy with peculiar pathology is the so called amaurotic family idiocy (Tay Sachs disease) which occurs almost exclusively in Jewish children and is fatal within two years or a little more It is associated with optic atrophy and blindness and the appearance of a cherry red spot at the macula in each retina The nerve cells throughout the brain and spinal cord undergo characteristic degeneration becoming greatly enlarged (ballooned) and the Nissl substance becomes fragmented and collects about the eccentric nucleus The neurofibrils are pushed to the periphery of the cell body This form of idiocy may affect several children in one family

In addition to this now well known type of the disease there is a late infantile type (Jansky Schob and Bielchowsky) and a juvenile type described by Spielmeyer and Vogt The late infantile form begins at about three and one half years of age and may run a course of four years The juvenile type begins later in life between seven and eight years of age and lasts longer It is found most often in Gentile children and the cherry red spot at the macula is often absent In 1928 it was discovered that the pathologic changes in the brain of amaurotic family idiocy might be part of a larger syndrome called Niemann Pick's disease which is a disturbance of the phospholipid metabolism

Gargoylism —Gargoylism is a heredofamilial disease which has recently attracted the attention of pediatricians and neurologists The changes in the nervous system resemble somewhat those found in amaurotic family idiocy although the mental defect is not nearly so great and there is no optic atrophy as a rule There is some defect in vision due to a lipoid like deposit in the cornea

The disease begins to be evident in some cases in the first few months of life—the features are peculiar and the bones do not develop normally As the child grows older the prominent characters of the disease become more noticeable—the child resembles somewhat an achondroplastic dwarf with short arms and legs and some kyphosis The head is large there are a saddle nose and coarse lips the eyebrows are bushy and the neck is short the abdomen is large and there is often an umbilical hernia genu valgum is present the liver and spleen are enlarged The mental defect varies in different cases apparently depending upon the number of cells affected in the cerebral cortex *Only*

a few cases have come to autopsy In one case recently examined the brain was large and very heavy with a slight hydrocephalus The *leptomeninges* were much thickened over the frontal lobes The *convolutions* were large and the sulci wide The sella turcica was lengthened anteroposteriorly

Sections of the brain and spinal cord showed many cells much enlarged and rounded with an eccentric nucleus and no normal tigroid substance

The *disease is not necessarily fatal* and these patients are quite *active and able to* play about.

Mental Deficiency and Epilepsy—At times mental deficiency and epilepsy are associated Epilepsy occurs in some cases in more than one member of a family

Tuberous Sclerosis—Tuberous sclerosis is a congenital *developmental anomaly of the* brain associated clinically with epilepsy as a rule and with some conduct disorder very often. It is characterized by enlarged convolutions which feel hard like marbles in the fresh brain The lining of the lateral ventricles has hard white *projections* in places resembling candle drippings Microscopic study of affected brain areas shows giant astrocytes and peculiarly developed nerve cells with many thick processes

The changes in the nervous system are usually *associated* with adenoma sebaceum over the nose and cheeks and *usually with* neurofibromatosis of the skin *Cafe au lait* spots and nevi are also present in the skin of some patients Often associated with these changes are rhabdomyoma of the heart and fibrous *nodules* on the serous coat of the intestine and *sometimes on the surface* of the kidney There may be skeletal changes such as fusion of two vertebrae etc In rare instances a peculiar tumor 'mulberry tumor' or phacoma of the retina can be seen with the *ophthalmoscope*

The condition may be well developed in the brain at birth and may even be associated with tumor formation in the brain This tumor is usually classified as spongioblastoma multiforme and in one case in our series there was a spongioblastoma polare. The x ray appearance *of the skull is* sometimes characteristic—small white apparently calcified nodules can be seen scattered throughout the brain Probably many cases of idiopathic epilepsy have tuberous sclerosis as their pathologic basis

Many cases resist the usual treament for epilepsy and because of their conduct disorders *must* be committed to an institution These patients *are often sullen* and danger ous and even criminal in their conduct

LITTLE'S DISEASE

(Congenital Spastic Stiffness of the Limbs)

The one well known disease *of the* pyramidal tracts which is associated with little or no mental defect is Little s disease This is congenital or infantile in origin and results *from lack* of development (*agenesis*) of the *pyramidal tracts which* leads to atrophy or sclerosis of the lateral *columns of the spinal* cord The condition is sometimes seen in twins The symptom complex can no doubt be produced by a number of conditions which operate before or at the time of birth but *its most* important cause is premature birth *Meningeal hemorrhage* and congenital syphilis are responsible *for some* cases and trauma to the head during difficult labor even without visible hemorrhage of the brain may arrest development of the *pyramidal tracts* The symptoms can be observed usually within a year of birth but may at times not appear *for a number of* years Patients begin to walk very late and manifest the well known cross legged *progression* due to spastic adduction of the thighs The *arms are less* involved The deep reflexes are *exaggerated especially* at the knee and ankle and there is often a *double*

Babinski sign When the condition is mild it responds slowly to massage and any necessary orthopedic therapy, such as tenotomy Some of the posterior roots of the spinal nerves supplying the spastic muscles have been resected at times with favorable results If the condition is severe the patient gradually becomes more and more helpless as the size and weight increase Death often results from intercurrent disease before he reaches twenty years of age

Hereditary Hemiplegia —This is a rare form of hereditary hemiplegia which is sometimes associated with atrophy of the paralyzed side

Hereditary Spastic Spinal Paralysis is a rare disease which affects several members in many generations of one family It causes slowly progressive paralysis of the legs which begins at about the age of five and continues twenty or thirty years

LEWIS STEVENSON

HEREDITARY SPINAL ATAXIA

(*Friedreich s Disease*)

A common disease which begins between the ages of six and fifteen years and may affect several brothers and sisters is hereditary spinal ataxia The lesion involves the posterior columns and pyramidal tracts of the spinal cord and there is some degeneration in the direct cerebellar tracts and cerebellum These changes lead to ataxia weakness in the legs pes cavus, scoliosis sometimes manus cava and occasionally to nystagmus and tremor of the head Two or more children of one family may have the scoliosis and characteristic deformity of the feet while one or more may manifest the complete syndrome which includes not only evidences of tract degeneration in the spinal cord but also well marked signs of cerebellar disturbance such as nystagmus nodding of the head syllabic speech and asynergy of both arms and legs The bilateral deformity of the foot is striking the dorsum is high the arch deeply hollowed and the great toe hyperextended at the metatarsophalangeal joint and flexed at the phalangeal joint There is a kind of 'permanent Babinski sign' The ankle jerks are absent and also the knee jerks The deep reflexes in the arms may be lost in the late stages of the disease Occasionally in well marked cases the palms of the hands are hollowed just like the soles of the feet, and the fingers are hypotonic and become hyperextended when the arms are held straight out in front with the palms down The bladder and rectal sphincters are not involved and there is no pain or loss of superficial sensation At times when the cerebellar signs are more marked than those referable to the spinal cord the condition may resemble Marie's hereditary cerebellar ataxia

Hereditary cerebellar ataxia, which is allied to Friedreich s disease, develops somewhat later in life and causes more degeneration in the cerebellum than in the spinal cord Many of these hereditary defects in the structure of the nervous system (*abiotrophies*) are not true to type, but merge one into the other as these two diseases quite commonly do

LEWIS STEVENSON

FAMILY PERIODIC PARALYSIS

This is a rare hereditary disease which begins in early life and lasts for many years The paralysis comes on very often during the night and is a flaccid palsy of legs trunk and arms without sensory disturbance or involvement of the cranial nerves It lasts for between a few hours and a few days and is associated at times with some dilatation of the heart

LEWIS STEVENSON

HEREDITARY CHOREA

(*Huntington s Chorea*)

This disease begins in middle life and affects several generations as well as more than one member of a single generation It is progressive and degenerative in type and is associated with gradual progressive dementia The disease is easily recognized by the jerky irregular movements of the entire body The gait is very much disturbed The head is twisted about from side to side and the shoulders are raised on one side and then on the other with irregular, jerky twisting movements of the hands and arms as the

patient walks rather hurriedly across the room. All movements seem to be exaggerated or overdone and there is much grimacing The patient can by an effort of the will control these movements for a minute or two but they soon begin again, and like other involuntary movements increase when the patient knows he is under observation Men and women are about equally affected Heredity is the chief etiologic factor rheumatism and other infections play no part as they do in the chorea of Sydenham The lesion is a degenerative change in certain brain cells The small motor cells of the caudate nucleus and the putamen are particularly affected by atrophy Some of the pyramidal cells in the psychomotor areas are also involved—a fact which no doubt accounts for the gradual development of dementia The choreic movements probably result from atrophy of the cells in the corpus striatum Sometimes there is a good deal of proliferation of the glia in the brain, and at times there are vascular changes suggestive of encephalitis Although the condition becomes gradually worse some improvement may occasionally be brought about by administration of such sedatives as bromides luminal or hyoscine and a course of tonic treatment.

There is a type of hereditary chorea without dementia which begins earlier in life than Huntington s type—often at the age of puberty It affects the muscles of the face and arms but leaves the legs unaffected Patients with this disease may lead a fairly normal active life

LEWIS STEVENSON

WILSON S DISEASE

(*Progressive Lenticular Degeneration*)

This is a familial somewhat rare condition It affects young people and is associated with a peculiar hobnail cirrhosis of the liver The clinical manifestations are bilateral athetoid movements of the hands arms legs, and face The face usually bears a grin which spasmodically breaks into a laugh since there is considerable emotional disturbance The athetoid twistings are rhythmic and increase on voluntary movement The limbs are more or less spastic and contractures eventually develop The deep reflexes are active but there is no Babinski sign because the pyramidal tracts are not affected There is no actual weakness of the muscles or loss of sensation The abdominal reflexes are preserved The speech is dysarthric and there is difficulty in swallowing The disease is progressive and fatal within a few years Postmortem examination of the brain reveals extensive changes in the lenticular nuclei sometimes cavity formation.

LEWIS STEVENSON

APLASIA AXIALIS EXTRACORTICALIS CONGENITA

(*Pelizaeus Merzbacher Disease*)

This is a rare congenital and familial disease which begins in infancy makes rapid progress at first and later follows a more chronic course It somewhat resembles multiple sclerosis The chief clinical features of the disease are slowness of speech fixation of facial expression nystagmus ataxia with spasticity of the legs and mental deficiency The lesion is an atrophy of the white matter of the brain

LEWIS STEVENSON

HEREDITARY PROGRESSIVE SPINAL AND NEURITIC MUSCULAR ATROPHIES

There are three types of hereditary progressive spinal and neuritic muscular atrophy the infantile form of Werdnig Hoffmann which begins in the first or second year of life and causes weakness and atrophy of the muscles of the buttocks back and legs and later of the muscles of the shoulders and neck with final involvement of other muscles the adult form (Dana) which is rapidly fatal and begins at about the age of thirty or fifty years the Charcot Marie Tooth form in which the muscles of the legs (peronei muscles) and later of the forearms atrophy

LEWIS STEVENSON

HEREDITARY PROGRESSIVE DYSTROPHIES

In the group of hereditary progressive dystrophies of the muscles and the nerves supplying them are included a number of conditions

Pseudohypertrophic muscular dystrophy is perhaps the best known It may affect several children in a family without any history of ancestral nervous or muscular disease It occurs in boys much more often than in girls At times the disease is inherited through several generations It usually begins in childhood The patient develops a waddling gait falls easily and finds difficulty in climbing stairs He cannot rise from the ground without the use of his arms and cannot stand erect until he has climbed up his legs with his hands Hypertrophy of the calf muscles becomes marked and the muscle is hard and unnatural to the touch The infraspinatus supraspinatus and deltoid as well as certain other muscles may also undergo hypertrophy Lordosis develops The child gradually becomes more helpless and the pseudohypertrophy may give place to atrophy of the muscles

Juvenile Form of Progressive Muscular Dystrophy (Erb s Type) —In juvenile progressive muscular dystrophy the muscles of the shoulder girdle are first affected There is hypertrophy of some muscles of the shoulder girdle and also at times of some of those of the pelvic girdle The thighs deep muscles of the back and of the upper arm become atrophic Later atrophy takes place in the hypertrophied muscles The face forearm hand and leg muscles remain normal for a long time The disease begins in childhood or a little later It is one of the rarest forms of dystrophy and like other primary myopathies gives evidence of no change in the central nervous system

Landouzy Dejerine Dystrophy —In the Landouzy Dejerine type of dystrophy there is no muscular hypertrophy but marked atrophy of the muscles of the face shoulder girdle and arm Those of the forearm hand and legs and the deep muscles of the back as a rule remain normal The facial atrophy usually begins early in life and produces a peculiar expression called the *myopathic facies* The lips appear thickened and the lower lip curves downward (*bouche de tapir*) because of the atrophy in the orbicular muscle of the mouth The ocular muscles and those of deglutition are not affected The patient later develops a marked lordosis the peculiar posture and awkward gait give the impression of a pouter pigeon

Sometimes forms of muscular dystrophy seem not to remain true to type and in certain cases characteristic signs of at least two of these types have been seen in one individual

LEWIS STEVENSON

MYOTONIA CONGENITA

(*Thomsen s Disease*)

This is a disease which usually affects several members of the same family and is transmitted from generation to generation The muscles are so affected that at the beginning of a muscular movement it is extremely difficult to overcome a certain muscular stiffness (hypertonus) After several contractions the muscle limbers up,' but this disappears as soon as the muscle is at rest again The disease begins very early in life and is chronic It has been demonstrated at Bellevue Hospital and amply confirmed elsewhere that quinine hydrochloride 5 or 10 grains two or three times daily acts specifically in the removal of myotonic symptoms in this disease probably by chemical reaction on the neuromuscular junction

LEWIS STEVENSON

REFERENCE

MYATONIA CONGENITA

(*Oppenheim s Disease Amyotonia Congenita*)

This is a rare disease in infants which was described by Oppenheim in 1900 Clinically it is the very opposite condition to myotonia congenita The two terms are often confused During the first few months of its life the child seems paralyzed—the muscles are flabby and atonic and the deep reflexes are absent or very sluggish The legs are most severely affected but the trunk and arms are also involved The arms and legs hang loosely and the child cannot move them to any great extent The muscles do not atrophy or at least do not appear to The

disease is congenital and does not usually occur in more than one member of a family Thirty per cent of patients die within the first year The pathology of the condition is not fully understood Some believe the disease to be a fetal form of poliomyelitis In one case recently studied at autopsy the lower part of the spinal cord showed marked changes in the anterior horns. The cells were reduced in number and those remaining were atrophic There was much fat in the anterior horns and fat in the radicles of the anterior roots running from the anterior horn cells to the margin of the cord This represented broken down myelin sheaths When stained with silver carbonate there was a very marked gliosis seen in the anterior horns The changes in the upper regions of the cord were much less pronounced Anatomically there seems to be no difference between Oppenheim s disease and Werdnig Hoffmann paralysis Oppenheim states that some patients have improved and he considers the condition to be one of delayed development of the muscles

MYOTONIA ATROPHICA

This is a rare disease which begins between the ages of twenty and thirty years and is characterized by peculiar myotonic stiffness of the muscles as well as by atrophy of special muscle groups *i.e* the orbicular muscles of the eyes and mouth (tapir mouth and myasthenic facies) the sternomastoids extensors of the arms supinator longus and the vasti muscles of the thigh Other features are increased lacrimation and salivation a peculiar defect in articulation and general emaciation The condition is most peculiarly associated with cataract of the eye several members of one family as well as the patient with atrophic myotonia may suffer from cataract

LEWIS STEVENSON

TERATOMAS TERATOID AND DERMOID TUMORS GLIOMA RETINAE

Certain tumors of the brain and of the spinal cord which are present at birth may become manifest almost at once or at times not until much later in life **Hypophysial** dermoids are found at the base of the skull in the sella turcica near the olfactory lobes or at the optic chiasm Other intracranial dermoids are found between the medulla and pons and elsewhere. Sometimes they grow from the dura mater, often in the median line in the tentorium cerebelli **Cholesteatoma** may occur in the bones of the skull or within the brain substance or ventricles **Glioma of the retina** is congenital, and is reported to have occurred in several children of a single family

LEWIS STEVENSON

CONGENITAL SYPHILIS

Congenital syphilis of the nervous system is not uncommon It gives rise to syphilitic meningitis and to juvenile paresis or tabo paresis. A child with congenital lues may very soon after birth have basilar luetic meningitis with secondary hydrocephalus and yellow spinal fluid (xanthochromia) or may develop normally until the age of five or ten years and then shows symptoms of general paresis The mentality drops the memory becomes poor and dementia sets in Epileptic fits may occur as in older paretics The deep reflexes at the ankle and knees are often absent (taboparesis) and the pupils are sometimes sluggish to light

LEWIS STEVENSON

MYASTHENIA GRAVIS

Myasthenia gravis is a disease of the muscles particularly those of the face the masseters and the muscles for deglutition and speaking which makes them fatigue very quickly The facies is nearly always characteristic with ptosis of one or both upper eyelids The generally sad expression is almost pathognomonic of this condition

Incidence —The disease occurs in adults as a rule but occasionally it is seen even in a malignant form in young people

Etiology —The cause of myasthenia gravis is not known The observation of a persistent thymus in the form of a thin sheet in some patients at autopsy and the fact that symptoms of the disease often disappear during pregnancy arouse suspicion of some endocrine defect.

Pseudohypertrophic muscular dystrophy is perhaps, the best known It may affect several children in a family without any history of ancestral nervous or muscular disease It occurs in boys much more often than in girls At times the disease is inherited through several generations It usually begins in childhood The patient develops a waddling gait falls easily and finds difficulty in climbing stairs He cannot rise from the ground without the use of his arms and cannot stand erect until he has 'climbed up his legs with his hands Hypertrophy of the calf muscles becomes marked and the muscle is hard and unnatural to the touch The infraspinatus supraspinatus and deltoid as well as certain other muscles may also undergo hypertrophy Lordosis develops The child gradually becomes more helpless and the pseudohypertrophy may give place to atrophy of the muscles

Juvenile Form of Progressive Muscular Dystrophy (Erb s Type) —In juvenile progressive muscular dystrophy the muscles of the shoulder girdle are first affected There is hypertrophy of some muscles of the shoulder girdle and also at times of some of those of the pelvic girdle The thighs deep muscles of the back and of the upper arm become atrophic Later atrophy takes place in the hypertrophied muscles The face forearm hand and leg muscles remain normal for a long time The disease begins in childhood or a little later It is one of the rarest forms of dystrophy and like other primary myopathies gives evidence of no change in the central nervous system

Landouzy Dejerine Dystrophy —In the Landouzy Dejerine type of dystrophy there *is no* muscular hypertrophy but marked atrophy of the muscles of the face shoulder girdle and arm. Those of the forearm hand and legs and the deep muscles of the back as a rule remain normal The facial atrophy usually begins early in life and produces a peculiar expression called the *myopathic facies* The lips appear thickened and the lower lip curves downward (*bouche de tapir*) because of the atrophy in the orbicular muscle of the mouth The ocular muscles and those of deglutition are not affected The patient later develops a marked lordosis the peculiar posture and awkward gait give the impression of a pouter pigeon

Sometimes forms of muscular dystrophy seem not to remain true to type and in certain cases characteristic signs of at least two of these types have been seen in one individual

LEWIS STEVENSON

MYOTONIA CONGENITA

(*Thomsen s Disease*)

This is a disease which usually affects several members of the same family and is transmitted from generation to generation The muscles are so affected that at the beginning of a muscular movement it is extremely difficult to overcome a certain muscular stiffness (hypertonus) After several contractions the muscle limbers up" but this disappears as soon as the muscle is at rest again The disease begins very early in life and is chronic It has been demonstrated at Bellevue Hospital and amply confirmed elsewhere that quinine hydrochloride 5 or 10 grains two or three times daily acts specifically in the removal of myotonic symptoms in this disease probably by chemical reaction on the neuromuscular junction

LEWIS STEVENSON

MYATONIA CONGENITA

(*Oppenheim s Disease Amyotonia Congenita*)

This is a rare disease in infants which was described by Oppenheim in 1900 Clinically it is the very opposite condition to myotonia congenita The two terms are often confused During the first few months of its life the child seems paralyzed—the muscles are flabby and atonic and the deep reflexes are absent or very sluggish The legs are most severely affected but the trunk and arms are also involved The arms and legs hang loosely and the child cannot move them to any great extent The muscles do not atrophy or at least do not appear to The

demonstrated Botulism, and the paralytic form of rabies are said at times to produce the syndrome of Landry's paralysis Other micrococci resembling the pneumococcus have been known to cause the disease

Morbid Anatomy —The lesions in the *spinal cord* vary greatly in severity In certain rapidly fatal cases they are very slight while in others there is an extensive change resembling that of acute poliomyelitis There may be vascular lesions in the gray matter of the cord particularly in the anterior horns, or merely simple chromatolysis with displacement of the nuclei in the motor cells of the anterior horns

Symptoms — At the onset there is a feeling of malaise slight pain in the back and heaviness in the legs which become weak There may be fever at first and sometimes myoclonic twitching of the abdominal muscles Within a day or two the patient cannot walk because of weakness in the legs and the paralysis spreads rapidly upward, involving the trunk arm respiratory and throat musculature The bladder and rectal sphincters are not usually involved The mind remains clear Deep reflexes disappear in the legs and later in the arms As a rule there is no definite loss of sensation in the legs or elsewhere

Diagnosis —Although clinical diagnosis from the point of view of neurology is usually easy attempts should be made to determine if possible the causal agent Cultures from the blood and spinal fluid should be made by a pathologist who is familiar with poliomyelitis and epidemic encephalitis Animal inoculations are desirable

Probably the only feature which distinguishes Landry's paralysis from *ordinary acute poliomyelitis* and *acute infectious neuronitis* is its rapidly progressive course. The *acute myelitis* due to syphilis of the cord and to neoplastic invasion of the cord and meninges must also be differentiated In these conditions the definite sensory level which can usually be discovered rises as the disease progresses upward in the cord *Acute multiple neuritis* caused by alcohol or other toxic agents can be distinguished by taking a careful history and by the pain in the limbs and loss of sensation in the hands and feet The possibility of *periodic family paralysis* must be kept in mind and should be suggested by the history of previous transient paralysis

Prognosis —Death has been known to result within two days and to be delayed for as much as a month but it usually takes place within a week after onset. In rare instances when the lesion in the cord has stopped before reaching the medulla the paralysis has gradually disappeared within one or two years

Treatment —The treatment consists of administration of warm sponge baths or packs colonic irrigation repeated lumbar puncture and the exhibition of urotropin The patient should be disturbed as little as possible

LEWIS STEVENSON

DISEASES OF THE MENINGES

Diseases of the Dura Mater —*Malformations*—Malformations of the meninges are commonly associated with such bony defects as spina bifida constituting meningocele Spina bifida occulta may be accompanied by abnormal formation of the meninges Incorporation of the roots of the cauda equina or lower portions of the spinal cord causes degeneration chiefly of the posterior column Symptoms referable to this may not become manifested until adult life and may be confused with those of such other diseases as tabes

Disease of the dura mater itself probably produces no symptoms except some pain Only when it leads to pressure on the brain cord or nerve roots is there manifested more important evidence of the disease.

Malignant growths of a sarcomatous nature may originate in the dura mater most frequently at the base of the skull In the early stages this produces symptoms suggestive of some chronic inflammatory condition by its implication of the cranial nerves in advanced stages the symptoms are those of brain tumor Malignant growths may also extend into the dura mater from such structures as the vertebrae and produce no other symptoms than those of the bony disease until the nerve roots or the spinal cord are pressed upon The same may be said of tuberculosis and syphilis when they involve the dura mater

Morbid Anatomy —There is no constant lesion in the nervous system but the muscles become infiltrated by small round cells ("lymphorrhage" according to *Buzzard*) The thymus gland persists in some cases and lesions may also occur in the liver and thyroid gland Developmental anomalies such as duplication of the great toe, malformation of the aqueduct of Sylvius, etc have at times been associated with this disease

Symptoms —The chief complaint is usually rapid fatigability of certain muscles In attempting to comb the hair for example it becomes impossible to raise the arm above the head more than once or twice Some individuals also cannot chew without the rapid onset of fatigue in the jaws Speech becomes an effort, and may undergo some alteration (dysarthria), swallowing is difficult, and there may be a good deal of general weakness Ptosis develops in one or both upper eyelids and the face assumes a sad sleepy appearance as the result of combined ptosis and facial diplegia It is difficult for the patient to close the eyes tightly and diplopia is often caused by weakness of one or other of the extra ocular muscles Sudden attacks of dyspnea and collapse are frequent and often fatal but the disease may run a subacute or chronic course for many years and may even in some cases disappear temporarily or even permanently

The muscles affected neither undergo atrophy nor show the reaction of degeneration The characteristic electric reaction the myasthenic reaction, does however develop When the muscles are stimulated by faradic current repeated at intervals of seconds the muscular contractions become weaker with each stimulation and soon disappear After a short rest the muscle regains its normal excitability

Treatment —Adequate feeding is essential and in acute cases, absolute rest in bed Tonics are useful Electric therapy should be avoided Some cases have been benefited by the use of ephedrine sulfate A creatinine-free diet and glycine by mouth have recently been tried with promising results.

Walker introduced the treatment of myasthenia gravis by physostigmine in 1934 Since then the use of prostigmin has become quite general in the treatment of this disease Intramuscular injections of 3 to 5 cc of a 1 2000 solution combined with atropine once a day or at intervals of several days have proved useful Atropine is given to offset the effect of the prostigmin in producing intestinal cramps and other disagreeable effects Some prefer to give 1 cc of the prostigmin solution three times a day before meals and then atropine is not required Prostigmin is sometimes more effective by mouth when given in doses of 0 015 Gm two to six times a day in the form of prostigmin bromide In spite of this treatment these patients often die suddenly Kennedy and Wolf have shown that myasthenia and myotonia are primary disorders of muscle or the myoneural juncture, and the prostigmin facilitates the action of the vagus stuff in myasthenia and quinine inhibits this action in myotonia—at the myoneural junction

LANDRY S PARALYSIS

Definition —Landry s paralysis is a form of acute ascending paralysis of the spinal cord, which was first described in 1859 and is still recognized as a clinical entity It is usually rapidly fatal

Incidence —The disease attacks for the most part healthy young adults, and frequently is preceded by influenza gonorrhea or other infectious diseases The author has seen it during epidemics of lethargic encephalitis, in one case except for the lack of sensory change it resembled the acute infectious neuronitis described by Kennedy

Etiology.—The causal agent is not always the same In some patients the condition is undoubtedly due to the virus of poliomyelitis while in others the virus of epidemic encephalitis or the acute infectious neuronitis probably plays the etiologic role although this has not yet been satisfactorily

1500 cells per cubic millimeter which produces turbidity visible to the naked eye is pathognomonic In acute meningitis most of these cells are polymorphonuclear leukocytes The formation of a pellicle in the cerebrospinal fluid after it has stood for several hours suggests tuberculous meningitis but may be associated with other types of leptomeningeal inflammation The spinal fluid may be so purulent that it only passes with difficulty through a needle of ordinary caliber The white cell count of the blood is usually high, as in other infections The temperature varies according to the virulence of the infection and its curve is usually of the septic type

PROGNOSIS—A benign form often designated *acute aseptic meningitis* may closely resemble tuberculous meningitis and in spite of showing as many as 2000 cells, usually lymphocytes per cubic millimeter usually recovers entirely after perhaps only one lumbar puncture and no further treatment

In other forms of meningitis the prognosis is serious, many patients dying within a few days Chemotherapy has greatly improved the prognosis of meningitis caused by meningococcus, yet has sometimes proved disappointing in the treatment of pneumococcal meningitis It should be pushed nevertheless as also in meningitis due to *Streptococcus haemolyticus*

Localized meningitis underlying fractures or forming an extension from a sinus or mastoid infection affords some measure of hope from combined surgical treatment and chemotherapy in appropriate cases

Residual defects such as mental defect paralyses and other manifestations of permanent damage to the nervous tissues are uncommon

TREATMENT—Lumbar puncture performed once or twice a day withdrawing 10 to 20 cc. of spinal fluid gives great relief The greater efficacy of continuous drainage is questionable but may be resorted to if the cell count does not fall with the first mentioned mode of treatment Hot packs and prolonged warm baths have a marked sedative effect Saline purges relieve intracranial pressure and eliminate toxins

Chemotherapy includes the use of sulfapyridine or sulfadiazine Either should be given early and an attempt made to sustain a level of at least 10 mg per cent in the blood The level in the spinal fluid should exceed half of this for satisfactory results Sulfathiazole does not penetrate the meninges satisfactorily An initial dose of 2 Gm followed by 1 Gm every two hours will usually effect the desired level which level can usually be maintained by 1 Gm every four hours for as long as there is evidence of bacterial activity If coma restlessness or vomiting should make oral administration difficult nasal tube administration of the drug as well as nourishment should be tried Failing this intravenous injection of the sodium salt in five per cent solution should be resorted to until one of the other methods become possible To conserve the veins the intravenous method can best take the form of a continuous drip to reach and hold appropriate levels Total fluids administered in twenty four hours should be kept between 1500 and 2000 cc unless dehydration is extreme at first

Unpleasant effects from these chemical agents are Gastro intestinal disturbances often controlled by bicarbonate of soda, cyanosis best treated by methylene blue in 2½ grain doses three times a day drug eruption not often requiring more than local applications fever that may be as high as 104° F but which will fall promptly on interruption of treatment if the spinal fluid count indicates that this may be done Hematuria especially if accompanied by a relative anuria may end in plugging the ureters with crystals necessitating immediate cessation of chemotherapy

Subarachnoid hemorrhages of apparently spontaneous origin are possibly much more common than has been suspected In a high percentage the serologic findings suggest syphilis as the etiologic agent but senility pregnancy endocarditis some of the severe anemias hemorrhagic diathesis and the acute infectious diseases may present this complication Some cases are ascribed to epidemic encephalitis Others result from congenital or preformed aneurysms

At onset the syndrome varies greatly Many patients have sudden severe headache with dizziness but no loss of consciousness These symptoms with marked stiffness of the neck may persist for weeks without other manifestations Prompt relief may fol

Infection (Pachymeningitis) —Metastatic abscesses of the vertebral bodies may irritate the outer surface of the dura mater and produce clinical manifestations suggestive of meningitis The spinal fluid, however, is free of cells and globulin though under increased pressure

In the skull extradural abscesses may occur from an extension of a mastoiditis or sinusitis usually frontal and ethmoid or may be the result of a head trauma This complication may give few symptoms beyond those of the original disease Thrombosis of the venous sinuses may be another consequence leading to chills, venous engorgement of the face and proptosis

Tuberculosis rarely affects the dura mater alone although tuberculous lesions (diffuse thickening or isolated tubercles) have been seen on both the brain and spinal cord

Syphilis not uncommonly causes chronic thickening of the dura mater usually over the cervical region of the spinal cord The diffuse pains in the neck shoulders and arms which are characteristic of this condition are very resistant to treatment Pressure on the motor roots may lead to muscular atrophy Claw hand is not an uncommon deformity Thickening over the cerebral hemispheres causes intractable headache localizing signs such as convulsions, or evidence of general paresis

Hemorrhage —Subdural hematoma is almost invariably the result of trauma At first it gives persistent headache often closely localized but later may exert sufficient inward pressure on appropriate centers to cause incomplete hemiplegia aphasia or hemianopia If this blood is not evacuated it becomes organized and *pachymeningitis interna hemorrhagica* with its characteristic chronic headache results Calcification of the clot is a less frequent late process

X rays of the head taken from before backward, may demonstrate this condition by the lateral shift of a calcified pineal gland

Diseases of the Leptomeninges —*Meningitis* —Inflammation of the leptomeninges may be caused by other organisms than the meningococcus tubercle bacillus and spirochete of syphilis As in the case of the dura mater the infection may be introduced by trauma extension from neighboring bony structures or by the blood or lymph Leptomeningitis may result from mastoiditis sinusitis, or trauma, if the dura mater has been penetrated This form of meningitis may occasionally remain more or less localized Significant evidence of such a condition is facial neuralgia, or paralysis of the face and eye muscles which results from involvement of the nerve supply by the exudate The type of meningitis derived from the blood stream frequently begins basally and produces about the same clinical manifestations but it more often involves both hemispheres

The lesion may vary in degree from a congestion and dulling of the luster of the pia arachnoid to a frankly purulent infiltration At times the purulent areas are more or less discrete especially in such crevices as the sylvian fissure or about the cerebellum

The constitutional diseases sometimes complicated by meningitis are endocarditis septicemias such as those of childbirth typhoid fever, and gonococcal infection or any of the infectious diseases, especially pneumonia The condition also results from such local infections as erysipelas of the scalp face and neck Although all types of organisms may produce the inflammation those most commonly recovered (direct smear or culture) are the pneumococcus and streptococcus

Symptoms and Signs.—The onset may be insidious particularly when the primary constitutional or local disease has been severe but it may also be fulminating when the condition develops as a complication of some other disease or as an apparently primary disturbance The early signs are headache malaise irritability, restlessness stupor or delirium Vomiting anorexia, and constipation are other common general symptoms Convulsions neuralgia and paralyses point clearly to the central nervous system as the site of the lesions Stiffness of the neck and Kernig s sign although characteristic may be absent and are not essential for diagnosis The reflexes are usually not affected but may be somewhat increased or abolished in the more severe cases. Lumbar puncture demonstrates that the spinal fluid is turbid except when the condition is particularly well localized A cell content of

and nerve fibers and usually more or less productive inflammation of granulomatous nature In acute traumatic myelitis an acute primary degeneration with some vascular reaction is characteristic.

In *chronic myelitis* the cord is usually shrunken soft, and pale Brownish pigment spots may be seen when there has been a preexisting acute stage with marked hemorrhagic reaction or hyperemia In luetic cases the pia is opaque When trauma has been the cause there are frequently fine adhesions between the meninges and marrow with calcified areas in the pia Microscopic examination reveals secondary degeneration with segmentation of the myelin and a progressive granular disintegration of the axis cylinders Proliferation of the ependyma and glia and small cavities caused by necrosis develop and there is cellular atrophy Distention of the perivascular spaces with granular debris is especially prominent when there has been preexisting inflammatory exudation Endarteritis is characteristic in syphilis

Symptoms.—*Acute Myelitis*—Infectious myelitis is usually rapid in onset and may be apoplectiform The constitutional symptoms which are usually present vary in severity Paresthesiae slight weakness limited to one or more extremities root pains, and disturbances of sphincter function are common prodromata When the condition is the result of syphilis however symptoms usually develop gradually In cases due to poisons and toxins either mode of onset may occur When trauma is causal symptoms appear immediately

The symptoms referable to the spinal cord depend less on the cause than on the level of the involvement and the intensity of the pathologic processes Even disseminated or extensive lesions often evoke a symptom complex referable only to one level of the spinal cord except when the cranial nerves are involved when the progress of the disease is gradual or when the cervical and lumbar enlargements are both seriously affected

Divisions of the Spinal Cord—For convenient description, the spinal cord may be divided into three levels a lesion in each of which produces a more or less distinct syndrome the cervical the dorsal and the lumbosacral which includes the cauda equina and conus Symptoms are referable to impaired function of the various cell groups and fiber tracts and may be classed as motor sensory reflex, visceral, and trophic in nature Some degree of paralysis and alteration of the tendon and superficial reflexes is prominent and present in all cases The other symptoms are more variable and may be present in mild degree only

1 CERVICAL CORD —When the cervical region of the spinal cord is affected, the symptoms can be classified as follows

Motor paralysis involves the upper and lower extremities to some degree flaccid in the upper and spastic in the lower If the damage is severe the involved extremities are flaccid at first High cervical myelitis usually ends in death within a few days Hyperkinetic phenomena are common and include fibrillary tremors in the arms and automatic movements in the legs

Sensory disturbances may be less severe than the motor They include hyperesthesia, paresthesia and root pain in the segmental areas involved with diminished sensibility below The type of sensory loss depends on the tracts involved.

Reflex—With the onset of acute and severe myelitis all reflexes are usually lost, although at times in the earliest stages all are exaggerated for a brief period The abdominal and anal reflexes may be retained for a day or two and the anal reflexes may be the only evidence that functional blocking of the spinal cord is incomplete Later the tendon reflexes return in the lower extremities the plantar responses become extensor in type and the confirmatory evidences of the Babinski phenomenon may be found In complete recovery the abdominal and cremasteric reflexes are usually the last to resume normal activity

Visceral—Among the visceral symptoms is retention of urine and feces with loss of bladder and rectal sensation Priapism is frequent It may be spontaneous or induced by catheterization or cleansing of the parts After a varying period usually about a fortnight the bladder becomes automatic and empties itself periodically Sphincter function as a rule returns early Permanent impotence may follow even mild myelitis.

Trophic—In severe cases prevention of decubitis is almost impossible Edema of the

low lumbar puncture and if this treatment is given every two or three days until the spinal fluid is clear the patient may be completely restored to health under favorable conditions Some patients particularly the senile suffer from great restlessness, delirium or mania during the hemorrhage and die from the resulting exhaustion At times unconsciousness, which develops slowly or suddenly according to the rapidity of bleeding is the first symptom Focal signs such as hemiplegia aphasia and visual disturbances are probably indications of clotting and organization over the appropriate areas or of actual laceration of the brain tissue by the hemorrhage

The spinal fluid may at first resemble pure arterial blood except that it does not tend to clot If centrifuged or allowed to settle the supernatant fluid has a yellowish or brownish tinge This discoloration may be considered evidence that the bleeding is not caused by a faulty lumbar puncture since such staining cannot develop until about twenty four hours after the manipulation

ROBERT G ARMOUR

MYELITIS

Definition —The term myelitis' should be restricted to pathologic processes and clinical conditions which are the result of trauma infection and toxins acting upon the spinal medulla alone Spinal apoplexy compression of the cord and degenerative involvement of the long tracts (as in tabes dorsalis and the various scleroses) are no longer classified as myelitis

Incidence —Myelitis as defined above is not common It is probable that variations in diagnostic nomenclature in various parts of the country make it impossible to state the actual frequency of myelitis as the term is used in this article. The term myelopathy is preferred in cases where tissue changes are not caused by direct infective inflammation

Etiology —The causes of myelitis are infection poisons and toxins and trauma If one excludes uncommon instances of epidemic poliomyelitis in which the fiber tracts and posterior horns are involved and the cases of virus infections limited to the spinal cord it can be said that there is no primary form of infective myelitis The list of infections in which secondary involvement of the spinal cord may occur is long A postvaccinal toxic or infectious myelitis may occur and is serious enough to compel caution in the use of immunizing sera and vaccines In cerebrospinal meningitis focal inflammatory damage to the spinal cord may occur In carbuncles and in chronic infections of the kidney bladder and pelvic organs lymphogenous extension to the spinal cord may occur Direct extension from empyema has been reported Embolism in septicemia and endocarditis may be responsible for myelitis *Toxic myelitis* may be due to poison by carbon monoxide carbon bisulfide or chloroform it may occur after spinal anesthesia and has been observed as a complication of subarachnoid injections of alcohol for the relief of pain In cachectic states and severe anemia the spinal cord may be affected Myelitis is not uncommon during pregnancy and the puerperium Whether the condition associated with the puerperium is toxic or due to a mild infection may be impossible to determine *Traumatic myelitis* may be the result of direct or indirect violence Electric shock and penetrating wounds produce local injury to the spinal cord but not myelitis of the type here considered

Morbid Anatomy —In the *acute stage* gross examination reveals a swollen somewhat soft and injected cord On cross section it may be difficult to distinguish the gray and white matter because of the hyperemia although in acute traumatic myelitis the cord may appear normal Microscopic examination reveals three abnormalities vascular inflammatory and degenerative which vary in proportion and degree with the etiology Edema and hemorrhages from the capillaries follow trauma and infection. Round cell infiltration in and outside the vessel walls and glial proliferation are noticeable only in infectious myelitis Toxic myelitis is characterized by edema and mild primary degenerative changes in the cells and myelin sheaths and by the absence of vascular reaction In luetic conditions vascular degeneration is prominent and endarteritis is often well developed There is also some edema with degenerative change in the cells

and nerve fibers and usually more or less productive inflammation of granulomatous nature. In acute traumatic myelitis an acute primary degeneration with some vascular reaction is characteristic.

In *chronic myelitis* the cord is usually shrunken soft, and pale Brownish pigment spots may be seen when there has been a preexisting acute stage with marked hemorrhagic reaction or hyperemia In luetic cases the pia is opaque When trauma has been the cause there are frequently fine adhesions between the meninges and marrow with calcified areas in the pia Microscopic examination reveals secondary degeneration with segmentation of the myelin and a progressive granular disintegration of the axis cylinders Proliferation of the ependyma and glia and small cavities caused by necrosis develop and there is cellular atrophy Distention of the perivascular spaces with granular debris is especially prominent when there has been preexisting inflammatory exudation Endarteritis is characteristic in syphilis

Symptoms.—*Acute Myelitis*—Infectious myelitis is usually rapid in onset and may be apoplectiform The constitutional symptoms which are usually present vary in severity Paresthesiae, slight weakness limited to one or more extremities root pains and disturbances of sphincter function are common prodromata When the condition is the result of syphilis however symptoms usually develop gradually In cases due to poisons and toxins either mode of onset may occur When trauma is causal symptoms appear immediately

The symptoms referable to the spinal cord depend less on the cause than on the level of the involvement and the intensity of the pathologic processes Even disseminated or extensive lesions often evoke a symptom complex referable only to one level of the spinal cord, except when the cranial nerves are involved when the progress of the disease is gradual, or when the cervical and lumbar enlargements are both seriously affected

Divisions of the Spinal Cord—For convenient description the spinal cord may be divided into three levels a lesion in each of which produces a more or less distinct syndrome the cervical the dorsal and the lumbosacral which includes the cauda equina and conus. Symptoms are referable to impaired function of the various cell groups and fiber tracts and may be classed as motor sensory reflex visceral and trophic in nature Some degree of paralysis and alteration of the tendon and superficial reflexes is prominent and present in all cases The other symptoms are more variable and may be present in mild degree only

1 Cervical Cord —When the cervical region of the spinal cord is affected, the symptoms can be classified as follows

Motor paralysis involves the upper and lower extremities to some degree flaccid in the upper and spastic in the lower If the damage is severe the involved extremities are flaccid at first. High cervical myelitis usually ends in death within a few days Hyperkinetic phenomena are common and include fibrillary tremors in the arms and automatic movements in the legs

Sensory disturbances may be less severe than the motor They include hyperesthesia, paresthesia and root pain in the segmental areas involved with diminished sensibility below The type of sensory loss depends on the tracts involved.

Reflex—With the onset of acute and severe myelitis all reflexes are usually lost, although at times in the earliest stages all are exaggerated for a brief period The abdominal and anal reflexes may be retained for a day or two and the anal reflexes may be the only evidence that functional blocking of the spinal cord is incomplete Later the tendon reflexes return in the lower extremities the plantar responses become extensor in type and the confirmatory evidences of the Babinski phenomenon may be found In complete recovery the abdominal and cremasteric reflexes are usually the last to resume normal activity

Visceral.—Among the visceral symptoms is retention of urine and feces with loss of bladder and rectal sensation Priapism is frequent. It may be spontaneous or induced by catheterization or cleansing of the parts After a varying period usually about a fortnight the bladder becomes automatic and empties itself periodically Sphincter function as a rule returns early Permanent impotence may follow even mild myelitis.

Trophic—In severe cases prevention of decubitus is almost impossible Edema of the

paralyzed extremities and abnormalities of sweat secretion may occur

2 DORSAL CORD —The dorsal region of the cord is most apt to be attacked by the sub acute or chronic forms of myelitis The symptoms of its involvement are the same as those of cervical myelitis except that the arms are not involved The patient may complain of paresthesiae in the upper ex tremities when otherwise there is no sensory loss higher than for example, the sixth dor sal segment This symptom may be impor tant in establishing the disseminated nature of the disease The upper abdominal reflexes are retained when the lesion is below the eighth dorsal segment

3 LUMBAR CORD AND CONUS —When the lumbar region and conus are attacked the paralysis which is confined to the legs, is flaccid in type and the paralyzed muscles atrophy The knee jerks are absent when the lesion affects the upper lumbar segments If the level of involvement is at the fifth lum bar and first and second sacral segments only the ankle jerks and the hamstring jerks are lost The plantar reflex is almost always abolished Incontinence results from paral ysis of bladder and rectum

Chronic Myelitis —When the onset of chronic myelitis is gradual the patient com plains chiefly of weakness This consists of heaviness and stiffness of the lower extrem ities when the dorsal cord is affected Pares thesiae may also develop in the legs and a girdle sensation or even lancinating pains corresponding to the segment involved Ob jective sensory impairment is deferred and less marked than the paralysis The patient may have his attention first called to the presence of a weakness by fatigability on exertion or long walking or he may observe that the thighs seem weak in going up or down stairs Should the segments involved be in the lumbar or cervical enlargements atrophic palsy of the muscles supplied by the affected segments develops gradually Disturbances of sphincter function are usu ally late in appearing

Traumatic Myelitis —Direct or indirect violence to the vertebral column may imme diately impair spinal cord function Injury without compression of the cord is often difficult to distinguish from the crushing lesions which result from displacement or fracture of the vertebrae The immediate result of even mild forms of trauma may be edema so profound that it completely abol ishes function at the level of injury, and constitutes what may be called a physiologic block The symptoms which result from simple concussion are practically the same as those due to contusion with diffuse petechial hemorrhages throughout the spinal marrow those referable to an injury at a given level are no different from the symp toms of the infectious and toxic type of myelitis except that root pains are frequent and prominent Degenerative reactions in the injured tissue will cause chronic residual symptoms

Disseminated myelitis may be a sequel to any infection and is often due to syphilis It is sometimes indistinguishable from acute multiple sclerosis The scattered lesions pro duce appropriate symptoms from the begin ning

Diagnosis —The anatomic diagnosis of well established myelitis is simple During the prodromal period of the acute form paresthesias or root pains weakness or dis turbance of sphincter function immediately arouse suspicion of myelitis *Acute rheu matic fever* in its early stages may simulat myelitis In the infectious form precedin; infectious disease is important Both foca and local infections must be searched for When a general infection is causal the myel itis is apt to occur in the lumbar and cervical enlargements because of their abundant vascular supply The spinal form of epidemic encephalitis and of epidemic poliomyelitis with involvement of the fiber tracts is dis cussed in other chapters

In toxic myelitis the onset is less abrupt Search for underlying constitutional or pre disposing environmental conditions is essen tial Differential diagnosis between toxic and mild infectious myelitis may be difficult Multiple neuritis may be difficult to dis tinguish Differentiation between acute mye litis and *spinal thrombosis or hemorrhage* is often practically impossible In elderly people with low blood pressure and in cachetic patients *thrombosis* should always be considered

Difficulties may arise in establishing the etiology of the subacute or chronic forms Syphilis is a common cause Naturally

chronic myelitis results from incompletely cured acute myelitis. *Kummels disease* may involve the vertebral column and in a small per cent of cases may compress the cord Adhesive arachnoiditis will often produce symptoms suggestive of chronic myelitis The laboratory aids to diagnosis are helpful A diagnosis of chronic myelitis implies the exclusion of *primary or metastatic tumors of the spinal cord and meninges vertebral disease combined sclerosis multiple sclerosis myelomalacia,* and *pachymeningitis with thrombosis or ischemia of the vessels of the cord* Erosion from aneurysms is rare but should be kept in mind

Examination of the spinal fluid is of special importance It is seldom that organisms can be cultured in the milder cases An *increase in protein and cell content is evidence* of inflammation. In *traumatic cases* the fluid may be discolored by pigment derived from blood and flow of spinal fluid may be blocked by swelling of the cord In subacute and chronic conditions when it is tinged with yellow, contains a marked excess of protein and few or no cells there is a compressing lesion which has disturbed its flow A partial or complete block of flow of spinal fluid during manometric examination by the Ayer method indicates some form of compression either neoplastic or inflammatory A positive Wassermann reaction which is the rule in *syphilitic myelitis* speaks for itself When there is an increase in protein abnormalities of the colloidal gold curve must be interpreted with caution especially when the Wassermann reaction is negative

Complications and Prognosis—*Unless the upper cervical region of the cord is involved* with ascent of the process to the medulla death seldom results from the myelitis itself Occasionally a case is seen in which the inflammation is so intense that abscess *formation* results with extension and widspread thrombosis Such a *condition* is always fatal The prognosis while always serious from the standpoint of complete restoration of function depends partly on the etiology and severity of symptoms and partly on the *complications The more complete* the loss of spinal cord function the less probable is complete recovery The type due to dissemination or extension of a local or focal infection as a rule causes death In syphilitic myelitis prompt and intensive specific treatment usually evokes a favorable response.

The serious nature of myelitis *often* lies in its *complications Extensive decubitus* is a forerunner of death, and in *paralysis of* the bladder an ascending infection of the kidney is always imminent

The rate of recovery varies considerably and one may be agreeably deceived Sensation *attains* its maximum improvement within three *to six months* and motor recovery is maximal within between six and twelve months Complete return of sphincter function is the rule in mild cases A spastic weakness of the lower extremities is the most prominent residual symptom When the primary stage of inflammation or softening *is chiefly exudative,* recovery is more rapid and complete than when *there has* been productive inflammation with degeneration or hemorrhage which produces scar tissue

In traumatic myelitis, prognosis may be *impossible* during the first two or three days *because complete physiologic* block produced by edema is clinically identical with crushing of the cord Examination of the spinal fluid at this time may not give definite data and deformity of the vertebral axis does not prove that the cord has been crushed Indirect violence may cause a momentary *dislocation of the lower cervical* vertebrae with varying degrees *of injury to* the spinal cord Improvement in traumatic myelitis may continue for an extended period of time Adhesions between the meninges and the cord, with at times local *accumulations of spinal fluid* may develop and be responsible for the delayed appearance of symptoms of compression Gliomatous changes in the spinal medulla have been known to develop they are associated with the syndrome of tumor of the spinal cord

Treatment—*The treatment of* myelitis includes first measures *appropriate* to the cause and second symptomatic *remedies* Counterirritation and diathermy applied over the most involved segments of the spinal cord given carefully are not objectionable There *is no satisfactory* local treatment and general nursing *really comprises* the entire therapy in acute or severe cases

without a cause which can be specifically treated Because of the susceptibility to decubitis, especially with lesions of the lumbosacral enlargement, it is wise to place the patient on an air bed The body must be kept clean and dry Frequent changes of position are helpful Application of protective pads to the heels and sacrum is quite necessary In the diet plenty of 'roughage' is desirable to prevent constipation Colon irrigation every three days and daily oil enemas serve to keep the alimentary tract clean Management of the bladder is perhaps the most important single item When there is incontinence, some urine is usually retained In patients with retention it is wise to avoid catheterization for it is very difficult to avoid infecting the bladder directly by routine catheterization Rupture of the bladder and hydronephrosis are equally rare Cystitis is a serious and intractable complication which is particularly liable to be associated with lesions of the lumbar enlargement or conus when the trophic nerve supply is impaired A retention catheter may be necessary Manual expression at regular intervals when performed skillfully usually serves to relieve intense distress until either there is improvement or the bladder becomes automatic A belladonna suppository or a hot enema may help start the flow of urine when there is retention

A tent at the foot of the bed to keep the covers off the feet is useful Slight elevation of the lower extremities aids return circulation and decreases edema Very light massage and limited passive motion should be given to the paralyzed extremities after the first fortnight to aid in maintaining circulation and preventing contracture No stimulating measures or electricity should be employed during the acute stages Should a bed sore develop dry dressings must be applied at first If there is wide extension and necrosis, a wet dressing is preferable

When the extremities are spastic light massage and mild galvanism or diathermy may be given Reeducative exercises are desirable for patients with persistent spasticity or ataxia For severe contracture surgical measures including tenotomy neurectomy, and muscle transplantation are to be considered Orthopedic appliances may enable the patient to walk Electrotherapy finds its chief use in cases with persistent flaccid palsy

In traumatic myelitis it is important to be certain that there is no deformity of the vertebral axis Laminectomy should be performed without delay when the cord is compressed This is almost always due to displaced vertebrae or fragments of bone, it is very rarely due to meningeal hemorrhage It may, at times be due to edema sufficient to cause not only physiologic block but mechanical compression of the cord This is indicated by obstruction to the flow of spinal fluid

GEORGE H HYSLOP

SUBACUTE COMBINED SCLEROSIS OF THE SPINAL CORD

Subacute combined sclerosis of the spinal cord is a progressive condition of middle life the course of which is variable and dependent upon associated conditions and their treatment It is characterized by sensations of numbness and tingling of the hands and feet and by increasing paralysis of the legs and hands It results from degeneration in the posterior and lateral columns of the spinal cord Anemia and *achylia gastrica* accompany the morbid process in the central nervous system

Although twenty years ago this disease was thought rare it is now comparatively common This increase in incidence may be due in part to improved methods of diagnosis

Etiology —At one time the disease was believed to be the result of pernicious anemia but it is now known that the symptoms produced by changes in the spinal cord often precede those of deterioration of the blood *Free hydrochloric acid* is usually absent from the gastric contents in the early stages of the disease This lack was once thought to be instrumental in promoting absorption of the toxic material from the gastro intestinal tract and thus cause deterioration of the spinal cord and the elements of the blood At the present time the lesions are believed to be due to deficiencies of some vital factor and perhaps of vitamins

The disease may first appear in the train of other exhausting disturbances such as

cancer or any prolonged illness but just as often it develops without apparent cause

Incidence—Combined spinal sclerosis is rare in individuals less than thirty five years of age or more than sixty five The incidence is highest in patients between forty five and fifty five The sexes are equally affected

Morbid Anatomy—Usually there are no lesions above the medulla and the spinal cord remains macroscopically unchanged Microscopically extensive degeneration is evident—chiefly in the middorsal region affecting the posterior tracts the direct cerebellar tracts, and the direct and indirect pyramidal tracts For the most part this is restricted to a discrete system The peripheral nerves also may be involved

Symptoms—The patient may have had vague dyspepsia for some years before he gradually becomes aware of a sensation of deadness and pins and needles' in the tips of the fingers of both hands and in the toes of both feet These sensations are symmetric and practically synchronized in all four limbs At first they are sharply limited to the extremities of the limbs only in the advanced stages of the disease do they extend to the elbows or the knees

No further symptoms may occur for some months even without treatment Then however unsteadiness of gait ataxia especially in the dark and poor stereognosis with consequent manual clumsiness may appear Examination at this stage shows the cranial nerves to be normal There may be sensory ataxia in the arms as in tabes Astereognosis dependent on impairment of the sense of position in the fingers is often accompanied by a lowering of vibration sense as well The abdominal reflexes are depressed or absent The knee jerks usually remain active Absence of ankle jerks and a bilateral Babinski phenomenon are signs of degeneration of the posterior column and the motor column respectively Sensory losses in the lower as in the upper limbs produce ataxia and a positive *Romberg sign* The sphincters at this stage are rarely affected

The intellectual faculties may deteriorate and occasionally in advanced stages a mild delirium appears

In most instances the disease is progressive Girdle pains are felt as tightness and pressure rather than as shooting pains, as in tabes Acute abdominal distention in attacks of several days duration bladder and rectal retention and incontinence and increasing weakness and ataxia of the legs and arms within a year render the patient bedridden The knee jerks will then probably have disappeared and increased losses of posterior column sensations will be found in the legs and hands but a double extensor response can usually be elicited until death Progressive prostration accompanies these local disabilities and if as is usual there be continuous blood decline the deterioration of general function is thereby accelerated Mental disturbance bed sores and total palsy of limbs and sphincters constitute the symptoms of the last stages Death is usually the result of heart failure or intercurrent pulmonary infection It may also be caused directly by neural dysfunction as evidenced by bedsores or cystitis due to retention of urine

Diagnosis—The outline on page 1392 may be useful in solving the difficulties which often arise in distinguishing subacute combined sclerosis of the cord from multiple (disseminated) sclerosis multiple neuritis and tabes dorsalis

In any of these symptom-complexes the presence of achylia gastrica or deterioration of the blood or both enormously increases the probability that the concomitant nervous symptoms are manifestations of subacute combined sclerosis of the cord

Treatment—Search should be made for areas of infection or toxemia The teeth should be examined and also the tonsils and sinuses The malign influence of a sepsis of the gallbladder in initiating the process which ends in pernicious anemia or subacute combined sclerosis of the spinal cord has already been mentioned

Some reliable preparation of liver extract forms the basis of treatment in this disease The introduction of this therapy has greatly improved the prognosis of cases of combined sclerosis of the cord It must be emphasized that the cord symptoms do not occur *pari passu* with or as a result of the anemia but the cord symptoms are influenced for the better by liver therapy and in some cases the cord changes themselves are checked by this agent Parenteral liver extract given in

Subacute combined sclerosis of the cord	*Multiple sclerosis*
Incidence highest between forty five and sixty	Incidence highest between twenty and thirty five years of age
Progressive course	Remittent episodic course.
No ocular symptoms	Transient blindness or blurring of vision
	Transient double vision
No change in the optic nerve	Pallor of the temporal portion of the optic disks
Sphincter trouble in late stages	Sphincter trouble in early stages
Deep reflexes usually absent.	Deep reflexes rarely absent

Subacute combined sclerosis of the cord	*Multiple neuritis*
Associated with Addison s anemia	Cause may be avitaminosis bacterial toxins and various other poisons
Usually no muscular tenderness	Muscular tenderness
Loss of posterior column sensation loss of the senses of position vibration and deep pain	Loss of peripheral sensation loss of superficial sensation of glove and stocking type
Abdominal reflexes absent Double extensor plantar reflexes	Abdominal reflexes present, and extensor plantar reflexes absent
Sphincter palsy in late stages	No sphincter involvement
Motor palsies referable to cord	Peripheral motor palsies (dropped wrists and feet)

Subacute combined sclerosis of the cord	*Tabes*
No history of syphilis Tests for syphilis negative	Positive history of syphilis Syphilitic tests positive, usually
Cerebrospinal fluid normal	Lymphocytosis in spinal fluid Wassermann test positive usually
Pupils normal	Pupils fixed or sluggish in response to light
Great loss of motor power	Slight loss of motor power
Extensor plantar reflexes	Flexor plantar reflexes
Rare lightning pains	Common lightning pains

tramuscularly once or twice a week is much more effective than mouth feeding the sphincter symptoms appear to be particularly amenable to this mode of therapy Vitamin B complex is especially effective in the peripheral neuritis which frequently accompanies the condition Arsenotherapy is contraindicated

MULTIPLE SCLEROSIS

(*Insular Sclerosis Sclerose en Plaques Disseminated Sclerosis*)

Definition—Multiple sclerosis is a diffuse disseminated structural disease essentially to the central nervous system characterized by a degeneration in multiple areas which leads to widely diversified symptoms often of transient character involving chiefly the motor system

History—The first recognition of the disease is credited to Cruveilhier (1835) although it was Valentiner (1856) who first tentatively described the symptomatology Charcot and Bouchard (1862–1863) clarified the conception of the syndrome and established the triad of signs—nystagmus scanning speech, and intention tremor—as pathognomonic of the disease Since the important monograph by Bourneville and Guérard appeared in 1869 the literature on the subject has become voluminous through investigations in Germany Scotland and later in the United States

Incidence—The disease occurs most frequently in young adults its onset is rare in patients less than fifteen and more than thirty five years of age Evidence thus far obtained points to its greater prevalence in Europe than in America Multiple sclerosis is one of the commonest organic diseases of the nervous system and by some observers has been regarded as even more prevalent than syphilis Further statistics should be obtained

Etiology—The cause of the disease is entirely unknown Infections thermal influences traumatism and intoxications by lead arsenic and the like have been regarded as possible etiologic factors The disease has been attributed to various micro organisms but no substantial evidence has been presented in support of any of them

Morbid Anatomy—The macroscopic changes are widely distributed throughout the central nervous system irrespective of gray or white matter and the special neuron tracts They appear as areas of degeneration

of varying size often sharply circumscribed mainly perivascular In the acute stage the lesion is edematous, but once the fluid has been absorbed contraction and sclerosis occur These stages correspond to the acute onset of symptomatic episodes and their remission Microscopic examination invariably reveals a primary change (tumefaction) of the myelin sheaths, followed much later by a certain degree of axon destruction This early myelin degeneration constitutes the sclerotic patch characteristic of the disease Changes in the neuroglia are secondary The reason for the disparity often observed between the apparently destructive pathologic lesions and the symptoms is the persistent preservation of the conducting axons in spite of extreme myelin degeneration The characteristic tendency to remissions is explained also by the restoration of axon function in affected areas through which in the acute stage no conduction was possible The roots of the spinal nerves may undergo change similar to that in the brain and cord

Symptoms —As would be expected from the pathologic changes the syndrome of multiple sclerosis is more varied than that of any other single organic disease of the nervous system The three classic symptoms nystagmus scanning speech and intention tremor, appear very inconstantly and are by no means essential to diagnosis Because of the multiplicity of the lesions and the varying sequence of their appearance in different parts of the cerebrospinal axis the resulting signs and symptoms must be irregular in character and development Spastic conditions in general predominate muscular atrophy is rare sensory disturbances are definitely subordinate to motor defects and pain seldom occurs A recent tabulation gives the following signs in order of diagnostic importance fatigue increase of deep reflexes nystagmus ataxic tremor of upper extremities and head loss of abdominal reflexes disordered gait and station disturbances of speech (often scanning) pallor of the optic disks on the temporal sides uncontrolled emotionalism remissions transitory palsies of ocular nerves vague sensory disorders vesical difficulty and mental changes Much stress should be placed on the frequent development of spastic conditions at some stage of the disease and less upon the supposedly characteristic tremor and scanning speech Spastic conditions are more likely to occur on account of the length of the motor (pyramidal) tracts than are nystagmus scanning speech, or motor ataxia, which have a much more limited cerebellar localization A tendency to remissions is a second most important symptomatic peculiarity

Diagnosis of so called typical cases' presents no difficulties In no other condition do the speech defect the ataxia on intended movement and nystagmus coexist in the same degree but this very fact has led to much confusion Experience has shown that the so called *Charcot triad* is so inconstant that it should not serve as a diagnostic criterion When present its evidence is conclusive, when absent as in a large proportion of cases other groupings of signs and symptoms should be considered *i e* spasticity loss of abdominal reflexes transient palsies in various nerve distributions tremors and atypical speech defects emotional instability and an irregular course That such a disorder with its recognized pathologic basis may simulate various functional and organic diseases is evident If this fact be borne in mind mistakes in diagnosis should be less frequent Examination of the spinal fluid affords some help in that a paretic gold sol curve is very frequently demonstrable (50 per cent of Ayer s series) as well as certain minor changes in the cellular content and other constituents A consistently negative Wassermann reaction in blood and spinal fluid distinguishes the disease from the various forms of syphilis with which in its purely clinical aspects it is often confused

Prognosis —Multiple sclerosis is always a long standing disease total recovery from which is doubtful The strong tendency to remissions may simulate recovery but evidence that recovery has actually taken place in any unquestioned case is still lacking It is not commonly in itself fatal The writer has seen many undoubted examples of this disease who in the course of twenty years have been able to maintain active living

Treatment —Since the cause of the disease is as yet undetermined there is no specific or really efficient treatment The possi

bility that a spirochete may be the cause is still too vague a basis for systematic treatment Silver arsphenamine sodium cacodylate and mercury have been given with some evidence of benefit Recently, patients have been treated with malaria and with typhoid vaccine in addition to malaria, but without beneficial results although some were temporarily improved Vitamin B intravenously or intramuscularly in doses of 100 or 200 mg daily or on alternate days is often definitely helpful In general symptomatic therapy and mechanical measures must be employed to combat the various manifestations as they arise

DIFFUSE AND FOCAL DISEASES OF THE SPINAL CORD

Affections of the Blood Vessels of the Spinal Cord—Branches of the anterior spinal artery enter the central part of the cord through the ventral fissure and supply all the gray matter except a large part of the posterior horn Branches from the posterior spinals penetrate from the periphery into the white matter of the posterior column. Although the white and the gray matter are not supplied by two independent systems there are regions of the cord in which the gray matter receives its supply exclusively from the central arteries, and the peripheral white matter obtains nourishment only from the vasocorona The veins of the spinal cord are arranged like the arteries except that they are much more in evidence on the surface of the cord

Anemia—The rapid development of paralysis after profound hemorrhage may perhaps be explained by resulting anemia of the spinal cord Intermittent claudication of the spinal vessels with temporary level phenomena has also been described

Endarteritis and Arteriosclerosis—Endarteritis of the cord is part of a general process associated with lues or senile atheroma Foster Kennedy and Elsberg have observed sclerotic changes in the vessels of the cord in individuals with neuritis of the cauda equina

Arteriosclerosis of the cord is of several types that characterized by senile degeneration of the posterior columns and clinical evidence of posterior sclerosis (diminution of the deep reflexes and disturbances in postural and vibratory sense), that which involves the lateral columns and gives rise to spastic paraplegia without sensory changes or cystic symptoms and that evidenced by softening of the cord (myelomalacia) with scattered lesions in both the white and gray matter, and with symptoms of disease of the anterior horn cells (isolated atrophy with electric change in the muscles involved) In the author s experience the first type has never been associated with the clinical manifestations of posterolateral sclerosis (anemia achlorhydria) The symptoms in posterolateral sclerosis are probably due to the introduction of a myelolytic enzyme by way of the blood vessels while similar symptoms in arteriosclerosis of the spinal vessels are to be explained on the basis of advancing ischemia.

Spinal thrombosis may give rise to the Brown Sequard syndrome and syringomyelic disturbances are known to occur in pachymeningitis luetica after blocking of the lumen of the spinal vessels by organized exudate

Meningeal hemorrhage may be epidural intradural or subdural the epidural type is usually the result of trauma which ruptures the venous plexuses intradural bleeding less

frequently follows injury Both epidural and intradural hemorrhages are relatively unimportant because they are merely coincidental phenomena of a more severe lesion Subdural hemorrhage may follow trauma to the nervous system and is also frequently associated with obstetric injury convulsions fever, and hemorrhagic diathesis It is much more common than the extradural type It rarely leads to compression of the cord The most frequent cause of subarachnoid bleeding is rupture of an aneurysm at the base of the brain In some cases of apoplexy however the blood may find its way into the ventricles of the brain or into the subarachnoid space, and appear in the spinal sac These are cases which usually end fatally

Symptoms —In some instances meningeal hemorrhage produces no symptoms but as a rule its onset is marked by sharp pain in the back and symptoms referable to the nerve roots. There may be muscular spasms or paralysis of the arms or legs Except in instances of rupture of an aneurysm at the base of the brain there are no cerebral signs The cord symptoms depend on the level of the lesion

Prognosis —The prognosis varies with cause Recovery may ensue in cases of hemorrhage associated with constitutional disease.

Treatment —Since the cord is rarely compressed the operative removal of blood clots from the spinal cord seldom gives relief

Hematomyelia (Apoplexy of the Cord) —In comparison with apoplexy of the brain that of the cord is infrequent It occurs most often in individuals between twenty and forty years of age and is more frequently observed in men than in women It may be a complication of syringomyelia

Etiology.—Bleeding into the spinal cord is apparently not due to the same cause that evokes cerebral bleeding although the sclerotic changes associated with the latter syndrome are not uncommon in the spinal arteries The most important etiologic factor in spinal cases is *trauma* The spinal column itself may not appear to be injured and yet hemorrhage may ensue A fall on the buttocks or the legs direct injury to the spine sudden forward flexion of the head or a headlong dive may give rise to hematomyelia The lifting of a heavy load and military drill are also known to be precipitating factors Inflammatory and neoplastic lesions may serve as predisposing factors Spinal hemorrhage is favored by an underlying diathesis Arteriosclerosis seldom causes bleeding into the cord or its membranes Difficult labor may be a cause of hemorrhage in the newborn

Morbid Anatomy —Although hemorrhage may occur at any level it is most often found in the cervical enlargement The bleeding may extend throughout the gray matter or be restricted to one side of the cord and spread only in a vertical direction Frequently even when there are no apparent abnormalities on the surface of the cord palpation with the finger may reveal swelling The color of the cord may be bluish red because the blood clot shines through the surrounding white matter The extravasation is in some cases limited to one or two segments in others it extends through many levels and frequently it assumes a spindle like shape Since the gray matter contains more blood vessels and is a looser tissue than the white matter the latter is seldom involved except at the site of maximum hemorrhage. The lateral columns are usually spared When the lesion is of very long standing the pathways of the hemorrhage are represented by a cyst containing clear fluid

Microscopic examination of the cord lesions in the fresh cases reveals edema and necrosis After a few days evidence of glial proliferation can be found and granular cells abound later only local sclerosis remains If the anterior horn cells are destroyed atrophy of the ventral fibers is apt to ensue

Symptoms.—The symptoms usually begin suddenly and suggest a transverse lesion of the cord The patient falls to the ground as the result of weakness in the legs and exhibits sensory changes and disturbances in control of the sphincters Trophic phenomena soon appear At times the symptoms are less fulminating and the complete syndrome does not develop until secondary necrosis and inflammation have taken place At the onset there may be pain in the back and stiffness In mild cases symptoms are either lacking or so slight as to suggest a functional disorder When this occurs only very

bility that a spirochete may be the cause is still too vague a basis for systematic treatment Silver arsphenamine, sodium cacodylate and mercury have been given with some evidence of benefit Recently patients have been treated with malaria and with typhoid vaccine in addition to malaria, but without beneficial results, although some were temporarily improved Vitamin B intravenously or intramuscularly in doses of 100 or 200 mg daily or on alternate days is often definitely helpful In general symptomatic therapy and mechanical measures must be employed to combat the various manifestations as they arise

DIFFUSE AND FOCAL DISEASES OF THE SPINAL CORD

Affections of the Blood Vessels of the Spinal Cord—Branches of the anterior spinal artery enter the central part of the cord through the ventral fissure and supply all the gray matter except a large part of the posterior horn Branches from the posterior spinals penetrate from the periphery into the white matter of the posterior column. Although the white and the gray matter are not supplied by two independent systems there are regions of the cord in which the gray matter receives its supply exclusively from the central arteries, and the peripheral white matter obtains nourishment only from the vasocorona The veins of the spinal cord are arranged like the arteries except that they are much more in evidence on the surface of the cord

Anemia—The rapid development of paralysis after profound hemorrhage may perhaps be explained by resulting anemia of the spinal cord Intermittent claudication of the spinal vessels with temporary level phenomena has also been described

Endarteritis and Arteriosclerosis—Endarteritis of the cord is part of a general process associated with lues or senile atheroma Foster Kennedy and Elsberg have observed sclerotic changes in the vessels of the cord in individuals with neuritis of the cauda equina

Arteriosclerosis of the cord is of several types that characterized by senile degeneration of the posterior columns and clinical evidence of posterior sclerosis (diminution of the deep reflexes and disturbances in postural and vibratory sense), that which involves the lateral columns and gives rise to spastic paraplegia without sensory changes or cystic symptoms and that evidenced by softening of the cord (myelomalacia) with scattered lesions in both the white and gray matter and with symptoms of disease of the anterior horn cells (isolated atrophy with electric change in the muscles involved) In the author s experience the first type has never been associated with the clinical manifestations of posterolateral sclerosis (anemia achlorhydria) The symptoms in posterolateral sclerosis are probably due to the introduction of a myelolytic enzyme by way of the blood vessels while similar symptoms in arteriosclerosis of the spinal vessels are to be explained on the basis of advancing ischemia

Spinal thrombosis may give rise to the Brown Sequard syndrome and syringomyelic disturbances are known to occur in pachymeningitis luetica after blocking of the lumen of the spinal vessels by organized exudate

Meningeal hemorrhage may be epidural intradural or subdural the epidural type is usually the result of trauma which ruptures the venous plexuses intradural bleeding less

the meninges and nerve root sheaths A common form is the dural endothelioma or psammoma *Primary vertebral tumors* are sarcoma, osteoma and chondroma, of *metastatic tumors*, vertebral carcinoma is frequent. Less frequently other metastatic forms syphiloma tuberculoma and cysts involve the cord and related structures

Symptoms.—The following course typifies an extramedullary intradural tumor in the middorsal region Superficial pain of varying intensity and duration is due to a gradual compression of sensory roots at a definite segmental level This pain is frequently described as a feeling of constriction or as a girdle sensation and visceral disease may be suspected Coughing or straining may aggravate pain by increasing spinal fluid pressure Symptoms of cord compression then appear producing spastic paraplegia with subjective stiffness in the legs increase of the lower tendon reflexes and pyramidal tract involvement such as extension of the great toe on plantar stimulation (Babinski sign) Objective sensory disturbances are manifested by diminished perception of superficial sensation below a definite segmental level at which there may be a zone of hyperesthesia. Complete interruption of cord conduction by compression results in spastic paralysis clonus, superficial and deep anesthesia below the level of the lesion loss of anal and rectal sphincter control and automatic cord reflexes such as involuntary movements of the legs and automatic bladder

Diagnosis—Compression of the spinal cord eventually blocks the subarachnoid space and the circulation of cerebrospinal fluid and changes occur in the fluid below the compression which are of considerable diagnostic importance Froin described a rapidly clotting fluid of canary yellow color rich in protein to which he gave the name *xanthochromia* In cases of early compression Nonne found an increase in protein content without change in color clotting time or cell content Ayer has advocated combined cisterna magna and lumbar puncture in order to study respective pressures and flow of fluid in cases of suspected block Jugular compression normally increases spinal fluid pressure and flow In block such is not the case below the lesion and may be demonstrated by spinal puncture (Queckenstedt test)

Injection of air or of lipiodol (iodized poppy oil) into the subarachnoid space may show deformities or blocking of this space demonstrated by the roentgen ray thus indicating tumor

The upper level of cutaneous sensory loss is of great importance in determining the spinal segment involved Certain anatomic relationships however must be kept in mind In the upper cord the tumor is often sought for *too low* because the anesthesia is lower than the involved segment This has been ascribed variously to sensory skin overlap delayed crossing of sensory fibers within the cord or compression of the superficially placed laminated fibers of the lateral spinothalamic tract supplying lower sensation Unilateral disturbance of vibratory sensation indicates that the tumor is located on the same side Less often the tumor is sought for *too high* due to edema of the cord above the lesion or to compression of sensory roots which have a long intraspinous course as in the lumbosacral region It must be remembered that the vertebral bodies and spines and the cord segments have a different numeric relationship and suitable charts or tables must be consulted to ascertain the spinal level after the involved cord segment has been determined

Sensory conservation or relatively less involvement of the lower sacral dermatomes is *frequently found in cases of extramedullary* tumors Thus a conserved area of riding breeches design is explained by the anteromesial location of the tumor which involves the inner lateral spinothalamic laminations but spares those more peripherally placed For a similar reason the sensory skin disturbances for pain in intramedullary tumors more nearly correspond to the segmental location of the cord lesion Tumors anterior to the dentate ligament sparing the posterior roots may be painless Spinal tenderness on percussion opposite the affected segment is frequently present and is an important localizing sign Atrophies are important in localization and the same root and segmental relationships must be considered as in sensory signs Intercostal atrophy is of particular value because of the unisegmental innervation of intercostal muscles The

careful search reveals the isolated muscular atrophy (with electric changes), the slight but characteristic sensory disturbances and the fibrillation

Many of the symptoms depend on the location of the hemorrhage If it occurs in the lumbar region there is flaccid paralysis of the lower extremities with loss of the deep reflexes sensory changes involving pain and temperature for the most part (dissociated type) and atrophy of the muscles When the cervical enlargement is the site of the lesion, as it often is atrophic paralysis of the upper extremities and spastic paralysis of the lower limbs (spinal hemiplegia) result Involvement of the lower cervical cord may give rise to sympathetic phenomena (miosis pseudoptosis and enophthalmos) Taylor and Collier describe papilledema in cases of hemorrhage of the upper cervical cord and the author has also observed choked disks with this lesion. The hemorrhage may extend upward to the medulla and even into the pons Very frequently an acute Brown Séquard syndrome develops, with partial atrophic paralysis of the arm, spastic paralysis of the corresponding leg and contralateral disturbances in the pain and temperature senses At times the symptom complex is that of a transverse myelitis The writer has observed bladder and rectal symptoms and a typical 'riding pants' anesthesia in instances with bleeding into the conus Patients who survive improve markedly within a few weeks The paraplegia diminishes the bladder may recover its function and only those symptoms which are due to permanent damage to the cord (degenerative atrophies and the dissociated sensory disturbances) remain

Diagnosis —Hematomyelia must be differentiated from *meningeal hemorrhage* which is characterized by pronounced root phenomena pain in the back, and stiffness and tenderness of the muscles In epidural extravasation, however there is little pain Lumbar puncture helps to differentiate epidural from subarachnoid bleeding Hemorrhage into the spinal cord must also be distinguished from *acute myelitis* This is usually less sudden in onset is associated with fever, and runs a more protracted course *Thrombotic softening* of the cord caused by obliterating vascular disease may be recognized by the usual luetic history positive serologic data (blood), and by the evidences of definite spinal level involvement *Acute poliomyelitis* is, of course not associated with objective sensory disturbances

Prognosis —Except in those instances in which there is a severe transverse lesion or extension of the process to the medulla, the condition usually improves Complete recovery, however is rare Invasion of the phrenic area renders prognosis poor

Treatment —In the treatment of hematomyelia *absolute rest for two or three weeks* is essential The patient should assume the lateral prone posture and avoid coughing and straining at stool Care must be taken to prevent decubitus and bladder infection Later, warm baths and electric therapy are desirable Epidural hemorrhage may be treated surgically

TUMORS OF THE SPINAL CORD AND RELATED STRUCTURES

Primary tumors affecting the cord may arise from the cord substance proper from the spinal canal or from the vertebrae They are accordingly classed as intramedullary extramedullary or vertebral growths Extramedullary tumors may be further classified as intradural and extradural. *Hour glass tumors* partly intra and partly extravertebral, are named from the constricted mid portion which traverses the intervertebral foramen The most common primary intramedullary tumors are the ependymoma glioma and hemangioblastoma, the most frequent primary extramedullary tumor and indeed the most frequent of all cord tumors is the fibroblastoma arising from

magnum Tumors high in the cervical region which implicate the foramen magnum may simulate brain tumor in that they cause papilledema bulbar symptoms and occipital headache due to cervical root pressure

Treatment —Practical recovery has followed the surgical removal of extramedullary tumors with symptoms of marked compression In intramedullary tumors cysts may be evacuated and pressure symptoms relieved Posterior root section or chordotomy may be performed for intractable pain such as often occurs in vertebral carcinoma Deep x ray therapy may be used in inoperable cases, in cases of incomplete removal or in patients who refuse operation

Walter F Schaller

SYRINGOMYELIA

True syringomyelia or cavity formation within the cord is due to degeneration of poorly nourished glial tissue formed from primitive ependymal cell rests The cavitation occurs most frequently in the cervicodorsal region and usually begins in the posterior horns or about the central canal Cavitation may accompany *dysraphia* or occur secondarily and as a complication from cord hemorrhage chronic adhesive meningitis or degeneration of an intramedullary cord tumor Sensory dissociation is characteristic as the pain and temperature fibers which cross in the anterior commissure are involved in the lesion whereas touch fibers ascending in the posterior columns are spared Painless burns and injuries are symptoms which should lead the clinician to suspect this disease Central pain is an occasional symptom The anterior horn cells and lateral pyramidal tracts may be involved directly or by pressure causing muscular atrophies and spasticity of the extremities The vertebral column may be scoliosed from atrophy of spinal muscles and the thorax deformed (*thorax en bateau*) Trophic changes are frequent Unusual forms of syringomyelia are *analgesic panaris* (Morvan s disease) and *syringobulbia* *Peripheral neuritis leprosy* and *intramedullary cord tumor* are to be considered in differential diagnosis The course is chronic and progressive

Treatment should attempt to arrest the disease Deep x ray therapy is indicated Surgical drainage of the cavities by relieving pressure has given symptomatic relief

Walter F Schaller.

DIFFUSE AND FOCAL DISEASES OF THE BRAIN

APHASIA

Definition — Aphasia, as ordinarily understood is a disorder of language of either the emissive or receptive type which is produced by a lesion in certain regions of the cerebral cortex or subcortic nerve fibers usually on the left side of the brain

History —Gall about 1800 was the first to suggest that the brain was made up of organs which controlled the "vital and moral faculties of man" Gall was not a quack and not the phrenologist he is usually described to be, but a scientific pioneer in brain physiology and his work had a great influence on the thought of his time He believed that speech and the memory for words were situated in the frontal lobes

About 1861 Broca began to give us our first important knowledge of speech defects due to lesions of the left hemisphere His ideas were based on certain cases of aphasia in which the brain was examined after death Lesions were found in the posterior part of the second and third frontal convolutions as well as elsewhere in the brain Broca described some of these speech defects as "aphemie" although he divided cases into two groups—"aphemie" and "amnesie verbale." The aphemic patient is able to understand what is said to him and can recognize words although he cannot pronounce or repeat them His vocabulary is reduced so that he can say nothing at all, or perhaps only a few short words or oaths The amnesic patient can speak and pronounce words correctly but they may have no meaning at all Broca believed that aphemia" was produced by a lesion in the third frontal convolution of the left side

The left inferior frontal gyrus of the brain is known as Broca s convolution" Broca s area lies within Broca s convolution embracing the base of the inferior frontal gyrus It extends, perhaps also to the adjacent part of the lowest region of the precentral convolution and to the anterior part of the insula.

Trousseau supported Broca s views in the discussion which followed Broca s papers and introduced the word "aphasia to replace Broca s "aphemia."

Brown Sequard syndrome, at least incomplete, is produced by extramedullary as well as intramedullary tumors In certain cases there are no absolute diagnostic criteria by which intramedullary and extramedullary tumors may be differentiated Tumors in certain parts of the spinal axis have distinguishing features cervical tumors may produce quadriplegia and involve the ciliospinal center and phrenic nerve Vertebral carcinoma may simulate an hysteric state because of loss of emotional control produced by pain Tumors of the conus evoke a characteristic riding breeches anesthesia early loss of sphincter control and symmetric peroneal palsy and foot drop loss of ankle and retention of knee jerk by involvement of the sacral centers Caudal tumors are characterized by severe bilateral sciatica like pain and palsy of the lower motor neuron type This may be relieved by sitting or lying with the lower limb flexed to relieve root tension

Cord tumor may be suspected in any case of painful paraplegia of gradual onset *Sub acute combined sclerosis* may be difficult to differentiate in the early stages if the usual anemia is absent Paresthesia absence of definite pain achlorhydria and marked disturbance of deep sensation with preservation of superficial sensation are important differential guides *Erb s syphilitic spastic paraplegia* usually has syphilitic signs and positive serology *Myelomalacia* (*transverse myelitis*) and *meningomyelitis* are of acute or subacute onset Syphilitic *meningomyelitis* may be confusing although the biologic aspects of the fluid are often deciding factors *Multiple sclerosis* although characterized by spastic paraplegia usually has other cardinal symptoms *Amyotrophic lateral sclerosis* and *primary lateral sclerosis* are pure motor syndromes *Syringomyelia* may closely resemble intramedullary cord tumor and indeed has been considered by some writers as due to necrosis in a glioma *Tuberculosis* of the spine is frequently evidenced by spinal deformity or the roentgen ray *Hypertrophic cervical pachymeningitis* may simulate an extramedullary growth and forms in effect a tubular growth with marked root pain and atrophy in the cervical distribution *Herniation of an intervertebral disk* may simulate tumor by compression *Adhesive arachnoiditis* may cause cystlike formations which compress the cord An *inflammatory disease of the cauda* described by Kennedy and Elsberg may be impossible to distinguish from tumor Developmental abnormalities such as basilar impression (platybasia) and the *Arnold Chiari* deformity may compress the cord at the foramen

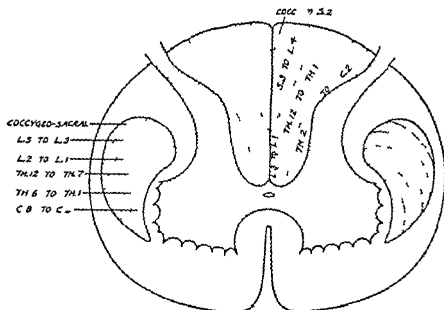

Fig 190 —Diagram to show lamellar arrangement of fibers in posterior column and in spino-thalamic tract (Purves Stewart, The Diagnosis of Nervous Diseases)

magnum Tumors high in the cervical region which implicate the foramen magnum may simulate brain tumor in that they cause papilledema bulbar symptoms and occipital headache due to cervical root pressure

Treatment.—Practical recovery has followed the surgical removal of extramedullary tumors with symptoms of marked compression In intramedullary tumors cysts may be evacuated and pressure symptoms relieved Posterior root section or chordotomy may be performed for intractable pain such as often occurs in vertebral carcinoma Deep x ray therapy may be used in inoperable cases in cases of incomplete removal or in patients who refuse operation

DIFFUSE AND FOCAL DISEASES OF THE BRAIN

APHASIA

Definition — Aphasia as ordinarily understood is a disorder of language of either the emissive or receptive type which is produced by a *lesion in certain* regions of the cerebral cortex or subcortic nerve fibers usually on the left side of the brain

History —Gall about 1800 was the first to suggest that the brain was made up of organs which controlled the "vital and moral faculties of man " Gall was not a quack and not the phrenologist he is usually described to be but a scientific pioneer in brain physiology and his work had a great influence on the thought of his time He believed that speech and the memory for words were situated in the frontal lobes

About 1861 Broca began to give us our first important knowledge of speech defects due to lesions of the left hemisphere His ideas were based on certain cases of aphasia in which the brain was examined after death Lesions were found in the posterior part of the second and third frontal convolutions as well as elsewhere in the brain Broca described some of these speech defects as "aphémie although he divided cases into two groups—"aphemie and amnésie verbale " The aphemic patient is able to understand what is said to him and can recognize words although he cannot pronounce or repeat them His vocabulary is reduced so that he can say nothing at all or perhaps only a few short words or oaths The amnesic patient can speak and pronounce words correctly but they may have no meaning at all Broca believed that aphemia" was produced by a lesion in the third frontal convolution of the left side

The left inferior frontal gyrus of the brain is known as Broca s convolution" Broca s area lies within Broca s convolution embracing the base of the inferior frontal gyrus It extends, perhaps also to the adjacent part of the lowest region of the precentral convolution and to the anterior part of the insula

Trousseau supported Broca s views in the discussion which followed Broca s papers and introduced the word "aphasia to replace Broca s "aphemia

Hughlings Jackson in 1864 began to write about the subject in quite a new way attempting to tell us more particularly the nature of aphasia He pointed out that aphasia on the emissive side is the inability to form or express a proposition in words and on the receptive side it is a failure of the mental processes which under lie perceptual recognition of a proposition—the more abstract the proposition the harder it is for an aphasic to formulate it or on the other hand, to understand it The work of Jackson was of great importance in many other ways and is only now receiving its full measure of appreciation

Bastian (1869) and Baginsky (1871) began to introduce schemas and diagrams of the speech centers and their relations to one another by nerve pathways attempting to reduce the knowledge of the subject to mathematic exactness and to postulate many theoretic types of aphasia Bastian described word deafness

Wernicke in 1874 localized the center for auditory images in the first left temporal convolution He believed that oral speech alone possessed cortical centers one guiding and the other emissive Between these two low to the subthalamic region The third frontal convolution and its subjacent white matter are excluded.

Moutier in 1908 published an important monograph on aphasia from Marie's laboratory Dejerine took issue with Marie's view and especially insisted that the term anarthria should be used only for troubles of articulation (as in pseudobulbar palsy etc.)

Head, in 1910 began to devise new tests for aphasia as a result of his belief in Jackson's views of the subject He regrouped cases of aphasia as follows

1 Verbal aphasia defective word formation both in internal and external speech

2 Syntactic aphasia, want of coherence and a tendency to talk jargon

3 Nominal aphasia defective use of nouns both spoken and written

4 Semantic aphasia deficient comprehension of the full significance of words and phrases

Head introduced the term symbolic thinking and expression Head's contribution to the subject in his papers of 1920 and 1923 in Brain" was mostly in the nature of an analysis of what aphasia is from a psychologic point of view He described his cases as showing certain defects in what he called symbolic thinking and expression and pointed out that defects in these two spheres included not only imperfections in spoken and written language and in the understanding of them but also such things as the inability to recognize the difference in symbolic meaning of the big and the little hands of a clock the inability to recognize the difference between making a turn to the right and to the left and so on

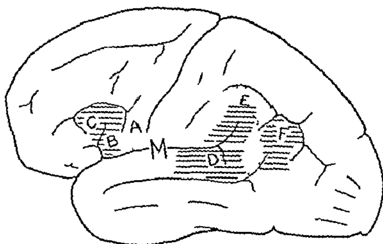

Fig 191.—The zone of language and the localization of the main types of aphasia A B C motor aphasia, characterized by aphemia D Temporal lobe aphasia characterized by word deafness anomia, jargon E Supra marginal gyrus aphasia characterized by global aphasia and apraxia F Angular gyrus aphasia, characterized by alexia M Mixed aphasia the common type of aphasia, characterized by aphemia, *agraphia, some alexia* with word deafness and marked hemiplegia

lay the island of Reil and therefore there were three possible kinds of aphasia The first was sensory with the lesion in the temporal lobe the second was motor with the lesion in the third frontal convolution and the third was a conduction aphasia with the lesion between these two centers

Wernicke's zone is the region including the posterior half of the first two temporal convolutions the angular gyrus the supramarginal gyrus and their subcortical areas

In 1906 Marie one of Broca's interns contributed a new theory to the discussion on aphasia His view in brief was that there was only one kind of aphasia the aphasia of Wernicke and that the motor aphasia of Broca is a combination of Wernicke's (sensory) aphasia with anarthria Anarthria he ascribed to a lesion of his lenticular zone which is a quadrilateral area defined anteriorly by a vertical plane passing through the anterior marginal fissure of the insula and posteriorly by a parallel plane through the posterior marginal fissure of the insula within it is bounded by the lateral ventricle and without by the surface of the insula. Above, it extends to the suprajacent convolutions, be-

Types of Aphasia.—Because the condition has not been fully understood and because various terminologies have been employed by different investigators it may be well to define briefly a few of the terms commonly encountered Cortical motor aphasia is the name sometimes given to a speech defect produced by a lesion in Broca's convolution Subcortical motor aphasia pure

motor aphasia and the pure word dumbness of Dejerine are terms used to describe a condition supposedly produced by interruption of nerve fibers which connect Broca s area and the center for articulation in the foot of the precentral convolution To the condition in which spontaneous speech is lost and the ability to repeat words is retained the name transcortical motor aphasia (Lichtheim's) is given This disturbance is caused by a cerebral lesion outside Broca s area, which interrupts the fibers passing to Broca s area from regions where word memories are aroused *Cortical sensory aphasia* is the disorder caused by abnormality in the cortex of the temporal lobe. The terms sub cortical sensory aphasia " Wernicke s pure word deafness and Dejerine s pure sensory aphasia are all used to describe functional separation of the sensory speech center from the auditory receptors by a lesion in the sub cortical nerve fibers Interruption of the fibers which connect Wernicke s zone with Broca s area (in the island of Reil for example) is known as *conduction aphasia* This does not destroy voluntary speech but produces paraphasia *i.e* skipping of words frequent repetition and confusion. "Dyslexia is the name applied to a condition in which the patient can only read a few words or sentences before he becomes fatigued and refuses to continue "Echolalia" signifies involuntary repetition of the last words spoken to the patient. Since a full description of all these types is impossible here the following discussion will include only motor and sensory aphasia

Motor aphasia is a condition in which a lesion in the speech center destroys the power to utter words which are in the patient s mind Its association with difficulty in reading depends on the previous mental habits of the individual. For instance the tendency to pronounce distinctly but silently each word that is read would doubtless lead to complete loss of the ability to read as well as to speak if a lesion developed in Broca s area Other variations in the clinical evidences of such lesions are probably to be explained by other mental habits Some individuals can normally remember words or figures only after seeing them, while in others retention is possible after they have been merely heard The great personal variation in the ability to form abstract propositions is sufficient to account for the various degrees of diminution in the power associated with lesions of similar situation and extent Because the few words which an aphasic patient can use are expletives and parts of the native language which have become automatic it has been suggested that the right hemisphere is responsible for their control. It is quite common for a patient to be able to use a few words of profanity such as Damn Oh Hell and so on, and it is well known that anyone who has acquired some facility in the use of a foreign language late in life may lose this entirely after becoming aphasic although he is still able to speak his native language The ability to solve simple arithmetic problems may be more or less affected (akalkulia)

In determining the location of the causative cerebral lesion it is first necessary as Kennedy has pointed out, to determine on which side of the brain the speech centers lie To do this it is essential to know whether the patient and also his stock are habitually right or left handed for heredity rather than use seems to determine whether the speech centers are on the right or left side of the brain The fact that the ability to write is often lost in aphasia is probably to be accounted for by involvement of the posterior end of the second frontal convolution by the lesion.

Perhaps the clearest conception of motor aphasia can be given by citing a typical case

Sir James Purves-Stewart in discussing Head s work described a condition in which all speech was suddenly lost, although the intelligence remained unimpaired. There was facial weakness on the right side. The patient was able to understand and execute all sorts of verbal commands, such as bending the thumb half way or straightening it out. The Babinski reaction was found on the right side No paralysis of arm or leg was discovered At autopsy there was a small lesion in the lower third of the left precentral gyrus due to embolic blocking of a small cortical arteriole This extended deeply into the operculum, but affected neither the insula nor the basal ganglia. Marie s "lenticular zone" was not involved. There was no other lesion elsewhere in the brain.

A somewhat atypical case mentioned by Bailey may also be of interest

A slight difficulty in reading was followed by inability to write a letter and later by definite aphasia, mainly of the motor type. The patient had great diffi-

culty in pronouncing words although she knew what she wanted to say Her comprehension of written speech was perfect and she could execute verbal and written commands easily The difficulty in reading and writing persisted although she could write her name There was some numbness in the right hand, and jacksonian fits involving the right face and tongue were associated with some residual weakness of the right lower side of the face and right hemihypesthesia with equivocal Babinski on the right side In this case the difficulty in reading was probably due to inability to say or write the words and not to inability to comprehend the meaning of the words—not a true alexia

A nodule of metastatic melanosarcoma (3×2 cm) was removed from the foot of the left second convolution at operation

"Sensory aphasia" is the term usually applied to inability to understand spoken or written language (word deafness word blindness alexia)

Word deafness is caused by a lesion of the posterior part of the left superior temporal convolution It is evidenced by inability to understand words which are heard by inability to repeat words and sometimes although not as a rule by loss of power to speak anything except jargon The patient is usually unaware of his errors of speech and is therefore not distressed by them as is the patient with motor aphasia Word deafness seems to be associated with some degree of mental impairment which may in certain instances arouse suspicion of insanity When the word deafness is not absolute the patient may understand an expected sentence from the doctor such as 'put out your tongue while he cannot carry out other spoken commands Gowers points out that expectancy seems to lower the resistance in certain nerve combinations just as it does so often in sleep Patients frequently have great difficulty in voluntarily naming an object which is held in front of them even when their normal vocabulary is large This so called *anomia* is not associated with loss of appreciation of the use of an object Sometimes a patient who cannot recollect a name after visual perception alone is able to do so when a second sense such as that of touch is called into play Another type of this indirect method of recollecting words is well illustrated by the author s experience On being asked what his telephone number was one patient said Olive 2–34–56–789 The number was Olive 2469 but it could be said only by means of gradual 'climbing up The same held true of the street address

For patients with word deafness the more automatic parts of speech, such as prepositions adjective etc , are easier to use than nouns Some individuals can say what they wish if they 'say it at once" At times words are uttered automatically as in the singing of a song Gowers suggests that when the left hemisphere is involved the automatic revival of words is probably made possible by the centers in the right side of the brain and he states that the slow recovery of the power of comprehension of spoken words is by the 're education' of the right hemisphere, since such regained power has been again lost in right sided disease"

Recovery from sensory aphasia seems easier than from motor aphasia.

Pure *word blindness (alexia)* which is produced by a lesion in the angular gyrus is not common The symptoms are inability to read print although it is clearly seen, and although the patient continues to write talk and understand spoken words well He can not copy satisfactorily Some suffer from hemianopsia and contralateral hemianesthesia or paresthesia There is seldom any motor weakness The intelligence is preserved

The most common type of aphasia is the *mixed* (frontolenticular lenticular zone aphasia) It is evidenced by total or marked loss of voluntary speech (aphemia) impairment of the ability to read difficult comprehension of spoken words and as a rule by marked hemiplegia without loss of sensation It results usually from hemorrhage from the branch of the middle cerebral artery which supplies the corpus striatum and internal capsule of the left side and involves the lenticular zone of Marie and some of the fibers from the frontal and temporal lobes

So called *global aphasia* which involves all parts of speech, is caused by a lesion of the left gyrus supramarginalis It is associated with apraxia or inability to perform certain acts where no paralysis prevents their execution According to Foix *apraxia* is of three kinds the motor which is usually unilateral right sided and renders the patient unable to imitate the voluntary movements necessary to perform such an act as brushing the hair when he is given the brush and asked to use it the ideational

(sometimes called *agnosia*) which seems to destroy the idea of how to perform an act alone although imitation is possible, and the ideomotor, which is a combination of these two and is characterized by loss of the idea of the act to be performed and by awkwardness in attempting to perform it

Examination of an Aphasic Patient.—In an aphasic patient the general neurologic examination is of great importance, because it often aids directly in determining whether the lesion is on the right or left side of the brain and whether it is situated in the frontal temporal parietal or occipital lobe In some individuals, exact localization of the abnormality depends entirely however on the type of speech disturbance. The following points are of great importance in the diagnosis of aphasia and should be carefully observed by the physician

Is the patient right or left handed, and is he of right or left handed stock?
How much voluntary speech is retained what are the defects in pronunciation and is the speech jargon?
If there is little or no voluntary speech is it possible to express ideas or emotions by pantomime or gesture?
Can the patient write voluntarily and to dictation?
Can he calculate or solve simple arithmetic problems?
Can he hum or sing a song?
Can he understand spoken language and obey simple commands, such as to bend the right thumb or to touch the right ear with the left thumb?
As commands become more complicated is it possible for the patient to obey them? For example, can he, on request, take your pen and pencil place the pencil on his table and return the pen to you?
Can he name a series of common objects (pen pencil, penny handkerchief notebook key box of matches the colors of different cards) which are placed in front of him and can he write the names of them as they are presented to him?
Does he appreciate their use?
Can he choose from a group of objects those for which you ask?
Can he correlate the printed name of an object with the object itself?
Does he understand the meaning of gestures? (Pretend you are going to hit him)
Can he read aloud and silently and can he repeat the substance of what he has read?

The degree of symbolic thinking and expression retained may be further tested by means of jig saw puzzles games of cards (bridge or poker) drawing both voluntarily and to command copying objects making a plan of a well known room telling time and placing the hands of a clock in certain positions at command

Treatment—In addition to removal of the cause of aphasia the treatment consists in reeducation Patient work under guidance often allows the subject to acquire a satisfactory vocabulary again Whether this is accomplished by vicarious activity of centers in the right side of the brain or not seems to make no difference in recovery of the function of speech Teachers accustomed to educate deaf and dumb children by the oral and lip reading methods are often very successful in such therapy

AFFECTIONS OF THE BLOOD VESSELS OF THE BRAIN

Cerebral Arteriosclerosis.—Arteriosclerosis of the brain may be part of a generalized arteriosclerosis or a process limited to the cerebral vessels

Symptoms—The symptoms of arteriosclerosis of the brain are varied There may be mild dizziness or severe syncopal attacks occasional nausea or vomiting which may lead to the erroneous diagnosis of indigestion transitory paralysis of one side, or fleeting aphasia Multiple small foci of softening may lead to intellectual deterioration or even obvious dementia they often produce the syndrome of *pseudobulbar paralysis* with dysarthria small step gait emotional instability and salivary drooling

EPILEPSY may also be a symptom, in fact many cases of epilepsy coming on late in life are caused by cerebral arteriosclerosis Mild types of arteriosclerotic disease of the brain appear under the guise of *neurasthenia* There may be severe vertigo which resists treatment or occurs in episodes headache mild delirium disorientation inability to concentrate or a syndrome resembling Korsakoff s psychosis In all of these cases it is very important to look for changes in the retinal arteries Occasionally however even advanced arteriosclerosis of the brain may not give rise to symptoms during life and the patient may retain his full mental vigor

In most cases postmortem examination reveals atrophy of the convolutions thicken

ing of the meninges and cortical vessels and an increase in the glia The patient exhibits emotional instability, impairment of memory, and various phases of mental deterioration Some individuals become irritable, highly emotional suspicious, and slovenly, indeed the personality may completely change The writer has observed great sexual hyperactivity in a man of seventy five

There are special types of arteriosclerosis of the brain The arteriosclerotic process may involve either the system of short cortical vessels or the long medullary branches In the first instance, the surface of the brain assumes the appearance of beaten silver, in the second extensive areas of softening and cyst formation in the subcortical layers and in the basal ganglia are observed In the *presbyophrenia of Wernicke* there is a tendency to fabrication and disturbance in memory with preservation of thought and judgment The *Binswanger form of presenile dementia* is characterized by loss of memory and mental hebetude *Alzheimer's disease* by progressive dementia, aphasia and at times focal symptoms

Treatment—The treatment is largely prophylactic Avoidance of physical or mental overexertion, and the institution of rest cures at home or in a sanatorium provide psychic rest and physical relaxation Graduated exercises may be tried but should be so regulated that the patient can rest for part of the day In the severe types complete cessation of work may be necessary Patients should be warned against straining at stool Sexual activity must be limited. The diet need not be restricted to milk and vegetables, but excessive consumption of meat cannot be permitted Curtailment of the salt intake is desirable The meals ought to be small and taken with as little fluid as possible The patient should not be permitted to gain weight in fact should reduce slightly Alcohol coffee and tobacco should be limited Mineral oil or mild cathartics may be given to regulate the bowels Warm baths and other forms of hydrotherapy are beneficial particularly for patients with nervous symptoms Nauheim baths also are of service Cold baths should be avoided For the headache and vertigo which frequently are troublesome hot fomentations may be applied to the forehead and neck Mild massage is also of value The high frequency current has its uses.

Iodides which still play the chief role in the medical treatment, are said to delay the advance of the disease They may be administered in the form of sodium or potassium iodide (0 3 Gm three times a day after meals) Occasional doses of diuretin (0 5 Gm two or three times a day) may be of service Nitrites have been recommended to reduce hypertension In neurotic individuals, bromides seem to relieve the headache, vertigo insomnia, and excitement For arteriosclerotic epilepsy, phenobarbital (0 03 to 0 06 Gm twice a day) is a great aid for the insomnia either sodium amytal (0 09 to 0 18 Gm), pentobarbital (0 09 to 0 18 Gm) or seconal (0 09 to 0 18 Gm) may be given before retiring Antineuralgic remedies may be employed for headache Treatment should also be devised for the accompanying nephritis and hypertension

Circulatory Changes in the Brain—Our knowledge of circulatory changes in the brain is incomplete Data are for the most part obtained during fainting spells or from plethoric patients Experiments have demonstrated however that a sudden, large loss of blood or the acute shutting off of the cerebral circulation usually gives rise to convulsions and coma In dogs simultaneous ligation of the carotid and vertebral arteries produces idiocy owing to definite changes in the nerve cells of the cortex These have been ascribed to anoxia

Anemia of the brain becomes manifest after severe hemorrhage or the aspiration of a large quantity of ascitic fluid in acute cardiac weakness and in spasm of the cerebral blood vessels The best example of an acute cerebral anemia is that resulting from the rupture of an ectopic pregnancy The face and mucous membranes are pale, the patient complains of blackness before the eyes, there is clouding of consciousness, and the gait becomes unsteady The patient experiences buzzing in the ears and nausea frequently vomits is apathetic and drowsy The pupils are small The syndrome resembles sleep Great loss of blood is followed by coma marked dilatation of the pupils and frequent convulsions

Mild hemorrhage simply produces "faintness The patient loses his senses," yawns a

great deal, and exhibits cold perspiration and pallor of the skin and mucous membranes. The pulse becomes rapid the respiration sighing and irregular There are no convulsions The syncope may last from a few minutes to an hour Consciousness returns when the patient is made to lie down

FAINTING may result from fear sorrow the sight of blood or severe pain Neuropathic individuals faint easily There may be a hereditary predisposition to syncope

CHRONIC ANEMIA is associated with chlor anemia pernicious anemia leukemia bleeding hemorrhoids and other causes of blood loss It is manifested by pressure in the head drowsiness apathy, vertigo tendency to faintness impairment of memory and Korsakoff like phenomena In some cases a change may be noted in the circulation of the retinal vessels The symptoms are usually worse when the patient is erect The delirium of inanition may be due to cerebral anemia. The mental symptoms in these cases are now ascribed to avitaminosis Severe diarrhea may evoke similar symptoms (hydrencephaloid state of Marshall Hall) A general spasm in the cerebral vessels may result in cerebral anemia That the cerebral blood vessels have a definite vasomotor innervation has been recently proved by the work of Forbes and Wolff Cobb and Finesinger

PROGNOSIS—Mild attacks of cerebral anemia are rarely dangerous. Severe hemorrhage with repeated convulsions may prove fatal Dilatation and fixation of the pupils is usually an ominous sign Primary optic atrophy aphasia or hemianopsia may follow severe hemorrhage

TREATMENT—In the acute cases after the cessation of the hemorrhage the patient is placed in the recumbent position The extremities are bandaged tightly and elevated in order to supply blood to the heart. Heat is applied Stimulants such as caffeine or hot coffee may be administered Amyl nitrite is sometimes of value Artificial respiration transfusion or saline infusions are powerful aids

Hyperemia—Cerebral hyperemia may be active or passive The possibility of permanent overfilling of the brain with arterial blood is remote but transitory hyperemia may occur in plethoric individuals with the apoplectic habitus It is manifested by ready suffusion of the face after meals or after exertion, and is often associated with elevation of blood pressure and cerebral congestion The patient has a subjective sense of warmth exhibits redness of the face and speaks of throbbing of the temples spots before the eyes headache and vertigo There is usually slight clouding of consciousness in the more severe forms of hyperemia there may be confusion and even manic excitement. Apoplectiform seizures with transitory paralysis, may occur

Amyl nitrite has been known to produce a temporary aphasia owing to cerebral congestion and disturbed vasomotor tone A tendency to congestion of the brain is frequently observed in psychoneurotics Onanism may be an etiologic factor in such cases Oppenheim has observed the association of cerebral congestive symptoms with stubborn constipation Among the other causes of cerebral hyperemia may be mentioned the contraction of the peripheral blood vessels after a cold bath and the suppression of menses The exacerbation of migraine with each menstrual period may be due to cerebral congestion or hydremia. Augmentation of the blood supply to the head may also result from dilatation of the cerebral blood vessels

PASSIVE HYPEREMIA is usually a chronic condition due to interference with the venous return from the head by tumors in the neck thyroid enlargement compression of the superior vena cava by mediastinal tumors cardiac decompensation or emphysema Pulmonary abnormalities which increase the intrabronchial pressure may also serve as etiologic factors by interfering with the return flow of blood to the thorax

SYMPTOMS—The symptoms are drowsiness headache which is aggravated by coughing vertigo and confusion. They become worse when the patient lies down Cyanosis of the mucous membranes and of the face is usually present

PROGNOSIS—The prognosis of simple congestion of the brain is unfavorable only if there is antecedent organic disease of the heart or blood vessels The apoplectiform habitus predisposes to cerebral hemorrhage

TREATMENT—The treatment is largely symptomatic it consists of catharsis and the

relief of headache and insomnia by the administration of mild narcotics (bromides and chloral) The effects of lesions of the superior mediastinum (substernal struma) may be ameliorated by surgical interference All forms of physical and mental exertion are to be avoided, the use of strong coffee and tea is best interdicted alcohol should not be taken

During the attack the patient must be made to sit up The room should not be too warm Application of mustard to the neck chest or lower extremities frequently gives relief In severe cases particularly in plethoric individuals venesection vigorous catharsis and hot foot baths are necessary For cardiac decompensation it may be desirable to give digitalis

Cerebral edema is not a clinical entity but is associated with serous meningitis In many cases of cerebral congestion the blood vesesls are distended and the brain is exceedingly moist This picture is often seen in uremia and in alcoholic intoxication it may occur as a sequel of trauma It sometimes is secondary to the formation of tumors or abscesses and renders the brain anemic and glistening A moderate degree of internal hydrocephalus is usually present. The symptoms are those of the underlying condition Uremic paralysis and convulsions have been ascribed to this edema of the brain

Cerebral Hemorrhage—*Incidence*—Hemorrhage into the brain is one of the *commonest cerebral accidents Although* it usually occurs in later life (after the age of forty) it can occur at any age It is more frequent in men than in women The hemorrhage is almost always the result of vascular disease—particularly atherosclerosis and usually follows rupture of some of the branches of the circle of Willis—especially the branches of the sylvian artery (middle cerebral)

Etiology—The causes of vascular disease of the brain are manifold among the most frequent are hypertension advancing age intoxications (alcohol lead tobacco diabetes gout), and infections such as syphilis In lues thrombosis occurs more often than hemorrhage Acute infectious diseases (typhus and scarlet fever) occasionally give rise to cerebral bleeding At times the cerebral hemorrhage is an incident in hemorrhagic diathesis (purpura, pernicious anemia and leukemia) Chronic glomerulonephritis with its associated hypertension increases the danger of bleeding There may be a familial tendency to cerebral hemorrhage

Bollinger described a clinical entity which he designated traumatic late apoplexy' This type of apoplexy follows in the wake of trauma and usually makes its appearance several days or weeks after the accident Bollinger postulated primary circulatory disturbances alteration of the tissues and subsequent hemorrhage into the softened area

The immediate cause of hemorrhage is a rapid rise in blood pressure This may occur as a result of severe muscular exertion coughing sneezing straining at stool coitus parturition or vomiting In children whooping cough, severe mental excitement and fear may be the precipitating factors Trauma may serve as an exciting cause in the presence of damaged vessels According to Volkmann a pressure fourteen times the normal is required to rupture the healthy carotid artery

Morbid Anatomy—Certain areas of the brain exhibit a predilection for hemorrhage *i e* the region of the basal ganglia (including the corpus striatum optic thalamus and the adjacent part of the capsule) the centrum semiovale the cortex and the pons Cerebellar hemorrhage is rare

Miliary aneurysms seldom develop in the arteries of the basal ganglia but sclerosis *may become advanced* The lenticulostriate and the lenticulo optic branches of the sylvian artery are the vessels most commonly involved The lesion may attain a diameter of 1 mm At first only the muscular coat atrophies later all the coats undergo degeneration This gives rise to dilatation of the vessel wall with consequent imminent danger of hemorrhage *

The size of the hemorrhage varies The escaping blood may plough through the brain tissue and make its way into the ventricles The largest foci are usually found in the basal ganglia and centrum semiovale those in the cortex and pons are as a rule much smaller Their color and nature vary

* Rosenblath and others have called into question the significance of miliary aneurysms in the genesis of cerebral hemorrhage They maintain that hemorrhage always occurs into a preexisting area of softening

with the age of the hemorrhage when fresh they have the color and consistency of recently coagulated blood later they may turn brownish black, brown or even yellow after the fifth week the yellowish color becomes more and more evident

At least four weeks are necessary for the formation of an apoplectic cyst. In the adjacent brain substance, proliferation of the glia precedes the formation of true connective tissue The contents of the focus are slowly absorbed and only a cavity remains This is later filled with yellowish fluid When the hemorrhage is extensive and causes immediate death, the convolutions are found flattened and the sulci narrowed

Symptoms—APOPLECTIC SEIZURE—The immediate sequel of cerebral hemorrhage is the apoplectic seizure Most patients exhibit *premonitory symptoms* such as dizziness a sense of pressure in the head hemiparesthesia anxiety confusion and disturbances of speech, others give a history of high blood pressure arteriosclerosis and pathologic urinary changes But the apoplectic seizure may occur suddenly in an individual who is in apparently perfect health Epistaxis or retinal hemorrhage sometimes precedes the acute manifestation *At the onset* the patient may suddenly fall to the ground and rapidly become unconscious (fulminating apoplexy), or may suffer merely a clouding of consciousness There may be only a transitory vertigo The clinical variations depend upon the size rapidity, and site of the hemorrhage Bleeding into the cerebellum and pons is less frequently associated with disturbances in consciousness

During the height of the attack the patient is comatose and cannot be roused The face is flushed and puffy the pupils do not react to light, they may be normal in size or dilated the corneal reflexes are abolished bilaterally the extremities are limp and both deep and superficial reflexes are absent The pulse is full and bounding at times rapid Breathing is slow deep and often stertorous because respiration sets the flabby palate and vocal cords in vibration at times it is of the Cheyne Stokes type The cheeks are often puffed out more so on the paralyzed side The patient cannot swallow even fluids There is incontinence of urine and feces occasionally retention occurs The urine contains albumin and often sugar (postapoplectic albuminuria and glycosuria) There may be generalized or unilateral convulsions Fever usually develops soon after the attack and if high, is of serious import

The apoplectic seizure may last from several hours to several days The causes of the coma are the circulatory disturbance in the brain the pressure of the exudate and diaschisis

In many cases there is conjugate deviation of the eyes A mild papilledema may be observed usually on the side of the lesion. If death does not result the patient gradually regains consciousness and exhibits a hemiplegia As he emerges from coma the reflexes return and, in spite of continued somnolence swallowing becomes possible There is some return of active motion Asymmetry of the face with sagging of the angle of the mouth on the affected side is noticeable the palpebral fissure is wider than normal the nasolabial fold is less marked and the patient drools on the paralyzed side The muscle tonus in the limbs is increased Cremasteric and abdominal reflexes are absent on the paralyzed side The Babinski sign is positive and the Oppenheim Rossolimo and Mendel reflexes as well * In respiration the involved side of the chest lags and the homolateral diaphragm functions poorly

If there is conjugate deviation of the eyes and the patient is in coma the hemorrhage is usually situated on the side toward which the head and eyes are directed Patient looks at his lesion' O Foerster found a number of oculogyric centers in the brain frontal parietal and temporal in location When these are irritated the patient looks away from his lesion when they are paralyzed the intact centers in the opposite hemisphere cause him to look at his lesion

Hemiplegia is often accompanied by vasomotor disturbances such as edema of the involved hand The pain which may be felt on the paralyzed side is either arthritic or central (thalamic) in genesis In conditions complicated by heart disease or nephritis

* The writer described the abolition of the corneal reflex on the hemiplegic side and emphasized the value of this sign in the diagnosis of vascular accidents of the brain

the edema may be more marked on the affected side When there has been no antecedent apoplectic manifestation, paralysis may be the first symptom The patient notes that he cannot hold or grasp things so well as previously or that his leg gives way under him

HEMIPLEGIA —The typical result of the apoplectic seizure is hemiplegia, i e, paralysis of the face tongue, arm, and leg, on one side of the body For a short period after seizure sensation is disturbed that associated with the posterior column i e the perception of vibration joint movements, and two point discrimination, more markedly than pain and temperature perception Speech is dysarthric and indistinct If the internal capsule is directly involved in the hemorrhage and more or less destroyed hemiplegia remains as a direct focal symptom Later on the picture changes somewhat There is marked increase of the deep reflexes on the paralyzed side and frequently a tendency to ankle clonus After several weeks a certain amount of mobility returns on the involved side owing to the functioning of accessory motor pathways The arm usually remains paretic for a longer period the leg is held in extension the arm may exhibit some return of power more proximally than distally The extensors of the hand and fingers seem to be seriously involved, those of the thumb most severely The flexors of the knee and the extensors of the feet and toes are very apt to remain permanently impaired Hemiplegic patients regain power slowly and usually can walk after six to eight weeks

After a time the *muscle tonus* in the affected limbs increases and contractures develop, especially in the arm The upper arm is adducted the forearm flexed at an angle, the hand pronated and flexed, and the fingers tensely flexed The leg usually becomes fixed in extension The contraction of the gastrocnemius group leads to the formation of pes equinus or pes equinovarus and gives rise to considerable difficulty in walking The patient therefore, supports himself on his sound leg and by circumduction lifts the paralyzed leg from the ground and swings it through an arc He thus avoids scraping the floor in walking Sometimes the paralysis remains flaccid this condition according to Oppenheim, results from very extensive disease of both the motor and sensory pathways In the author s experience the incidence of rigidity seems to depend on the proximity of the lesion to the basal ganglia Fulton ascribes the rigidity to a lesion of the fibers from the premotor zone The musculature usually remains intact, but there may be some atrophy from inactivity There are however, no changes in electric irritability aside from altered chronaxie

If the hemorrhage extends to the posterior limb of the internal capsule or into the optic thalamus there occurs in addition to the hemiplegia a *hemianesthesia* All forms of sensation are diminished or lost, the sense of touch being most involved The sensory changes may be limited to the distal parts of the extremities Hemiataxia may result from loss of postural sensation and is usually accompanied by astereognosis and tabetic athetosis

A certain amount of *mental disturbance* follows in the wake of cerebral hemorrhage. There may be diminution of intelligence, irritability, and disturbance of memory Actual dementia develops only when cerebral softening takes place owing to generalized atherosclerosis or lues The involved limbs may be unduly warm or cold and cyanotic Trophic changes in the joints have been described (Charcot) In right handed individuals, if the hemorrhage involves the subcortical pathways of association on the left side there may be aphasia The more extensive the hemorrhage and the more it damages the speech center the more permanent the aphasia When the hemorrhage bursts into the ventricles and reaches all chambers of the brain as it occasionally does, the paralysis spreads to all the extremities Convulsions may ensue, but more often generalized rigidity of one or both sides develops The pulse is slowed The temperature falls There are marked respiratory difficulties Lumbar puncture releases bloody fluid Such a hemocephalus usually proves fatal within twenty four hours

Hemorrhage into the pons and medulla may be bilateral or unilateral it may involve the tegmentum Clinically bleeding into the pons may be manifested only by vertigo The most common objective sign is the alternating hemiplegia (homolateral

cranial nerve palsy, contralateral hemiplegia) The paralysis is usually associated with disturbances in articulation and deglutition. The pupils are usually narrow often fixed The third cranial nerve, the motor fifth and the sensory fifth may also be involved owing to extension of the lesion upward in the brain stem General convulsions may occur Opisthotonos is not uncommon Respiration is often seriously disturbed Hemorrhage into the pons may evoke symptoms of acute bulbar paralysis but these are much more frequently observed in apoplexy of the medulla Cerebellar hemorrhage gives rise to cerebellar ataxia vertigo and vomiting

Differential Diagnosis—The differential diagnosis of apoplexy is of great importance The condition must be distinguished from simple fainting epilepsy uremia hysteria and the coma caused by intoxication *Simple fainting* can easily be distinguished by the absence of a profound loss of consciousness and by its short duration The pulse is usually rapid and feeble The fainting person is pale, but not comatose The *epileptic seizure* is indicated by tongue bite scarring of the tongue from previous seizures and the absence of hemiplegic phenomena Epilepsy is much more common in younger individuals *Attacks of hysteria* are easily excluded by retention of the pupillary reflexes and the presence of normal deep reflexes. The general attitude of the patient is quite different from that of the apoplectic individual. The face and tongue are rarely involved The Babinski sign is absent Abdominal reflexes are retained The hysteric hemiplegia is also frequently accompanied by a characteristic hemianesthesia The condition yields readily to psychotherapy *Uremic coma* can be differentiated by the presence of albumin and casts in the urine the demonstration of edema or albuminuric retinitis the history of headache vomiting and asthmatic attacks and the study of the blood chemistry *Diabetic coma* can also be ruled out by examination of the urine and the incidence of acidosis (acetone odor in the breath low CO_2 content of the blood) *Alcoholic coma* can be detected by the odor of alcohol the tendency to delirium and motor restlessness Morphine intoxication renders the pupils typically miotic *Acute hemorrhagic encephalitis* is also characterized by clouding of consciousness but is usually preceded by headache and fever The coma is less profound and the reflexes are often retained

In apoplexy not accompanied by profound coma the corneal reflex is diminished or abolished on the side of the hemiplegia. This unilateral diminution or abolition of the reflex is often of great value in distinguishing the coma due to apoplexy from that dependent on other causes The differentiation of cerebral hemorrhage from softening due to *embolism* or *thrombosis* is not always easy Hemorrhage is rare before forty" embolism is most common in children, and thrombosis usually occurs in middle life The presence of cardiac lesions suggests embolism arteriosclerosis indicates thrombosis and so also does syphilitic infection Simultaneous hypertrophy of the left ventricle and nephritis would point to hemorrhage The history of recent rheumatism even without endocarditis suggests embolism Redness and puffiness of the face and a full strong pulse should arouse suspicion of hemorrhage Most apoplectic patients exhibit hypertension The coma of hemorrhage is deep and persistent Premonitory symptoms such as paresthesiae transitory weakness of one side and intermittent disturbances in speech favor a diagnosis of softening or thrombosis With embolism preliminary symptoms are unusual Repetition of the vascular injury suggests embolism The absence of loss of consciousness and the appearance of symptoms indicative of an extensive lesion point to softening The incidence of phenomena of *motor irritation* especially of jacksonian seizures is higher in embolism and thrombosis

The symptoms of *cerebral tumor* may be simulated by *focal signs owing to the presence of an arteriosclerotic cyst*

Hemorrhage into a hitherto *latent neoplasm* may simulate thrombosis The onset of a metastatic neoplasm of the brain may resemble a vascular accident. There have been reported cases of transitory hemiplegia resulting from *cerebral angiospasm* The condition is allied to intermittent claudication of the lower extremities These vascular crises" as they have been termed by Pal are particularly common in smokers

Prognosis—The apoplexy may rapidly prove fatal especially in those cases in which the hemorrhage is extensive and perforates into the ventricle If the coma persists more than twenty four hours or constantly deepens there is grave danger to life. A steady *fall or an unusual rise in* temperature is also of serious import *Decubitus acutus* and Cheyne Stokes breathing are unfavorable manifestations Hemorrhage into the pons and medulla is often fatal Secondary aspiration or hypostatic pneumonia is a frequent cause of death After the occurrence of hemiplegia the symptoms diminish in severity the less complete the apoplectic attack the better is the outlook although a small hemorrhage in the region of the motor tract may evoke permanent unilateral paralysis Careful observation of the symptoms during the first week is necessary If the hemiplegia persists unchanged for a month or more it is *indicative of invasion of the motor* tract and recovery is unlikely If on the other hand muscular power returns somewhat during the first few days the prognosis is much better The character of the reflexes does not seem to be significant The presence of contractures is of serious import Most aphasias associated with hemiplegia seem to improve although frequently only after considerable time and then only partially Hemianopsia is also apt to be permanent The rapid subsidence of paralysis within a few days particularly in a young adult without hypertension suggests very strongly that the attack may be the first episode in general paresis This need disturb neither the intelligence pupillary reaction nor speech but the serologic findings characteristic of syphilis can usually be demonstrated

It may take the individual three or four months to regain the power of locomotion and then only with the patient help of the physician and family The prognosis for patients who have sustained a cerebral hemorrhage is uncertain because the etiologic substratum remains Fifteen to twenty years however may intervene between the first apoplectic attack and the one which causes death

Treatment—The treatment is *first prophylactic* *i e* that of the underlying vascular disease The patient should avoid liquor and tobacco and if adipose receive a diet carefully regulated to allow reduction of weight For the existing arteriosclerosis iodides (potassium or sodium iodide 0 3 to 0 9 Gm) are useful even in the nonsyphilitic cases Some observers advise reduction of the calcium intake while others favor the administration of milk About the need for restriction of salt and purines there seems to be general agreement Highly seasoned foods are undesirable. The patient should be instructed to avoid everything that suddenly elevates the blood pressure *i e* straining at stool sexual intercourse, the carrying of heavy weights undue physical exertion, and mental excitement A sojourn in a warm climate is often helpful

During the acute apoplectic attack the following therapy may be employed the patient should be put to bed with the head elevated If he has fallen to the ground the clothing around the neck must be loosened *Difficulty in swallowing contraindicates the* administration of nourishment by mouth An enema may be given When the face is puffy the pulse full and strong and there is reason to suspect hemorrhage venesection is advisable It should be employed only for plethoric individuals not for patients who seem asthenic or arouse suspicion of thrombosis Usually 250 to 300 cc of blood are removed No attempt should be made to arouse the patient For those with stertorous breathing the prone position is better If the tongue tends to fall back into the throat it should be held forward Attempts to treat the hemorrhage surgically have produced no striking results * If the diagnosis of hemorrhage can be made with reasonable certainty an ice bag may be placed over the site of the lesion Unless there is special need it is best during the first few days to avoid medication For restlessness bromides and chloral may be tried If there is much headache or sleeplessness an opiate or some other mild soporific should be administered If there is reason to suspect lues bismuth and salvarsan must be administered The attendant should guard against the development of decubitus The tendency of pulmonary congestion should be counteracted by frequent shifting of the patient from side to side

* In recent years there have been isolated reports of cases of improvement following surgical intervention

Treatment of the hemiplegia itself includes general massage of the paralyzed limbs and passive exercise In order to avoid contractures and changes in the joints such therapy may be instituted in the second week of illness After two or three weeks electric treatment (mild faradic current) may be employed The electric stimulation is best applied to the antagonists of the contracted muscles several times daily for four or five weeks At times surgical measures such as tenotomy and muscle transplantation may have to be employed The patient should make no effort to walk for three weeks and even then should spend the major part of the day in a bed Movements of locomotion may be carried out while he is sitting in a chair or lying down. If dependent limbs are cold and cyanotic support is helpful

Massage and passive motion should be continued for some time Aphasia requires adequate reeducation Warm baths are frequently useful The patient should be instructed to lead a more or less sedentary life in order to avoid further vascular accidents

Cerebral Softening (*Encephalomalacia*) —*Etiology*—Softening of the brain is caused by occlusion of an artery with resulting tissue ischemia and degeneration of the area of the brain deprived of nourishment Blocking of the vessel may follow either embolism or thrombosis *Embolism* takes place in chronic valvular disease (particularly in mitral stenosis) or in the auricular thrombosis *consequent upon dilatation of the* heart Occasionally the embolus originates in the aorta and in chronic suppuration of the lung it may come from the pulmonary veins Sometimes tumors of the heart lungs or other organs give rise to metastatic occlusion of the cerebral blood vessels The embolus may also be derived from a thrombus in one of the larger cerebral blood vessels

Thrombosis of the cerebral blood vessels is usually the result of arteriosclerosis or specific endarteritis Disease of the blood vessels may be produced by chronic intoxications (lead tobacco etc) or may be a result of hereditary weakness of the arterial tree Oppenheim thought that those psychoneuroses which were associated with symptoms referable to the cardiovascular apparatus often led to atherosclerosis early in life Laborers are also particularly prone to cerebral vascular disease

Certain diseases which increase the coagulability of the blood may give rise to thrombosis although the vessel walls are normal In this category are included infectious diseases (typhus scarlet fever polycythemia) and the puerperal state. Thrombosis is said to be more common in individuals with cardiac weakness owing to the circulatory retardation Chloranemia and leukemia may also be contributing causes, the former probably on account of the associated hypoplasia of the cardiovascular system Carbon monoxide poisoning often evokes softening particularly in the lenticular nucleus In some cases of tuberculous meningitis thrombosis induced by proliferative vascular changes has been observed Both embolism and thrombosis occur as the result of some precipitating factor such as fear excitement physical exertion or parturition The embolus usually remains fixed at the bifurcation of large vessels into smaller branches.

Morbid Anatomy—The sylvian artery (middle cerebral) and its branches especially on the left side, are most frequently involved the left vertebral artery is also occasionally affected Thrombosis occurs principally in the large vessels at the base of the brain Embolism may lead to secondary clotting of the blood in the neighboring vessels Occasionally there may be absorption or recanalization of the thrombus In cases of endarteritis the entire lumen of the vessel may be obliterated over a large area. The vessels descending from the cortex into the brain substance and white matter are usually end arteries In the cortex of the brain collateral circulation is more readily established than in the brain stem Occlusion of the sylvian artery therefore may not result in softening of the cortex but the deeper structures may be the seat of extensive degeneration According to Monakow occlusion of the main trunk of the middle cerebral (sylvian) artery leads to softening of the entire lenticular nucleus the anterior part of the optic thalamus the subthalamic region the motor area the island of Reil and the third frontal convolution Occlusion of the posterior cerebral

artery evokes softening of the occipital lobe the calcarine area the cuneus and the posterior part of the optic thalamus Occlusion of the anterior cerebral artery leads to softening in the frontal zone and along the longitudinal sulcus including the paracentral lobule

Softening may be found in all parts of the brain but most often in the cortex The caudate nucleus and putamen are also frequently affected thrombotic lesions are rare in the cerebellum The process of softening does not occur immediately upon occlusion of the vessel but may be delayed two or three days As soon as the brain assumes the characteristic consistency serous infiltration of the involved area takes place rapidly

Softening is of three types—red, yellow, and white, the color depends on the blood content of the tissues Red softening is particularly common in the cortex owing to its rich blood supply, it may also be frequently observed in the central gray matter near the aqueduct of Sylvius After a few weeks fatty changes in the diseased tissues and degeneration of the blood pigment render these red softened lesions yellowish in color In the white matter the softening usually assumes a whitish or bluish white color, in such areas we find droplets of myelin, detritus and granular cells The presence of these elements distinguishes true softening from *postmortem* maceration

After absorption of the degenerated material a cyst remains at times we find scarring This is particularly noticeable in the cortex which may become 'mouse eaten in appearance The size of the softened areas varies from that of a pin head to that of a fist An entire hemisphere may undergo softening for example after thrombosis of the carotid artery At times cerebral embolism may be associated with embolism of the central artery of the retina

Embolism occurs most often in young adults while thrombosis exclusive of the syphilitic type is seen chiefly in old people

The thrombosis involving the basal ganglia chiefly the lenticular nucleus is described as the lacunar type and leads to a clinical syndrome of paralysis agitans

Symptoms—In cases with large areas of softening particularly those due to embolism the *onset* is apoplectiform Embolism and thrombosis of the smaller vessels may occur without loss of consciousness If consciousness is lost the coma is not profound and is shorter in duration than that produced by hemorrhage It may be followed after several days by a rise in temperature, and in septic conditions by chills and fever Embolism of a large trunk always gives rise to loss of consciousness owing to mechanical injury to the brain or diaschisis The vascular occlusion may also be initiated by a convulsion Vomiting is a frequent symptom, occasionally there may be considerable prostration and mild delirium

Thrombosis of the principal vessels may also begin with apoplectiform symptoms but the loss of consciousness is usually less profound At times the paralysis develops very quickly There may be only a period of transitory confusion or mild disturbance of cerebration In some instances the patient complains simply of headache and vertigo In cases of embolism there are no premonitory symptoms while in thrombosis these are usually present and vary with the extent of the underlying arteriosclerosis The prodromata include pressure in the head, headache intensified by coughing sneezing straining at stool, or lying down as well as disturbances in memory and intelligence mild confusion and excitement or transitory aphasia Many patients suffer from sleeplessness exhaustion loss of interest and ambition emotional dulness irritability tendency to weep transitory paresthesiae and paralysis

The characteristic *result of cerebral softening* is the *hemiplegia* which is often progressive The mild hemiparesis is often followed by increasing weakness At first only one limb may be involved later the entire side is implicated In right handed individuals the motor phenomena are associated with aphasia When the area of softening is very circumscribed either a monoplegia with aphasia aphasia alone or hemianopsia ensues Indirect local signs may result from diaschisis * In such cases the paralysis may be an indirect symptom and the motor phe

* Diaschisis is a term suggested by Monakow for the mechanism which gives rise to transitory symptoms of brain disease owing to radiation of the insult from the focus involved to adjacent areas of the brain

nomena may disappear Hemianesthesia may accompany the hemiplegia exist alone or be associated with hemiataxia The hemiplegia may disappear owing to the establishment of a collateral circulation or the relaxation of angiospasm

Occlusion of the internal carotid especially if the anterior cerebral and the sylvian artery are involved evokes very extensive softening with hemiplegia and profound coma It leads rapidly to death Occlusion of the main branch of the sylvian artery causes hemiplegia with permanent or transitory hemianesthesia and aphasia if it occurs *on the left side in right handed individuals* When the plugging process involves only the branches the symptoms vary according to the area involved Occlusion of the first branch of the sylvian artery on the left side gives rise to motor aphasia with facial lingual and sometimes brachial paralysis, that of the second branch to hemiplegia or faciobrachial paralysis that of the third and fourth branches (which supply the lower parietal and upper temporal lobe) to alexia and word deafness The latter is especially noticeable after occlusion of the fifth branch Embolism or thrombosis of the anterior cerebral artery is followed by paralysis of the leg and psychic disturbances (akinesis) * Occlusion of the arteries supplying the white matter gives rise to hemiplegia and hemianesthesia Unilateral softening of the basal ganglia may evoke symptoms of motor irritation and all kinds of sensory abnormalities When the lesions are bilateral articulation and deglutition may be disturbed loss of mimetic display hyperemotionalism and bladder symptoms become evident (basal ganglion type of pseudobulbar palsy) In such cases phenomena referable to the pyramidal tract are not observed

Occlusion of the posterior cerebral arteries usually leads to hemianesthesia and hemianopsia. There are usually premonitory symptoms such as dizziness mental aberration headache transitory hemianopsia and other visual disturbances With the acute apoplexy there may be hemiplegia with convulsive manifestations After recession of the general symptoms the hemiplegia also disappears but the characteristic hemianopsia remains

Thrombosis of the basilar or vertebral artery commonly leads to acute bulbar paralysis A fairly typical symptom complex is engendered by thrombosis of the posterior inferior cerebellar artery (a branch of the vertebral) It frequently has an anomalous distribution but its blocking gives rise to a rather characteristic syndrome. In some cases death with bulbar symptoms ensues rapidly but if the patient survives the initial stage he exhibits a crossed sensory paralysis (homolateral involvement of the sensory *fifth and contralateral involvement of* pain and temperature senses) with ipsolateral ataxia of cerebellar type The innervation of the vagus and glossopharyngeus is also so disturbed that dysarthria dysphonia and difficulty in deglutition occur Sympathetic phenomena (Horner syndrome) also appear on the side of the lesion

Sometimes in cases of arteriosclerosis a number of small areas may undergo softening although there has been no major apoplectic seizure In these cases we find disturbances in intelligence bulbar speech spasmodic outbursts of laughing and crying and bladder symptoms (pseudobulbar palsy) Such softening when fully developed produces the syndrome of amnesia and aphasia which may go on to true senile dementia.

Diagnosis—If the symptoms (aphasia or monoplegia) point to a focal cerebral lesion and there is no history of trauma they are probably due to softening The differentiation of softening of the brain from *tumor* may be very difficult and can be made only after prolonged observation In most cases of cerebral softening evidences of increased intracranial pressure are lacking There is no papilledema slowing of the pulse or vomiting except in cases of thrombosis of the basilar artery † *Localized atrophies* of the brain occurring in advanced age may simulate softening but give rise to more profound coma and much more mental disturbance *Alzheimer s disease* must also be eliminated Many cases of softening of the

* Akinesis denotes an inhibition of psychomotor reactions i e disinclination to execute voluntary acts

† Within recent years the procedure of encephalography has become an important and valuable aid in distinguishing vascular from neoplastic lesions of the brain

brain without focal symptoms appear under the guise of *neurasthenia* The patients complain of headache vertigo prostration, and insomnia The constancy of the symptoms the absence of a neuropathic history and the signs of vascular disease especially in the retina will help to clarify the diagnosis Occasionally hemiplegia occurs in individuals in whose brain no changes can be found at postmortem examination This has been observed in *tuberculosis alcoholic intoxication uremia diabetes* and *lead poisoning* It is particularly difficult to distinguish uremic hemiplegia from that due to cerebral thrombosis although the former is more apt to be transitory Similar evanescent hemiplegias which may occur in the course of *pneumonia* or *allergic states* have been ascribed to edema of the brain or mild meningitic changes *Diabetes* may also be complicated by transitory hemiplegia

Prognosis —Death is less apt to occur in these cases than in cerebral hemorrhage Jones reports that death occurred in 30 per cent of a series of patients with cerebral hemorrhage in 15 per cent of those with thrombosis and in only 7 5 per cent of those with embolism Thrombosis of the basilar and carotid arteries is usually fatal The duration of the loss of consciousness is less significant than its profundity The general condition of the patient including that of the heart is important Those who suffer from localized softening may live for years If the paralytic symptoms do not improve within three or four weeks the ultimate prognosis is poor

Treatment —The treatment is first prophylactic *i e* that of the underlying arteriosclerosis Venesection is not necessary in cases of softening For the attack itself the treatment is with some modifications that of hemorrhage. For cardiac weakness stimulants may be given When there is reason to suspect a syphilitic origin of the vascular process bismuth and iodides should be administered at once and promptly followed by arsenotherapy The treatment of the paralysis has already been discussed

Intracranial Aneurysms —*Etiology* —Syphilis is rarely the cause of intracranial aneurysms They are the result of embolism of the vessel wall in infectious endocarditis or of cerebral atherosclerosis they may be congenital In the latter case there is frequently evidence of the constitutional dyscrasia known as status thymicolymphaticus '

Morbid Anatomy —The aneurysm may be of the miliary type or may involve the larger vessels Aneurysmal dilatation is more frequent in the cerebral vessels than in the other arteries of the body with the exception of the aorta The vessels most commonly involved are the arteries at the base of the brain or their branches before they penetrate the substance of the brain The lesions are frequently multiple and are usually sacculated. Their size varies from that of a pea to that of an egg They are more frequent on the left side The adjacent parts of the brain are usually compressed and may undergo atrophy or softening

The aneursyms usually develop in blood vessels which have lost their contractile substance in a circumscribed area Aneurysms of the cerebral vessels are more common in early and middle life Trauma has been said to be an etiologic factor There may be considerable softening around the sac only a small slit demonstrable in the vessel wall may indicate the site of rupture

Symptoms —The aneurysm may evoke no symptoms, or it may rupture spontaneously and lead to death There may be signs of mild cerebral hemorrhage or of fulminating apoplexy owing to rupture into the ventricles The site of perforation may be so small that there is only slow oozing into the subarachnoid space If it occurs periodically such oozing may give rise to a syndrome of meningeal irritation resembling that of pachymeningitis hemorrhagica. Rupture usually follows trauma exercise coitus fear or any other condition which elevates blood pressure The evidence of intrameningeal bleeding is obtained by lumbar puncture The spinal fluid is bloody or yellowish in color on account of the presence of derivatives of blood pigment Its cell content may be increased The bloody fluid does not coagulate spontaneously and after sedimentation in the test tube the supernatant liquid remains discolored This is not the case in instances of contamination of the spinal fluid by blood extravasated at the site of the lumbar puncture. Here only the first fluid obtained is bloody there is rapid co

agulation of the admixed blood which settles at the bottom of the test tube and leaves the supernatant fluid clear and colorless Such spinal phenomena as rigidity of the neck and positive Kernig sign are usually present

The symptoms of aneurysm are local and general. An important *general symptom* is *headache* which is often pulsating or migrainous in character It may be associated with vertigo and vomiting *Papilledema* is as a rule absent. Rupture of the aneurysm directly into the sheath of the optic nerve may cause *changes in the fundus of the eye* The hemorrhage may also spread from the subarachnoid space into the optic sheath and appear under the retina

There may be a *murmur* synchronous with the pulse, over the entire skull or over a circumscribed area this murmur however is not pathognomonic of aneurysm as it can be evoked by pressure of a growth on a blood vessel and may also be audible over a highly vascular neoplasm In children it has no significance because it accompanies rickets and hydrocephalus Such murmurs can also be heard in women with vasomotor disturbances and in adults suffering from idiopathic hydrocephalus They are also said to occur in Basedow s disease Compression of the carotid usually abolishes them

Although the symptoms depend on the site of the aneurysm they usually suggest the presence of a lesion at the base of the brain The symptoms progress as the aneurysm increases in size At times apoplectic attacks occur

Aneurysm of the internal carotid usually affects the nerves innervating the eye muscles the olfactory nerve the ophthalmic division of the fifth and the optic nerve It may give rise to exophthalmos amblyopia and various forms of hemianopsia. There may be changes in the disks paralysis of the oculomotor nerve pain hyperesthesia or hypesthesia in the region innervated by the sensory fifth and at times neuroparalytic keratitis Pressure on the cavernous sinus may lead to hyperemia of the retinal veins and dilatation of the superficial veins of the face In cases of left sided lesion pressure on the temporal lobe and peduncle may evoke aphasia and motor disturbances Perforation of the aneurysm into the cavernous sinus causes pulsating exophthalmos The aneurysm may also erode the sella turcica (Bramwell)

An aneurysm of the anterior cerebral artery may compress the optic and olfactory nerves In the middle cerebral artery, it may involve the olfactory nerve in addition to the oculomotor The pressure is for the most part exerted on the brain substance and gives rise to aphasia monoplegia or hemiplegia Aneurysm of the posterior communicating artery may produce hemianopsia by implication of the optic tract

Aneurysm of the basilar artery exerts pressure chiefly against the pons medulla, or peduncle The patient with such a lesion usually experiences pain in the occipital region and difficulty in moving the head. Compression of the pons with symptoms of alternating subacute hemiplegia or bulbar paralysis may be evident Manifestations of irritation or paralysis are sometimes referable to the individual cranial nerves (fifth to twelfth) In aneurysm of the basilar artery the hemiplegia shifts from one side to the other without ever disappearing completely until finally the condition becomes a diplegia or paraplegia Vomiting and respiratory embarrassment are particularly apt to occur in these cases

Aneurysm of the vertebral artery evokes similar symptoms and in some individuals the palate and vocal cord on one side and the hypoglossus on the other side may be involved The author has observed a case of aneurysm of the vertebral artery which gave rise to the syndrome of tumor of the upper cervical cord Cardiac arrhythmia may also be associated with the condition In aneurysm of the posterior fossa forward flexion of the head may evoke respiratory disturbances

The *symptoms* according to Symonds may be classed as local or pressure signs dependent on the localization of the aneurysm those due to the underlying disease and those peculiar to the aneurysm itself *Local* or *pressure signs* include such phenomena as have been enumerated above The symptoms referable to the *underlying disease* are either those of atherosclerosis or infectious endocarditis Disturbances attributable to the aneurysm itself include leakage from the sac meningeal irritation

and the presence of blood in the spinal fluid

The symptoms become acute when the sac ruptures Loss of consciousness is sometimes only slight Blood may escape into the spinal subarachnoid space The appearance of pain and rigidity of the neck after an apoplectic attack suggests subarachnoid rather than cerebral hemorrhage

Diagnosis—The history of a number of attacks of meningeal irritation is suggestive of intracranial aneurysm, especially if the spinal fluid is bloody or xanthochromic In some patients, the syndrome of Weber is produced by an aneurysm near the crus (homolateral lesion of the third nerve and contralateral involvement of the limbs) The fever has been ascribed to effusion into a serous cavity The conjunction of signs of basal meningeal hemorrhage with signs of tumor at the base is evidence in favor of aneurysm especially if these occur during the course of arteriosclerosis or infectious endocarditis (Symonds)

The diagnosis of aneurysm of the cerebral blood vessels is extremely difficult and can usually be made only after death Many experienced clinicians however have ventured the diagnosis on the basis of the clinical syndrome already described Sudden development of coma with hemiplegic phenomena in young individuals without a history of syphilis or hypertension should arouse suspicion The possibility of brain abscess must also be considered in these cases One third of the patients show evidence of intra cranial disease

The condition must be differentiated from *hemorrhagic pachymeningitis* from the various types of *ophthalmoplegia* from *migraine* with or without ophthalmoplegia from *tumor of the trigeminal nerve* and from infectious meningitis If coma is pronounced the disease must be distinguished from *cerebral hemorrhage* Symptoms pointing to the region of the internal carotid (oculomotor signs or trigeminal phenomena) are highly suggestive If in addition we find subretinal hemorrhages bloody or xanthochromic fluid the diagnosis is fairly certain (Symonds)

Owing to the presence of meningeal signs coma fever and leukocytosis the diagnosis of infectious meningitis is erroneously made in some cases of subarachnoid hemorrhage Lumbar puncture promptly clears up the difficulty in diagnosis

Prognosis—The ultimate prognosis in most cases is poor Rupture of the aneurysmal sac with subarachnoid hemorrhage constitutes the chief danger In case of seeping through a very small perforation there may be recovery and the patient may survive for months or even years The prognosis depends somewhat on the primary cause In individuals with extensive atherosclerosis or subacute endocarditis the outlook is poor Death may rapidly follow cerebral compression

Treatment—Lumbar puncture may be employed to drain off the extravasated blood but should not be made a universal practice because the lowering of the spinal pressure entails the danger of reopening the point of perforation and reinducing hemorrhage It may also cause sudden death by jamming the brain stem into the foramen magnum as it does in tumors of the posterior fossa If the signs of cerebral compression are so severe that there is danger to life either lumbar puncture or cisterna puncture should nevertheless be employed. Later on after the acute stage has passed and there are symptoms of meningeal irritation lumbar puncture may relieve the pain

Sinus Thrombosis—*Incidence*—Sinus thrombosis is rarely a primary affection it is usually secondary to phlebitis of the sinus or the veins communicating with it This in turn is almost always the result of an *infectious process in the vicinity of the sinus*

Sinus thrombosis may however be non infectious in origin when it occurs as a sequel of extreme cardiac weakness or of marasmus This type appears in either the very young or the very old In very young individuals it may follow in the wake of exhaustive diarrhea or of long standing suppuration The associated cardiac weakness retards the circulation sufficiently to permit coagulation of the blood In the terminal stage of exhausting diseases like tuberculosis carcinoma persistent typhoid fever and chlorosis the contributory factors are cardiac weakness fatty degeneration of the endothelial lining of the sinus and an increase in the number of blood platelets

Secondary sinus thrombosis usually fol

lows infective lesions adjacent to the sinus or its formative veins it is particularly common in cases of otitis with caries of the petrous bone or the formation of cholesteatoma It is most apt to develop in acute cases of ear disease but may come on at any time. In instances of bone necrosis there may be extensive involvement of the sinus wall or the phlebitis may extend along veins which connect the internal ear with the sinus. It is also frequently complicated by meningitis extradural suppuration or brain abscess Since the thrombosis is usually septic in character the process extends to the jugular vein and leads to general sepsis Sinus thrombosis may also be secondary to necrosis in other parts of the skull It may follow septic affections of the cranium scalp orbit nose or accessory sinuses In infected wounds of the face in facial furunculosis in septic processes involving the neck or the parotid gland and in facial erysipelas the cavernous sinus may become involved owing to extension of the infectious process along the emissary veins

Morbid Anatomy—Sinus thrombosis may be sharply localized or very extensive In the involved sinus either a fresh grayish red clot or an older paler somewhat organized thrombus adherent to the wall of the sinus may be found The older the thrombus the more firm the adhesion In secondary thrombosis the process is often purulent and the wall of the sinus is greenish or greenish yellow in color The purulent material may extend into the jugular and subclavian veins and even into the superior vena cava Streptococci and pneumococci have been recovered from such thrombi There may be destruction of the wall of the sinus with the formation of a perisinuous abscess The unthrombosed part of the sinus is usually very tortuous dilated and distended with blood The parts of the brain from which the involved veins normally carry the blood are hyperemic and are often the sites of capillary or larger hemorrhages

In most otitic cases the lateral sinus is involved while the superior longitudinal sinus is the most common site of marantic thrombosis The cavernous sinus is also frequently affected The involvement may extend from one sinus to another

Symptoms—The symptoms of sinus thrombosis are not characteristic In the marantic type they are obscured by the fundamental condition in the secondary types by such complications as meningitis and abscess Signs of venous stasis may appear *e g* in thrombosis of the cavernous sinus we may find dilatation of the frontal veins cyanosis of the orbital region swelling of the eyelids chemosis and exophthalmos Some observers have noted dilatation of the retrobulbar veins and at times papilledema owing to stasis in the retinal veins. There may be amblyopia Occasionally a history of neuralgic pains in the region innervated by the ophthalmic division of the fifth nerve can be obtained Paralysis of the eye muscles is common

Thrombosis of the sigmoid or lateral sinus leads to edema of the soft parts in the mastoid region and swelling of the upper part of the jugular vein (Jansen found the jugular vein involved in one third of his cases of otitic thrombosis) Sometimes a thickened cord may be palpated. The soft parts may become edematous owing to the presence of lymphangitis near the involved vein the lateral movements of the head become limited and there may even be spasmodic torticollis At times paralysis of the ninth tenth eleventh and twelfth cranial nerves has been observed If either the jugular vein or the lateral sinus on one side be thrombosed pressure on the jugular vein of the sound side may evoke engorgement of the retinal veins * Uhthoff found ophthalmoscopic changes in about 40 per cent of his cases of otogenic thrombosis

Thrombosis of the superior longitudinal sinus leads to dilatation of the veins of the frontal parietal and temporal regions In some cases there may be epistaxis The fontanels may bulge If marantic thrombosis occurs in the superior longitudinal sinus of a child there may be convulsions epistaxis and visible distention of the nasal veins also ensue owing to the communication between this sinus and the nasal veins In cases of primary sinus thrombosis following

* The Queckenstedt maneuver has recently been employed in order to determine the patency of the sinus In cases of complete occlusion of the sinus by thrombosis compression of the jugular vein on the ipsolateral side will not evoke rise in the spinal fluid pressure as determined by the spinal manometer

chlorosis, prolonged diarrhea, or tuberculosis the onset may be acute with violent headache vomiting and stupor There may be convulsions or paralysis, and occasionally rigidity of the neck. The pulse is not typical The patient usually fails rapidly and succumbs within a few days The diagnosis of such a condition depends largely on the knowledge and consideration of the etiologic factors and the slight signs of venous stasis The general symptoms usually arouse suspicion of meningitis or focal disease of the brain (hemorrhage or softening)

The symptoms of secondary otogenic thrombosis vary When thrombosis of the lateral sinus occurs during the course of chronic otitis (without sepsis or complete blocking of the vein) there are fever and headache but these symptoms also occur in meningitis, brain abscess or extradural suppuration

Very often an extradural abscess is the etiologic factor Among the symptoms of extradural suppuration are edema over the mastoid pain on pressure over this area limitation of movement of the head and nystagmus There may also be optic neuritis or papilledema The latter however is more frequent in sinus thrombosis than in extradural abscess

Sinus thrombosis usually gives rise to headache, vertigo, vomiting slowing of the pulse some rigidity of the neck, and other manifestations of meningeal irritation In the septic types such evidences of generalized infection as rapidity and irregularity of the pulse chills fever sweats enlargement of the spleen diarrhea jaundice and metastatic deposits in the lungs and the joints are soon added to the syndrome The blood culture is usually positive

Lumbar puncture often helps to determine whether there is suppurative meningitis in addition to the thrombosis The cerebrospinal fluid is as a rule not under increased pressure it may be sterile (meningitis sympathica) or it may contain organisms In the former case the predominating cells are usually lymphocytes in the latter polynuclears Its sugar content falls rapidly in infectious cases The thrombosis may extend from the lateral sinus to the inferior petrosal and cavernous sinus The latter may be involved on one or both sides

Occasionally evidences of the so-called 'Gradenigo syndrome' appears, this consists of palsy of the external rectus and symptoms referable to the sensory fifth. These are ascribed to an inflammatory process near the apex of the petrous portion of the temporal bone (petrositis) Usually the sixth nerve palsy is transitory

Prognosis —The prognosis of sinus thrombosis is unfavorable although benign types have been described in which the thrombus is absorbed or recanalized This is more apt to occur in primary thrombosis but recovery from the secondary type has also been reported In infectious cases the chief dangers are general sepsis and suppurative meningitis Pyemia seems to develop more readily in thrombosis of the lateral and inferior petrosal sinus than in thrombosis of the superior petrosal and cavernous sinus When the thrombosis extends from one lateral sinus to the other, meningitis is particularly apt to ensue

In modern times the outlook has been improved considerably by early operation A well developed, diffuse meningitis always makes the prognosis poor The incidence of localized meningitis or brain abscess is of serious but less grave significance

Treatment —In primary thrombosis treatment is symptomatic and designed to relieve the underlying condition Stimulats are given the strength of the heart maintained, and nutrition supplied The headache is relieved by an ice-cap or a sedative The patient should remain in bed with the head elevated In infectious thrombosis exploration with free drainage is necessary The treatment should also be prophylactic, including careful treatment of the primary disease (infectious lesions of the face, parotid mastoid) and the evacuation of extradural abscesses Operative therapy has proved very effective and may be employed in cases of septic thrombosis with gangrene of the wall of the sinus repeated chills optic neuritis and profound constitutional symptoms Ligation of the jugular vein has helped in some instances The presence of a diffuse suppurative meningitis is a contraindication to the active treatment of sinus thrombosis but the demonstration of pus cells or bacteria in the spinal fluid does not preclude operation

The recent addition of the sulfonamides to our therapeutic armamentarium will probably help to diminish the incidence of complications of otitis, including sinus thrombosis

INTRACRANIAL TUMORS

All expanding lesions within the skull may for clinical purposes be regarded as tumors It is only rarely possible to diagnose accurately before operation the exact nature of the lesion on the other hand it is often easy to name its situation in regard to brain areas

These conditions are much more common than has been believed Cushing found in a General Hospital Surgical Service 200 brain tumors in 2500 admissions it is certain that these lesions are often diagnosed as meningitis apoplexy and so on Even in the autopsy room centrally situated brain tumors may often be overlooked if very careful search is not made

Tubercle in mass formation often attacks the pons cerebellum and midbrain of young persons but unless there is calcification of such granulomatous formation capable of obstructing the passage of x ray it is difficult to be sure that such a lesion is not gliomatous in character Gummata of the brain and meninges do not appear in the autopsy room so often as in the textbooks, nevertheless careful exploration for lues must be made in all cases of suspected brain tumor

The frequency of various types of tumors can best be realized from a study of Harvey Cushing s statistics of 2023 cases

	Per cent
Gliomas	42 6
Pituitary adenomas	17.8
Meningiomas	13 4
Neurinomas	8 7
Congenital tumors	5 6
Metastatic and invasive tumors	4.2
Granulomatous tumors	2.2
Blood vessel tumors	2 0
Sarcomas (primary)	0 7
Papillomas (choroid plexus)	0 6
Miscellaneous and unclassified	2.2
	100 0

Various cellular types of tumor show a selective affinity for certain definite regions of the brain for example

Meningioma—Usually in the rolandic zone the sphenoidal wing or the olfactory region
Medulloblastoma—Midline vermis cerebellar syndromes
Astrocytoma—In the cerebellar lobes
Glioblastoma—Most frequently invades the temporal or the occipital lobes
Neurinoma—Most frequently involves the cerebellopontine angle

The commonest types of tumor are glioma and neuroglioma these are rarely discrete and are consequently essentially malignant in behavior Some are highly vascular and into their substance hemorrhages may occur others may undergo cystic degeneration The whorl celled endotheliomata and the fibromata which grow from the acoustic sheath are benign in character Both are encapsulated and grow very slowly they are often meningeal in position and so accessible to operation The slow growth of the endothelial tumor may produce by irritation of the periosteum of the skull such localized thickening of the bone as to invite the diagnosis of primary osteomata

Sarcomata are difficult to distinguish by the naked eye from gliomata they are often

metastatic, as from a hypernephroma, and occasionally pigmented as from the uveal tract Metastases to the brain may occur in both sarcomata and carcinomata, they are usually multiple Primary sarcoma of the base of the skull is not rare in young persons It damages, seriatim the contiguous cranial nerves and is quite inoperable

Symptoms—The symptoms are those due to rise of *general* intracranial pressure headache vomiting and papilledema This triad in the absence of cardiorenal disease is presumptive evidence of an expanding intracranial lesion One or all may be absent Irritative or paretic phenomena of gradually cumulative character may be so precise that the observer can be sure of the presence of tumor formation before intracranial tension is raised sufficiently to give rise to these general signs Papilledema or choked disk is a mechanical process whereby cerebrospinal fluid is forced from the general pond into the potential space of the vaginal sheath of the optic nerves it then appears as a swelling at the nerve head and as it does not involve the nerve fibers directly, it is compatible for weeks or months with normal vision Eventually the albuminous fluid becomes organized the nerve fibers are constricted and consecutive or secondary optic atrophy occurs Sudden blindness may come in cases of severe ventricular distention through bulging downward of the floor of the third ventricle which compresses directly the optic chiasma or the optic tracts behind and to the sides In Bellevue Hospital the release of third ventricle pressure by puncture of the corpus callosum or better still by ventriculostomy (opening the third ventricle wall—Scarff) has relieved this type of blindness Headache is due to stretching of the dura mater, and vomiting to irritation of the center in the medulla which is pressed into the bony ring of the foramen The slow vagal pulse is produced in the same manner Attacks of dizziness are common due to irritation of the labyrinths or other parts of the cerebellar mechanism or they may accompany attacks of transient diplopia Drowsiness frequent yawning and a depression of mental acuity are seen in individuals with ventricular distentions generalized convulsions may occur even though the neoplasm be not placed in either motor area

Focal Signs—In some cases of brain tumor, focal signs and symptoms never appear in others, they are equivocal

Tumors of the Motor Area—These are usually easy of recognition The early appearance of focal epilepsy is presumptive evidence of a lesion affecting either the meninges or cortex A constant site of inception and direction of spread may give precise information as to its position Transient hemiplegia following a focal fit may gradually become a permanent condition If the growth be entirely prerolandic there is no objective sensory loss in the contralateral limbs Should the neoplasm be placed more posteriorly there may be much paresthesia and loss of the sense of position in even the large joints of the opposite side in which case astereognosis would be evident in the affected hand Loss of tactile sense in such conditions is rare and changes in pain and temperature appreciation are unknown

The progress of all tumors one must remember is apt to be slow Deterioration necessarily precedes destruction of function inability to finger a violin properly exists before any appreciable loss of power is discovered. It will be found that lesions of the motor zones if situated on that side of the brain on which the speech faculties are represented produce defects of speech emission comparable to the losses of fine movement just referred to Words come sluggishly and are slurred Inapposite terms are unlikely to occur but accurate descriptions are pronounced badly and with difficulty, hesitation and effort If the growth be low enough to press on the first left temporal gyrus inaccuracies of name and description appear rather than difficulty of emission and articulation

Subcortical growths of the motor areas either do not produce focal epileptic seizures or do so later in the course of the disease Instead a progressive hemiplegia occurs if the tumor be deep enough to infringe on the optic thalamus there may be some alteration of all forms of sensory stimulation on the opposite side of the body which may also be the seat of deep burning pain produced especially by contact with cold or sharp objects. Athetosis is occasionally present

Tumors of the frontal lobes are apt to

give rise to an inapt purposeless jocosity, occasionally frequent yawning and urinary incontinence appear early If the tumor begins in the subfrontal area it may cause pressure on the optic nerve of one side thereby producing a primary optic atrophy without papilledema though the disk on the opposite side is choked Vision there is still normal

Expanding lesions of the occipital lobes are characterized especially by homonymous hemianopic defect in the contralateral visual field Primarily subcortical growths interfere with optic radiations and produce hemianopia primarily cortical lesions of the occipital pole especially of the walls and floor of the calcarine fissure cause visual fits in the opposite visual field followed later by loss of function in that field

These fits consist of crude phenomena lacking constructive quality twinkling or flashing lights in the affected visual field one patient said he saw objects in that field "as though through multicolored rain Alexia or hemianopia may follow visual fits as a transient phenomenon which may later become permanent

Tumors of the temporal lobe are difficult to recognize especially on the right side, owing to the comparative latency of the region affected Irritation of the uncinate lobules however, gives rise to paroxysmal crude subjective sensations of taste and smell and pressure on the neighboring internal capsule may produce a slight hemiplegia of the opposite side of the body pressure on the optic radiations will possibly result in partial quadrantic homonymous hemianopia Further there occur as a result of disturbance of these areas so called temporosphenoidal fits which may consist of true dreamy states in which consciousness though retained is oddly transformed and the relationship between the individual and the external world becomes subjectively altered Some of these attacks are accompanied by remarkable highly constructed hallucinations such as a woman dressed in blue who beckons to me an old woman in stinking rags ringing a bell figures dressed in eighteenth century costumes a lot of Negroes If the growth be on the side of the speech centers there is difficulty in naming seen objects but no real trouble in speech emission This condition is perhaps the most characteristic of all the temporo sphenoidal defects and is dependent on a degradation of function in the association tracts uniting the visual and auditory centers These naming errors are instantly perceived by the patient and annoy him The right word is recognized as soon as it is heard and so far are these people from being word deaf that an inaccurate prompting is always rejected

Tumors of the Centrum Ovale and Basal Ganglia—If the optic thalamus be implicated the syndrome peculiar to disease of this organ appears contralateral athetosis astereognosis and depression of the power to appreciate touch on the affected side explosive sensibility for superficial and deep pain and temperature with subjective burning pain of characteristic nature in the same parts Motor hemiplegia may be slight. Tumors of one striate body do not usually give rise to postural defects such as occur commonly from epidemic encephalitis

Tumors of the corpus callosum are characterized by a slow paralysis of all four limbs Cranial nerve palsies are uncommon The profound interference with association tracts produces blurring of the mind and interference with speech Reflexes may not be abnormal the muscles are waxy and overtoned so that alternating movements are initiated with difficulty One patient under the writer s observation a police sergeant, first discovered his illness by finding himself unable to relax his grasp of an offender s arm'—an instance of forced grasping'

Tumors of the quadrigeminal plate almost always originate in the pineal body in young persons Precocious puberty paints a picture in colors complementary to those used to portray the effects of certain pituitary growths The cerebral tissue is compressed but rarely invaded by glandular hypertrophy the passage from the third to the fourth ventricle may be completely corked by neoplasm and pressure on the oculomotor nuclei gives rise to palsies of conjugate deviation of the eyes upward and downward movements being first impaired Slowness of pupil reaction precedes immobility Nystagmus is almost always present. The gait is ataxic as are also the movements of the arms Bilateral pyramidal tract

metastatic, as from a hypernephroma and occasionally pigmented as from the uveal tract Metastases to the brain may occur in both sarcomata and carcinomata they are usually multiple. Primary sarcoma of the base of the skull is not rare in young persons It damages seriatim the contiguous cranial nerves and is quite inoperable

Symptoms—The symptoms are those due to rise of *general* intracranial pressure headache vomiting and papilledema This triad in the absence of cardiorenal disease is presumptive evidence of an expanding intracranial lesion One or all may be absent Irritative or paretic phenomena of gradually cumulative character may be so precise that the observer can be sure of the presence of tumor formation before intracranial tension is raised sufficiently to give rise to these general signs Papilledema or choked disk is a mechanical process whereby cerebrospinal fluid is forced from the general pond into the potential space of the vaginal sheath of the optic nerves it then appears as a swelling at the nerve head and as it does not involve the nerve fibers directly, it is compatible for weeks or months with normal vision Eventually the albuminous fluid becomes organized the nerve fibers are constricted and consecutive or secondary optic atrophy occurs Sudden blindness may come in cases of severe ventricular distention through bulging downward of the floor of the third ventricle which compresses directly the optic chiasma or the optic tracts behind and to the sides In Bellevue Hospital the release of third ventricle pressure by puncture of the corpus callosum or better still by ventriculostomy (opening the third ventricle wall—Scarff) has relieved this type of blindness Headache is due to stretching of the dura mater and vomiting to irritation of the center in the medulla which is pressed into the bony ring of the foramen The slow vagal pulse is produced in the same manner Attacks of dizziness are common due to irritation of the labyrinths or other parts of the cerebellar mechanism or they may accompany attacks of transient diplopia Drowsiness frequent yawning and a depression of mental acuity are seen in individuals with ventricular distentions generalized convulsions may occur even though the neoplasm be not placed in either motor area

Focal Signs—In some cases of brain tumor focal signs and symptoms never appear, in others they are equivocal

Tumors of the Motor Area—These are usually easy of recognition The early appearance of focal epilepsy is presumptive evidence of a lesion affecting either the meninges or cortex A constant site of inception and direction of spread may give precise information as to its position Transient hemiplegia following a focal fit may gradually become a permanent condition If the growth be entirely prerolandic there is no objective sensory loss in the contralateral limbs Should the neoplasm be placed more posteriorly, there may be much paresthesia and loss of the sense of position in even the large joints of the opposite side in which case astereognosis would be evident in the affected hand Loss of tactile sense in such conditions is rare and changes in pain and temperature appreciation are unknown

The progress of all tumors one must remember is apt to be slow Deterioration necessarily precedes destruction of function inability to finger a violin properly exists before any appreciable loss of power is discovered It will be found that lesions of the motor zones if situated on that side of the brain on which the speech faculties are represented produce defects of speech emission comparable to the losses of fine movement just referred to Words come sluggishly and are slurred Inapposite terms are unlikely to occur but accurate descriptions are pronounced badly and with difficulty hesitation and effort If the growth be low enough to press on the first left temporal gyrus inaccuracies of name and description appear rather than difficulty of emission and articulation

Subcortical growths of the motor areas either do not produce focal epileptic seizures or do so later in the course of the disease Instead a progressive hemiplegia occurs if the tumor be deep enough to infringe on the optic thalamus there may be some alteration of all forms of sensory stimulation on the opposite side of the body which may also be the seat of deep burning pain produced especially by contact with cold or sharp objects Athetosis is occasionally present

Tumors of the frontal lobes are apt to

the vertebrae as in lumbar puncture When intracranial pressure is obviously raised, the former procedure (ventriculography) is safer than the latter (encephalography) Such air *injections should only be done in carefully* selected cases, there is danger of sudden death during the procedure, especially in cases of tumors below the tentorium or of the midbrain Radiotherapy, as yet, has not justified the hopes once placed in it surgery is still the better instrument He who cares *for patients suffering from brain tumor must* bring to his task much thought and stout action There is need, too of formidable optimism for the dice of the gods are loaded!

ENCEPHALITIS

(Exclusive of Epidemic Encephalitis)

Nervous symptoms of any kind developing during the course of infectious diseases should always bring to mind the possibility of inflammatory changes in the cerebrum, cerebellum spinal cord or the meninges Furthermore it is impossible to speak of encephalitis without recognizing the possible occurrence of a myelitis and so the term encephalomyelitis represents the more accurate conception The meninges are implicated to varying degrees in different cases and yet again a peripheral neuritis may seem to dominate the picture

The inflammatory lesions are rarely if ever generalized in their full intensity but tend to be isolated or patchy in their distribution and many diverse pictures may be presented by different cases suffering from the same types of disease

Attempts have been made to associate certain nervous patterns with the different *underlying infectious diseases*, but although meningeal involvement may usually seem most intense with mumps cerebellar symptoms more often in chicken pox measles and German measles and perhaps myelitis complicating influenza such coincidences are by no means invariable and the obvious *nature of the primary disease usually* renders such speculations useless for clinical purposes.

Etiology—It would seem that influenza is by far the commonest disease to incite encephalitis or myelitis *In addition to this* others acting as incitants are measles *German measles* chicken pox *mumps* whooping cough small pox and psittacosis also occasionally in apparent epidemics vaccinia These it will be noted are all virus diseases, and suggestions have been made that the *complicating encephalitis is due to their re*spective viruses, but the occurrence of encephalitis in the course of certain diseases not of virus nature would seem to invalidate this theory Such diseases are chorea scarlet fever diphtheria tonsillitis putrid bronchitis pneumonia erysipelas typhoid fever, dysentery, typhus fever relapsing fever puerperal and other septicemias Bacterial endocarditis may be complicated by what appears to be a diffuse encephalitis rather than the more discrete lesions due to em*bolism Stuporous states occurring during* epidemics of acute poliomyelitis might legitimately be regarded as a cerebral form of that disease especially where some such paralytic phenomenon as ptosis constitutes a residual It is not always easy to differentiate between a simple delirium occurring in a fever and an encephalitis particularly in senile patients suffering from chronic bronchial infections but postmortem findings may in some instances establish the occurrence of the latter Certainly in none of these latter diseases is it thought that the complicating encephalitis is necessarily due to the organism causing the original disease The suggestion is that a latent virus already within the nervous system is activated or that the primary disease permits the entry of a virus from without.

pressure is usual and produces the characteristic paralysis and alteration of reflexes Severe ventricular distention is the rule

Tegmental growths usually produce a coarse tremor in the contralateral hand through implication of the rubrospinal tract and the red nucleus An ipsolateral third nerve paralysis may occur also Such tumors are often conglomerate tubercles most often found in children and adolescents

Tumors of the pons produce combinations of ipsolateral palsies of the fifth sixth, and seventh nerves together with paralyses of the opposite limbs It is important to determine the nuclear origin of these palsies as abducent lesions often arise from increased general intracranial pressure In such cases however they are not accompanied by ipsolateral facial paralysis nor is the movement of the contralateral internal rectus muscle decreased in amplitude or force Pontine gliosis may be diffuse and produce the appearance of simple pontine hypertrophy Papilledema appears late The fillet is extraordinarily resistant to compression and objective sensory change from this cause is consequently rare

Tumors of the cerebellum may arise within the brain itself or from the infratentorial meninges or nerve sheaths Intracerebellar tumors are soft rapidly expanding and usually malignant while those originating outside the cerebellum are usually hard fibrous and of tardy growth Papilledema appears early Dizziness is common

The sidedness of the growth can usually be determined by the nystagmus motor ataxia decreased muscular tone and weakness Nystagmus is usually slower and of greater amplitude on looking toward the side of the lesion and finer and more rapid on looking away from the lesion The other signs are all more evident on the same side as the tumor Decomposition of rhythmic movement may be present in the ipsolateral arm the finger nose test may be poorly performed on the same side and hypermetria, may also be seen The patient stands less well on the ipsolateral than on the contralateral leg A curious tilted attitude of the head seen in these cases is probably of vestibular rather than purely cerebellar origin

Tumors growing in the *cerebellopontine angle* more often arise from the sheath of the acoustic nerve their first symptom is apt to be tinnitus and vertigo followed by progressive nerve deafness The fifth nerve is next involved, subjective numbness and tingling in the face and the side of the tongue ensues By the time the facial nerve is implicated definite evidence of cerebellar compression is forthcoming These tumors grow slowly, two to five years may pass before successive involvement of contiguous structures makes plain the diagnosis

Tumors of the medulla oblongata produce bilateral pyramidal signs and affections of the lowest cranial nerves which result in difficulties in articulation and swallowing and arrhythmia of the heart and respiration If the fourth ventricle be invaded glycosuria is usual and vertigo becomes even more evident

Tumors of the hypophysis may be recognized both by neighborhood signs and the evidences of altered pituitary function The former is most characteristically bitemporal hemianopia but almost any form of hemianopic defect may occur Choked disk is rare and is seen only when the growth has blocked drainage by invading the fluid ventricle Primary optic atrophy is usual An incomplete Frohlich syndrome—adiposity eunuchism and abnormal sugar tolerance—may be an expression of defective pituitary secretion acromegalic symptoms are less usual

Intraventricular tumors and cysts arise from the choroid plexuses the ependyma or the medullary vela The symptoms produced by these tumors are essentially due to pressure on or invasion of structures bordering on their ventricular position

Treatment —There is nothing to be said for the expectant treatment of brain tumors though headache may be relieved by intravenous glucose solution of hypertonic strength *Action*—even though it be but a decompression operation—should follow diagnosis

A distinction can often be made between similarly appearing cases of expanding and degenerative brain disease by x ray photography of the ventricles and subarachnoid spaces air having been introduced to replace cerebrospinal fluid either through a trephine opening over the posterior ventricular horn or through a hollow needle inserted between

rest In considering the apparent lack of proportion between the severity of the primary disease and the incidence of encephalitis it would seem possible that the milder exanthemata since they do not inhibit the activities of the patient may increase the risk of encephalitis Exertion undertaken too early in convalescence would seem undoubtedly to aggravate the complicating encephalitis. Six weeks absolute confinement to bed is strongly recommended

Medicinally 90 to 120 grains of sodium salicylate with twice that amount of bicarbonate of soda daily appears to accelerate the recovery of some stubborn cases It may be given in divided doses every two hours for two days in succession in each week and repeated if improvement is noted Five grains of hexylamine every hour for nine doses a day may benefit some patients In fulminating cases, 50 cc. of 50 per cent glucose may be given intravenously or 100 cc of 15 per cent sodium chloride with the purpose of reducing cerebral edema Cerebral congestion and edema may also be reduced by free saline purgation or by magnesium sulfate glycerin and water enema in the proportions of 1 2 and 3 ounces respectively

Sulfapyridine or sulfadiazine are indicated in such infections as they have been found to influence but probably no effect is exerted by the sulfa drugs on virus infections Sulfathiazole having little if any power of penetration of the meninges should not be used

Withdrawal of 5 cc of cerebrospinal fluid by lumbar puncture daily or more often is of benefit when meningeal symptoms are troublesome Small amounts taken at intervals are probably more beneficial than larger amounts which might lead to undesirable changes in the cerebral circulation

ABSCESS OF THE BRAIN

Etiology.—The conditions which may lead to brain abscess by direct extension are *trauma* of the head or face *infective conditions* of the ear, eye or nose and its accessory sinuses and infections of the face and scalp such as erysipelas Metastatic abscess may develop from bacterial endocarditis particularly of staphylococcic origin osteomyelitis bronchiectasis abscess or gangrene of the lung pneumonia rarely pulmonary tuberculosis empyema streptothrix infection, actinomycosis carbuncle, influenza and other infectious diseases septic endometritis following abortion puerperal infection amebic dysentery liver abscess pyonephrosis and epidemic cerebrospinal meningitis Metastatic abscesses are likely to be multiple whereas those due to direct extension are usually solitary

Septic diseases of the ear are the most common cause of brain abscess and are responsible for 33 to 50 per cent of the cases seen in civil practice Chronic aural diseases cause many more brain abscesses than acute ones. Otitic disease may extend into the brain along thrombosed blood vessels or lymphatics The infection may travel along the seventh or eighth cranial nerve Granulations which develop after operation may block free outward drainage and force infection into the brain Sequestra in the temporal bone may be the exciting cause Extension from the ear may take place through the roof of the tympanic cavity into the temporal lobe of the cerebrum or from the mastoid cells into the cerebellum. Possibly in a large proportion of cases of aural disease there is some degree of serous, sterile meningitis but something more than this is required to cause abscess Even extradural or intradural collections of pus may not lead to abscess

Trauma of the head, not necessarily fracture of the skull is the next most frequent cause Brain abscesses have apparently resulted from injuries which affect neither the skull nor even the scalp seriously but the condition may be an extension from infected bruises of the scalp One would expect an abscess resulting from a head injury to be located near the surface of the brain but this is not always the case especially if the infection has been carried to

A different and really noninflammatory condition is that caused by malaria in which clumps of plasmodia may plug the smaller vessels of the brain or cord Syphilis, except perhaps in the case of general paresis acts through its destructive action on the blood vessels this leads us to consider some of the exogenous poisons such as arsenic and carbon monoxide as well as trauma which act on the brain only indirectly as the blood ves sels thereof degenerate or are otherwise in jured Caisson disease and fat embolism pro duce nervous symptoms by local anoxia Lead thallium and many other exogenous poisons used in industry particularly the solvents or dopes act more directly on nerve cells causing degeneration and some of them on the white matter of the central nervous system or on the peripheral nerves producing toxic degeneration rather than inflammation

Morbid Anatomy —Vascular congestion and edema most obvious in the gray mat ter and in some instances hemorrhages are found These are accompanied by more or less degeneration of cortical cells Perivas cular demyelination in the white matter characterizes other cases and perivascular cuffing is frequently found in such instances Glial proliferation is possibly a result rather than a part of the acute process Some of the most fulminating cases may show almost no postmortem changes

Symptoms —Special attention should be directed to the milder symptoms such as vertigo and numbness and tingling in vari ous parts of the body The two latter may or may not be accompanied by objective sen sory disturbances and all three in themselves may seem trivial until motor phenomena develop with the risk of serious disability Such are cranial nerve palsies particularly of the eyes hemianopia aphasia mono plegias hemiplegia paraplegia often of the ascending type and with or without sensory loss chorea athetosis incoordination sug gesting cerebellar disturbance and more spectacularly convulsions

It is perhaps more common for these to develop without such symptoms as head ache stupor and neck rigidity in cases of milder onset yet not a few such mild cases progress to serious and permanent dis ability

There would seem to be no correlation be tween the occurrence of encephalitis and the severity of the primary disease in fact it often complicates the milder forms of infec tion for reasons that will be speculated upon under treatment

The *temperature pulse rate* and *respira tory rate* are not much raised in the average cases which however may run a protracted course and leave permanent effects A tem perature rising to 104° F for more than the first day or two carries with it a grave prog nosis The pulse rate may be accelerated by changes in the heart or it may be acceler ated or slowed by disturbances of nervous control Tachypnea has been observed re sulting in a fatal issue A few cases result fatally from paralysis of breathing or swal lowing

The *reflexes* are frequently reduced or abolished in the earlier stages but later may become increased in those cases likely to leave permanent effects in the form of hemiplegia or paraplegia

Laboratory findings are on the whole of little assistance in the average case The white blood count is rarely much raised in the favorable type of case, the cerebrospinal fluid usually shows only a moderate pleocy tosis of less than a hundred cells per cubic millimeter, and some increase of the total protein content Xanthochromia may also occur but all such changes in the spinal fluid probably depend on the approxima tion of the inflammatory changes to the meninges and severe cases may run their courses with little if any change in the cerebrospinal fluid except an increase of its pressure

Prognosis —As regards life the prog nosis is usually most favorable except in the hyperpyrexial cases As to permanent dis abilities they would seem to be dependent on the success of treatment although on the whole they are not greatly to be feared Aphasia and epilepsy have been seen to fol low chorea in a child Spastic paraplegia or some degree of hemiplegia is not uncommon Such residuals are not however as common as the sequelae of epidemic encephalitis (See p 63)

Treatment —Of all forms of treatment the writer would like to emphasize most strongly the beneficial effects of prolonged

rapidly enough or become sufficiently extensive to cause shock but when only the surrounding areas of congestion and edema implicate these motor areas or tracts, spastic disturbances are more likely to ensue Furthermore, if the paralysis of a part be incomplete the abscess is probably not exerting its destructive action at the center representing that part and careful search should be made for signs of more complete loss of other functions This statement, however, must not be too literally accepted in the case of facial paralysis referable to the upper motor neurons since under these circumstances the lower part of the face is affected much more than the upper part and the paralysis even of the lower face is frequently inconstant and incomplete The paralysis may be complete hemiplegia or be restricted to as small an area as the thumb The minute lesions are liable to spread and the more or less rapid involvement of one part after another may be important in differentiating brain abscess from a neoplasm

Convulsions are suggestive of abscesses at or near the cortex purulent conditions within the ventricles have been found to cause great *drowsiness* or *coma*

The *reflexes* both tendon and cutaneous demand careful interpretation. Reduction or actual loss of the tendon reflexes and of the cutaneous reflexes with more or less weakness and hypotonia of the corresponding limbs suggests a homolateral cerebellar lesion but as has been pointed out above might be produced by a contralateral lesion of the upper motor neurons Disturbances of the tendon reflexes may be interpreted as an increase of those of one side above normal (contralateral lesion of the pyramidal tract) or a reduction of those of the other side below normal (ipsolateral cerebellar lesion) In the first instance some degree of spasticity probably exists in the corresponding limbs and the plantar cremasteric abdominal and epigastric reflexes may determine diagnosis In the second instance hypotonia and ataxia out of proportion to the actual muscular weakness may be the deciding factors

Homonymous hemianopsia may be caused by an abscess in the occipital lobe but if accompanied by hemianesthesia the region of the posterior limb of the internal capsule is involved If hemiplegia exists the anterior limb of the capsule is also included

Aphasia in its different forms may help locate the abscess but is often misleading possibly because the popular conception of the speech areas is incorrect but undoubtedly also because pure types of aphasia are rare The speech centers are located in the left cortex in right handed people and sometimes in the right cortex in left handed people *Anomia* is the sign most commonly produced by abscess of the brain because the purulent processes so frequently occur in the temporal lobe following aural disease Incomplete *sensory* or *motor aphasia* may in some cases be confused with the indefinite mental changes and so lose its value as an aid to localization

Astereognosis may aid diagnosis of abscesses of the parietal lobe but care must be taken to distinguish this condition from aphasia which prevents description of things the patient recognizes and can name

Olfactory hallucinations especially if associated with convulsive attacks or *periodic dream states* are indicative of a temporosphenoidal lesion Abscesses of the midbrain pons and medulla are rare and almost certainly fatal *Eye palsies nystagmus facial paralysis difficulty in swallowing respiratory disturbances* (Cheyne Stokes respiration) and various *pulse disturbances* may be expected to occur just before death Implication of the cranial nerves is more often produced by pus in the meninges than by abscess in the brain stem

Diagnosis —Abscess of the brain is often difficult to recognize on account of the frequent absence of signs and symptoms and the possibility of misinterpretation of those which appear

Choked disk may be absent in a greater proportion of these cases than in those of brain tumor possibly because the process is largely one of breaking down tissue rather than of additional growth For the same reason headache may not be a prominent symptom and vomiting may occur no more frequently than in mild gastro intestinal disorders It is frequently accompanied by nausea Intracranial disease may not be suspected by those who place too much reliance on projectile vomiting

some depth by a fragment of bone or a foreign body

An exacerbation of symptoms or the appearance of new symptoms several days after injury of the head should arouse suspicion of abscess of the brain After such injury or in disease of the ear and nose meningitic symptoms may mask those of brain abscess

Morbid Anatomy —An abscess of the brain is a softening which usually contains greenish pus In chronic abscesses this pus may be sterile or contain organisms of all kinds Abscesses which develop during exanthemata often contain organisms not usually associated with the primary disease. The lesion may or may not have a well-formed wall In many instances there is merely a simple gradation from pus to softened brain tissue, edema, and hyperemia while in others a somewhat hardened yellowish wall forms which is perhaps a protection against spread of the disease Some abscesses rupture into the ventricles of the brain Evidence of the spontaneous healing of others is thought to be the calcified nodule occasionally discovered after death

Symptoms —Brain abscesses may be acute or chronic that is the development of the abscess may fairly rapidly produce symptoms which cause death or demand immediate treatment or run a slow insidious or apparently asymptomatic course without evidence of the pathologic process until an exacerbation of symptoms or even autopsy reveals its existence. Such chronic abscesses may persist one or two years or more rarely for ten, twenty, or thirty years Those situated in the depth of the brain tend to remain quiescent longer than those near the surface

The *general symptoms* of both chronic and acute abscess of the brain are general malaise loss of weight poor appetite constipation, furring of the tongue and a heavy breath Chills are not common but may occur The patient may not be aware of fever, and the temperature may never except in the more acute conditions or terminal stages rise above 100° F Jaundice may be noticeable in the more chronic cases When abscesses break into the ventricles general convulsions delirium stupor tetaniform spasm chills, hyperpyrexia rapid pulse and respiratory disturbances result to be followed by death with signs of meningitis within a few hours

In addition to these general symptoms there may be *certain evidences more suggestive of intracranial disease* i e those associated with increased intracranial pressure (headache, vomiting, and papilledema) as well as mental signs suggesting hysteria neurasthenia unaccountable change of character or even a definite psychosis The most helpful indications of all are those physical signs which not only point with certainty to disease of the brain but may even indicate clearly the particular area involved

Of the signs of increased intracranial pressure associated with abscess of the brain *headache* is the most constant Any constant, or frequently recurring headaches especially those which prevent sleep, are most suggestive of intracranial hypertension The location of the headache may vary or, if fixed be remote from the seat of the disease In some cases the skull is tender on percussion. The headache is very often of the congestive type that is intensified by stooping, coughing and straining at stool

The *mental symptoms* of brain abscess are most varied and it is doubtful if the lesion can be localized with any accuracy by their nature Hallucinations of formed images have been considered characteristic of disease of the temporal lobe Delusions, disorders of memory, retardation and other symptoms suggesting either indefinite or well recognized psychoses may occur Difficulty of concentration, susceptibility to mental and physical fatigue moral turpitude, insomnia, restlessness, irritability, drowsiness and an infinite variety of mental disturbances result from such disease but without the physical signs do not indicate the probable location of the lesion

Signs —Physical examination is of the utmost importance since it alone indicates which area of the brain is to be explored Its nature is suggested by the character of some of the more common signs *Paralysis* of a part or a whole side may follow involvement of the motor area or its vicinity and of the pyramidal tract in the corona radiata internal capsule or crus It may be of the flaccid type if the abscess has developed

sage through arachnoid villi into the venous sinuses and partly by less obvious paths

The various lesions producing hydrocephalus do so by interfering with this normal circulation and absorption Leaving out of consideration the pressure of tumors which cannot be considered here the block may be the result of congenital anomaly infection or injury The aqueduct may be blocked by *failure of development* which results in obliteration of its lumen Naturally such a condition causes distention of the ventricles which cannot be drained by lumbar puncture When spina bifida exists hydrocephalus may occur either at birth or after surgical treatment of the spina bifida The exact relation between the two conditions is not clear but there is no question that hydrocephalus is one of the most serious dangers involved in surgical relief of the meningocele of spina bifida

Infections in fetal life or later may obliterate the foramina of Magendie and Luschka and prevent the flow of fluid into the subarachnoid space. This causes hydrocephalus and the fluid cannot be drained by lumbar puncture Any serious adhesions about the midbrain or extensive obliteration of the subarachnoid space over the hemispheres prevents fluid from reaching the areas where greatest absorption takes place The ventricles can be easily drained by lumbar puncture however and to this type the name of communicating hydrocephalus has been given to distinguish it from the obstructive' or noncommunicating types.

Injuries particularly the common birth injuries involving tentorial tears may result in effusion of blood and arachnoid tears about the midbrain Adhesions may form and prevent entrance of the fluid to the absorbing area As Beneke pointed out injury of the vein of Galen may produce back pressure on the choroids Whether this is a common cause of hydrocephalus is doubtful but Dandy and Blackfan s work lends support to the theory

Symptoms —Advanced hydrocephalus in infancy is unmistakable The child s head enlarges with a great disproportion between the normal face and the large cranial vault The sutures spread the fontanels enlarge and become tense and the eyes are dislocated downward by pressure upon the thin orbital plates For a time even in rapidly progressive cases the baby may remain bright maintain its nutrition, and show no evidence of cerebral involvement but sooner or later unless the process is arrested the thin cortex fails to resist the constant pressure and idiocy spasticity and optic atrophy result with eventual death from malnutrition or intercurrent infection In other instances the condition is arrested before serious damage occurs In some of these babies the hydrocephalus is so transient that downward dislocation of the eyes and bulging of the fontanel alone suggest the accumulation of fluid

Obviously the signs are quite different if the increase in fluid takes place after the skull has become rigid Headache vomiting thinning of bone early optic neuritis or atrophy dominate the syndrome These late cases however are usually the consequence of meningitis or of tumor and cannot be discussed in detail here

Diagnosis —The absolute diagnosis of internal hydrocephalus depends on the demonstration of enlarged ventricles If on lumbar puncture hardly any fluid can be obtained it is fair to assume that noncommunicating hydrocephalus exists if on the other hand the fluid flows freely and the fontanel becomes soft it is reasonable to conclude that a communicating type is present There is I believe only one important error that occurs with any frequency If enlargement of a baby s head is due to subdural hematoma surgical relief is urgent The paper of Ingraham and Heyl on this subject demands careful consideration

The diagnosis can be made more certain by puncture of the ventricle through the lateral angle of the anterior fontanel The dilated ventricle can be easily tapped and of course the thickness of the cortex measured by observing the depth at which fluid is obtained Dandy s method of ventriculography after injection of air furnishes absolute evidence of internal hydrocephalus Whether it is a reasonable procedure is a question The therapeutic resources are so few and the added information gained is so slight that the writer doubts its usefulness Certain it is by no means a trivial operation though before the closure of the sutures

The differentiation of brain abscess from *brain tumor* depends on the development of fever and leukocytosis as signs of infection These symptoms may, however be absent in the former condition or be caused by incidental factors during the latter Chills are most suggestive of abscess as are also the rapid development and extension of signs and symptoms but it is to be remembered that *hemorrhage into a glioma* may evoke the *same symptoms* The *absence or late* development of choked disk can be more readily explained by abscess than by tumor

The symptoms produced by some brain abscesses may be simulated by *uncomplicated otitic disease* and by exacerbations of chronic disease of the ears The disappearance of such conditions after operation on the ear or their failure to develop farther if the operation fails to abolish local infection entirely, offers some reassurance although continued observation is necessary *Meniere s disease* occurring in isolated attacks with complete recovery and absence of physical signs between exacerbations should not offer difficulty An *extradural abscess* is not likely to produce localizing signs or those of increased intracranial pressure but may cause tenderness and edema of the scalp far in excess of that produced by abscess of the brain

Diffuse purulent meningitis can be diagnosed with certainty by lumbar puncture If pus be found in the cerebrospinal fluid in the case of brain abscess there is also meningitis and the diagnosis of abscess must depend entirely upon the localizing signs

The sedimentation rate may be of aid in differentiating brain abscess from cerebral neoplasm

The *traumatic and reflex neuroses hysteria neurasthenia* and the *psychoses* may confuse diagnosis at times The presence of recognized physical signs of organic disease of the nervous system should prevent diagnosis of these conditions unless they can be referred to some preexisting changes It is not safe to diagnose these disturbances merely by a process of exclusion and if there is evidence of a possible abscess of the brain such diagnoses should be made only with the greatest reluctance

Prognosis—The prognosis is always serious Most brain abscesses lead to death

Treatment—The only treatment is surgical both with regard to the primary course of infection, particularly mastoiditis or sinusitis, and also in locating and evacuating the abscess This latter may often be done through a small burr hole remote from the infected area preventing later herniation of brain tissue through a large cranial defect then through this canal and the underlying clean brain tissue needling the abscess

Chemotherapy has not proved effective in the treatment of abscesses in themselves but should be employed for its possible effect on the source of the infection

INTERNAL HYDROCEPHALUS

Definition—Internal hydrocephalus is a condition characterized by an increased accumulation of fluid within the ventricles of the brain

History—Dandy and Blackfan in 1914 published a paper giving pathologic and experimental data which established a definite conception of the condition and rendered previous discussions of purely historic value

Etiology—An elementary knowledge of the physiologic factors governing the formation of the cerebrospinal fluid is essential to the understanding of the pathology of hydrocephalus In details there are many points where evidence is lacking or where opinions clash but it is clear that most of the fluid forms in the choroid plexuses within the ventricles and flows through the aqueduct of Sylvius to the fourth ventricle whence it escapes into the subtentorial subarachnoid space Part goes down into the spinal canal part flows upward through channels about the midbrain and reaches the subarachnoid space over the cortex of the cerebrum It is here that absorption in large measure takes place partly by relatively direct pas

alysis. The importance of birth injury is further emphasized by the fact that it may cause idiocy and epilepsy which are of great social and economic importance

Etiology —In this discussion the fetus during birth can be considered as a central nervous system surrounded by a relatively fragile envelope of flexible bone and connective tissue During the act of birth this envelope yields to force with consequent distortion Obviously the central nervous system is affected by pressure but remains undamaged if the balance between the forces imposed and the resistance of the fetus is not disturbed The fetus perishes if the vital centers of the medulla and the upper cord are seriously damaged but it may survive serious destruction of the cord below the vital level or of the brain above the medulla Usually although not always cord injury is the result of the maneuvers incident to breech extraction or to accidents consequent to severe traction on the brachial plexus.

Symptoms —The character of the symptoms is determined by the extent and location of the injury In a general way it can be assumed that injuries high in the cord will cause death by damage to the phrenic nuclei while subtentorial damage will probably cause death by pressure upon the medulla For practical purposes therefore it is essential to consider the physiologic disturbances due to cord injury below the fatal region or to cerebral damage at the midbrain or above

The intracranial injuries affect two different parts of the brain If the hemorrhage as usually happens is from branches of the vein of Galen or from that vessel itself the chief damage will occur in the subcortical regions notably in the basal ganglia. The consequence will be general disturbance of associated movements involving rigidity and athetosis If the circulatory disturbance is severe enough to involve the internal capsules as they pass between the basal ganglia spasticity will be added to the syndrome

In more severe cases practically complete decerebration may occur and lead to rigidity and idiocy In other cases prolonged labor particularly after the rupture of the amniotic membranes give rise to edema and extravasation of blood which is widely scattered within the substance of the brain Such lesions may easily produce diffuse injury to cortical cells and cause idiocy without conspicuous motor disturbances

Although our understanding of epilepsy is too slight to allow dogmatic assertions as to its etiology it is quite clear that among the infinite varities of damage caused by meningeal or intracerebral injury some may cause attacks

The fundamental point about the symptoms of cerebral injuries is that the symptoms produced by the injury are exactly analogous to those produced experimentally in animals The possible variations are infinite In order to understand them it is essential that the child should be considered from a physiologic point of view It is necessary to get away from a preconceived idea of spastic paralysis and from the still more mischievous notion that cerebral palsy means mental deficiency and to find out by rather simple physiologic reasoning what the undamaged residue is Upon this residue rather than upon what is gone depend rational prognosis and treatment.

Diagnosis —To determine whether any particular neurologic lesion dating from early infancy is due to birth injury faulty development or infection is frequently impossible Certain syndromes however such as mongolian idiocy congenital hydrocephalus microcephalus or spina bifida can be clearly distinguished and likewise the various familial degenerative diseases such as Werdnig Hoffmann progressive atrophy pseudohypertrophic muscular dystrophy Friedreich s ataxia and so on

There remains however a great group of nonprogressive conditions which may be considered from two points of view From the first the physician may attribute to birth injury only those conditions with conclusive history He will then be forced to rely on vague conceptions of heredity fetal infections and faults of development conceptions which although safe from an argumentative standpoint lead nowhere in particular The second point of view depends on the pathologic evidence that the central nervous system of babies dying at birth or shortly thereafter shows evidence of vascular injury in at least 50 per cent and prob

the risks are not great In children with rigid skulls injection of air is a major operation involving serious risks Injection of dyes into the ventricles with later attempts to recover them from the spinal fluid or the urine furnishes a valuable means of studying the conditions present but again adds to the risks without giving definite indications for treatment

Treatment —Drugs and endocrine therapy are illogical and of unproved efficiency The one exception is the indication for mercury and salvarsan in luetic cases If *syphilis* be present particularly with involvement of the cerebrospinal system demonstrable by examination of the spinal fluid active and persistent antiluetic treatment must be instituted As Jeans has pointed out, this treatment should be as vigorous as that used in adult cases

Early in the course particularly after birth injuries or meningitis *drainage* either by lumbar or ventricular puncture may be a life saving temporary measure or may aid reestablishment of normal circulation In these cases puncture should be repeated frequently enough to prevent harmful pressure, until it is clear that the condition is permanent, or until equilibrium between production and absorption is established One danger must be faced If spinal puncture does not drain the ventricles it is obvious that it will do harm because the release of pressure below may favor herniation of the medulla

Prompt release of cerebral pressure by ventricular puncture is necessary under these conditions

Surgery is the only hope in progressive hydrocephalus The problem is largely ethical for although no operation offers great hope, the alternative is so appalling that well considered skilfully performed operations are justified if the parents request them An almost infinite number have been suggested The fundamental objection to most of them is that the success depends on the establishment and maintenance of a path from the ventricles into the subarachnoid space and the tendency of the injured arachnoid to form adhesions has I believe never been overcome Dandy has extirpated the choroid and feels that this serious operation offers hope In Bellevue Hospital remarkable success is said to have followed the operation of ventriculostomy, *i e* opening the wall of the third ventricle. The whole question really comes down however to the search for a logical alternative to disastrous inactivity

BIRTH INJURIES OF THE CENTRAL NERVOUS SYSTEM

Under the classification of birth injuries is included any condition which may justly be ascribed to damage to the nervous system of a normal fetus as the result of the forces of labor asphyxia accident or hemorrhagic disease within the first few days of life It should be constantly borne in mind that the occurrence of a birth injury does not necessarily imply that obstetric care has been incompetent or unwise

History —W J Little established in 1861 the relation between difficult labor and disorders of the nervous system At irregular intervals since that time many authors have added important evidence until gradually a clear understanding of the various pathologic lesions and their effect upon the development of the child has been built up It is possible to explain with reasonable accuracy how the forces imposed upon the baby act upon the fetal nervous system

Incidence —It is probable that injury of the central nervous system during birth or immediately thereafter accounts for more than half of the deaths of viable babies Furthermore it is almost certain that such injuries are responsible for the disability of more children suffering from organic diseases of the nervous system than any other single etiologic factor except infantile par

nerves, when it is known as a "multiple neuritis" or "polyneuritis."

Mononeuritis (*Localized Neuritis*).—Although the disease may be limited to a single nerve trunk, as in traumatic neuritis, several nerves may often be involved. The condition is then termed "mononeuritis multiplex."

Etiology.—Localized neuritis may result from trauma, chronic intoxication, infection, extension of inflammation, and chilling. Not only direct *injury* of the nerve but also the contusion, traction, and compression resulting from forced muscular movements, the tearing and stretching caused by dislocation or fracture, the reduction of dislocations, and the traction on the head or arms of the infant during labor may evoke mononeuritis. Other etiologic factors are compression by callus, exostoses, cervical ribs, tumors, hypertrophic osteo-arthritis, and repeated severe compression by crutches or industrial instruments, accidental hypodermic introduction of chemical (arsphenamine, sera, ether, alcohol, etc.). *Chronic intoxication* by alcohol or metallic poisons frequently renders a nerve so sensitive that a subsequent slight injury may produce neuritis. During and after *infectious diseases* (typhoid fever, smallpox, diphtheria, tuberculosis) neuritis may develop in its localized as well as in its multiple form. Focal infection, particularly in the tonsils or teeth, is often the cause of a mononeuritis and sometimes of a polyneuritis. *Extension of inflammation* from adjacent parts (caries, bone syphilis, and more rarely diseases of joints) also causes the disturbance. *Cold* is an etiologic factor which has been overemphasized, although it is a common precursor of peripheral facial palsy.

Morbid Anatomy.—An inflammation of the nerves may originate in and be practically limited to the perineurium (perineuritis), be situated mainly in the interstitial tissue (interstitial neuritis), or within the nerve fibers (parenchymatous neuritis). In the first two conditions the nerve is swollen, infiltrated, and red. An exudation of migrating leukocytes is found in the fibrous framework of the nerve. The nerve fibers may not be involved, but there is usually an increase of the nuclei of the sheath of Schwann. The myelin is fragmented and the axis cylinders at times become varicose or undergo granular degeneration. Finally, the nerve fibers may be completely destroyed and replaced by fibrous connective tissue.

Parenchymatous or degenerative neuritis produces a lesion similar to the wallerian or secondary degeneration which occurs in the peripheral end of a severed nerve. It first affects the medullary sheath, then the axis cylinder, and last the neurilemma. The myelin becomes turbid and splits into fragments, small globules, and granules. The axis cylinder likewise becomes subdivided, swollen, and liquefied. Extravasated leukocytes engulf the disintegrated products and become granule or scavenger cells. The neurilemma and its nuclei frequently remain intact. The nerve shrinks in volume and appears grayish, grayish red, or translucent and may finally appear as a fibrous cord. The inflammation is sometimes limited to a portion of the nerve or to several isolated areas. Occasionally the whole trunk may be affected. Thus a focal, a disseminated, and a diffuse neuritis are described.

Recently clinical and pathologic evidence has been adduced to raise the question of whether in such cases as are characterized by degeneration the term "neuritis" should be used or be replaced by "neuropathy." Thus it has been shown that the pathology in the multiple neuritides associated with beriberi, pellagra, alcohol, lead, and other heavy metallic poisoning is uniformly one of a true degeneration.

Symptoms.—The symptoms may be divided into two groups: loss of function of the nerve and irritative phenomena of the inflammation. The first group when present differ only in degree; the second are variable and inconstant. In conditions due to trauma the loss of function produces flaccid paralysis with atrophy and reaction of degeneration in the affected muscles, sensory loss, and at times trophic disturbances. Unless the median or internal popliteal nerves are affected, pain is not a constant, severe, or prominent symptom. Various paresthesias, crawling, slight burning, and formication may be present. When the median or internal popliteal nerves are affected an exceedingly painful type of neuritis (causalgia) may appear. This is characterized by severe diffuse burning pain which is increased by movement, sudden noise, or other startling occurrences. It is partially relieved

ably in about 65 per cent of all cases Such evidence leads to the conviction that a baby of apparently normal development at birth who presents evidence of neurologic disturbance is handicapped by the results of the forces used in bringing him into the world Such a view is unquestionably difficult to establish, but it presents points of value Prophylaxis may be rendered possible by certain revisions of obstetric technic The horror of tainted heredity or other menacing phrases being eliminated the way is prepared to study the physiologic possibilities of a central nervous system damaged by sudden accident

The essential points in diagnosis are to differentiate the fixed nonprogressive type of disturbance from the progressive type and to bear in mind that tumors occur in babies

Treatment may for convenience be divided into measures for the immediate relief of injury and the later efforts to minimize the existing physiologic disturbances

The recognition of increased intracranial pressure is the most important single point in caring for the injured baby after birth Munro and Eustis advocate early lumbar puncture with manometric observations on the cerebrospinal pressure followed in many cases by repeated drainage if the pressure remains high This relatively simple procedure supplemented by ventricular puncture and by transfusion where there is adequate evidence of decreased coagulation constitutes the immediate therapeutic measures Decompression is a serious operation and on the whole is falling into deserved disrepute Ingraham and various others emphasize the frequency of subdural hematomata and properly urge search for evidence by puncture of the subdural space even if the skull must be trephined

Later on operative intervention to attack the intracranial or intraspinal lesion is extremely unsatisfactory Most surgeons after considerable experience have abandoned such operations or perform them only as desperate measures

The effort of the physician should be centered upon the attempt to make use of every bit of intact nervous tissue and to avoid hopeless therapy Idiocy severe convulsions and disability due to total transection of the spinal cord cannot in all probability be relieved by treatment On the other hand practically every child with less than these maximal disabilities is worth working over

Education, patiently and hopefully carried on restores certain patients to efficiency Orthopedic procedures of infinite variety may help but it cannot be too persistently repeated that the successful education of the child handicapped by birth injury is of primary importance and that this education cannot be properly directed unless a clear survey of the physiologic assets is made at the beginning of treatment In every case educational measures should be reappraised at intervals Optimism may be carried to a harmful extent The services of a skilful psychologist should be called upon to help in judging intellectual capacity in certain cases since in many of these children specific disabilities exist

DISEASES OF THE PERIPHERAL NERVES

NEURITIS

(Inflammation of the Nerves)

Neuritis is an inflammation of the nerves It may involve a single nerve when the condition is known as a mononeuritis or localized neuritis or a large number of

zation of vitamins in food which may be adequate Thus it may occur in gastro intestinal disturbances resulting from alcoholism primary anemias malignancy, old age and functional intestinal disturbances Furthermore when the intake is adequate and the factors satisfactorily utilized there may be an increased vitamin requirement and unless this is supplied by additional diet or active factors deficiency effects may ensue Among such conditions are overwork prolonged emotional strain, excess of carbohydrate in the diet states of increased metabolism fever infectious processes, pregnancy etc

Morbid Anatomy—It is now generally admitted that multiple neuritis is not confined to the peripheral nerves The nerve lesion is only part of a general intoxication which affects the spinal cord and the brain In one of the types described by Osler acute febrile polyneuritis widespread changes in the posterior root ganglia spinal roots, ventral horn cells and Betz cells of the cortex occur The condition differs from acute infectious multiple neuritis (acute pernicious multiple neuritis Heine Medin disease) which is allied to poliomyelitis occurs during epidemics of this disease and usually proves fatal within a few days or weeks Foster Kennedy has described a type of polyneuritis which he designates as *neuronitis*—in which the entire neuron is affected—the spinal roots, especially in the cauda equina and at times also the cord itself

The alcoholic paralysis undoubtedly due to polyneuritis may be associated with slight central changes in the spinal cord The central changes in diphtheritic paralysis are even more marked Lead sometimes affects the spinal cord and frequently the brain Arsenic more rarely affects the spinal cord So-called diabetic neuritis has been shown by Kraus to be in many cases a disease of the posterior roots and posterior columns of the spinal cord

Symptoms—Whatever the cause the general symptoms of multiple neuritis are similar and vary only because of the characteristics of the particular intoxication or infection The disease often begins with prodromata which sometimes persist for weeks The patient complains of numbness slight fever tingling in the extremities and sensations of heat and cold weakness then follows either suddenly or subacutely At times the paralysis is accompanied by fever Convulsions may occur particularly in children Some pain develops and the weakness increases The muscles and nerves become very tender while the skin may be reddened or slightly edematous. After a few days the patient may be unable to stand Complete paralysis of the anterior tibial muscles and of the extensors of the wrists may ensue after a week or two

The *paralysis* is flaccid and is followed by atrophy and other trophic changes The response to electric stimulation varies from an early loss of reaction to faradism to the complete reaction of degeneration The paralysis *is usually symmetric Certain groups of* muscles (the extensors) are more susceptible than others One of the characteristic features is the association of *sensory changes* with the paralysis Tactile anesthesia often associated with hyperalgesia may be an early symptom Later the temperature and pain senses are diminished and retarded The sensory loss is either patchy or diffuse The frequent loss of deep sensibility produces a pseudotabetic or ataxic form of the disease (diabetes diphtheria)

The *deep reflexes* are usually diminished or absent and the superficial reflexes disappear As a rule the distal portions of the extremities are the first to be affected In rare instances the motor cranial nerves may show the first signs The bladder may occasionally be affected for a short time Other visceral reflexes are not disturbed

Special characteristics of certain forms of multiple neuritis are noteworthy *Alcoholic polyneuritis* most often affects women The extensors are the muscles usually involved this produces foot drop and wrist drop The sensory symptoms are variable The course is as a rule favorable Mental symptoms are striking delirium is common and hallucinatory states delusional states and delirium tremens may occur In other cases Korsakoff s syndrome characterized by disorientation loss of memory for recent events and fabrication appears Jamaica ginger paralysis due to adulteration by tri orthocresyl phosphate produces a degeneration of the myelin sheaths of the peripheral nerves and changes in the anterior horn cells *Arsenic polyneuritis* resembles alcoholic

by continuous application of moist dressings So severe is the pain and so urgent the need for moisture that wounded soldiers under fire have often been known to apply rags saturated in urine to the sensitive areas

The consistency of the symptoms due to injury leads to the conclusion that many manifestations of the conditions due to other causes are the result of pathologic changes outside the nerve In disturbances due to sepsis arthritis and infectious diseases, pain is a prominent symptom It is dull aching boring at times continuous at times throbbing and often complicated by sharp lancinating lightning like flashes Nocturnal exacerbations are common All movements which tend to stretch the affected nerve increase the pain it is also aggravated by coughing sneezing and straining Frequently the pain is increased by distortion of the inflamed parts about the nerve as by an arthritic joint for example. The inflamed nerve may be swollen on palpation and is frequently tender to pressure The skin may be reddened glossy dry or moist and clammy the subcutaneous tissue edematous and the nutrition of the nails defective

Prognosis —The extent of injury and the character of the underlying lesions determine prognosis Minor degrees of trauma produce only temporary disability if the cause can be removed Accidental introduction of chemicals may produce irrecoverable lesions The neuritis produced by adjacent osteo arthritis can usually be cured whereas that consequent to caries cannot

Treatment —Neuritis due to trauma may produce a permanent physiologic interruption in the nerve and can be treated only by such surgical procedures as resection and suture Conditions which follow compression are likewise treated surgically by removal of the cause and in addition by neurolysis Causalgia may finally require injection of 60 per cent alcohol into the nerve In other types of neuritis the underlying cause (arthritis etc.) must be treated Proper splinting to prevent overstretching of paralyzed muscles and contractures should be applied The general treatment is the same as that for multiple neuritis

Multiple neuritis, polyneuritis or peripheral neuritis is an acute or subacute disseminated inflammation or degeneration of symmetrically distributed nerves which affects principally their distal portions

Incidence —It is a comparatively uncommon disease although rarely a widespread epidemic may occur, like that which resulted from arsenic poisoning among beer drinkers in England and from lead poisoning among children in Australia The two sexes are equally affected Multiple neuritis is most frequent in the second third and fourth decades of life Nondiphtheritic polyneuritis in children is rare Thomas and Greenbaum who reviewed the literature in 1007 found 138 cases and added eight The aged are sometimes affected with senile or atheromatous polyneuritis

Etiology —The causes may be grouped as toxic, infectious, and unknown Among the most common *exogenous toxins* are alcohol lead arsenic coal tar products carbon monoxide nitrobenzol mercury copper zinc phosphorus silver emetine apiol and thallium The *endogenous toxins* develop during diabetes and the cachexia of tuberculosis and syphilis Deficiency diseases such as beriberi pregnancy and perhaps alcoholism often cause polyneuritis The *infectious diseases* which most often play an etiologic role are diphtheria influenza typhoid fever measles scarlet fever whooping cough puerperal fever septicemia parotitis gonorrhea and syphilis Focal infections in the mouth or sinuses are responsible for some cases There are in addition various unknown factors

Suggestive proof has been adduced that in most cases of neuritis associated with alcoholism and diabetes or with arsenic lead and carbon monoxide poisoning a deficiency factor is the ultimate cause This proof consists of the amelioration of polyneuritis by thiamine chloride and studies upon pyruvic acid metabolism

Although marked improvement and often recovery follow the use of thiamine chloride alone it is felt that a multiple vitamin deficiency is responsible for many of the nervous system lesions which are common in beriberi pellagra polyneuritis associated with many morbid conditions such as alcoholism pregnancy diabetes gastro intestinal disturbances diphtheria and others

Such multiple deficiencies result not *only* from restriction of dietary intake but also from conditions that interfere with the utili

nign and vary in size from that of a pea to that of a child's head They may be relatively soft or very hard Multiple true neuromata have been observed chiefly in children They have been distributed in the peripheral part of the body under the skin They are very numerous in Bruns' case 100 were counted The patients otherwise are quite well

The *false neuromata* are tumors which originate in the perineurium epineurium or endoneurium They may be neurofibroma neurosarcoma, neuromyxoma etc Although they develop on all the nerves the spinal are those chiefly affected Their etiology is obscure Usually they develop in the first half of life and in many instances have been hereditary In multiple false neuromata (general neurofibromatosis) large numbers of tumors form on many or all of the peripheral nerves. R W Smith has reported a case in which 450 were counted on one extremity and 2000 were present on the body All types—plexiform neuromata pachydermatocele or elephantiasis neuromatosa and multiple neuromata neurofibromata or molluscum fibrosum (von Recklinghausen's disease) as well as tubercula dolorosa—are expressions of the same abnormal tendency These lesions may be associated with pigmentation of the skin in the form of freckles blotches or diffuse areas

The most prominent *symptom* is pain which radiates from the tumor to the periphery of the nerve. It is usually intermittent but may become continuous and agonizing Paresthesia is occasionally observed weakness is rare and the deep reflexes are seldom affected

The only available *treatment* is excision although Ludwig Kenez reported that the hypodermic administration of fibrolysin produced successful results

DISEASES OF THE CEREBRAL NERVES

PERIPHERAL AND CENTRAL DISTURBANCES IN FUNCTION

THE OLFACTORY APPARATUS

BEFORE any conclusions can be drawn concerning the acuity of smell careful local examination of the nasal fossae is necessary The essential oils (lemon wintergreen peppermint and clove) may be employed to test the sense of smell first in one nostril and then in the other

Organic Hyposmia and Anosmia —Organic hyposmia or anosmia is the result of various conditions The sense of smell may be diminished or lost if the free endings of the nerve cells in the olfactory epithelium are involved by alterations in the nasal mucous membrane These changes may be caused by coryza influenza or diphtheria by lesions of the fifth nerve producing trophic changes in the mucous membrane by caries of the underlying supporting osseous tissue (ethmoid sinusitis) or by the growth of nasal polypi Pressure on the olfactory neurons at any point between their peripheral distribution in the nasal mucous membrane and their incorporation into the hemispheres may in

neuritis and is distinguished by the general symptoms of intoxication gastro intestinal disturbances puffiness of the lids dermatitis, hyperkeratosis changes in the nails jaundice and other evidences of hepatic disease Muscular tenderness is especially common and the changes in the muscles often lead to severe contractures of the toes and fingers Poisoning may follow administration of medicinal drugs contamination of food and drink or accidentally ingestion of vermin destroying mixtures *Lead neuritis* is often associated with the general signs and symptoms of lead poisoning a lead line' in the gum margins secondary anemia stippling of erythrocytes and abdominal pain and constipation The neuritis is frequently confined to the upper extremities Sensory changes rarely are present Intoxication results from the handling of lead products (paints type lead pipe) the smelting of ores the contamination of water and the use of cosmetics *Diphtheritic paralysis* is frequently associated with dysphagia regurgitation of fluids and nasal speech Paralysis of the ocular accommodation reflex is very common When the polyneuritic symptoms occur in the extremities they are often associated with ataxia This may at times be present without paralysis Rarely recurrent polyneuritis has been described

The course of the disease varies with the intensity of the underlying lesions As a rule the symptoms increase during the first four to six weeks and then diminish While the disease is progressing the sensory symptoms are particularly prominent The paralysis disappears later than the disturbances of sensation At times contractures develop as the result of the paralyses

Diagnosis is not difficult The disease is differentiated from *tabes dorsalis* by the acute onset the absence of Argyll Robertson pupils and bladder disturbances and the presence of paralysis Serologic findings in the spinal fluid are pathognomonic in tabes Multiple neuritis is differentiated from *anterior poliomyelitis* by the massive paralysis in the latter disease this gradually recedes in the former the motor disability gradually increases The absence of sensory changes and the asymmetric distribution of paralysis as well as the very late changes in reaction to electric stimulation in anterior poliomyelitis, are further means of differentiation There is a remote similarity between multiple neuritis and progressive muscular atrophy the dystrophies periarteritis nodosa, polymyositis, acrodynia and hysteria

Treatment —The first step in the treatment of multiple neuritis is to be remove the cause Elimination of some of the metallic poisons may be favored by administration of potassium iodide catharsis and sulfur baths Sodium thiosulfate may be given for arsenic polyneuritis

In the endogenous types of polyneuritis Oppenheim used diaphoresis If the patient s strength permits the secretion of sweat may be stimulated by hot baths otherwise by hot packs or hot air applications and hot drinks and aspirin A strengthening diet is necessary in all forms of neuritis The close relationship of polyneuritis to avitaminosis has led to many quick recoveries following the oral intravenous or intramuscular use of vitamin B_1 A daily dose of 100 to 200 mg of thiamine chloride intramuscularly is a popular method of administration Artificial hyperpyrexia has also been valuable

The *pain* may be relieved by warm fomentation or antineuralgic drugs General tonic medication may be prescribed—cod liver oil iron quinine and strychnine During the first stages of the disease absolute rest in bed is imperative Proper splints must be applied to prevent contractures and over stretching of the paralyzed muscles When the condition has become stationary or shows the first signs of improvement physiotherapy consisting of massage passive movements gradually increasing resistive exercises and electrotherapy is necessary Subcutaneous injection of strychnine is useful in persistent paralysis Residual paralysis and contractures must be treated surgically

LEWIS J POLLOCK

NEUROMATA

Nearly a century ago Odier recognized that tumors may grow from nerves Neuromata have been classified according to Virchow as true and false *True neuromata* are tumors arising from or composed of actual nervous tissue They are exceedingly rare and are found practically only in connection with the sympathetic system They are be-

companied by other congenital defects such as deafness deficient intelligence and sometimes by cataract and other visual disorders. The condition appears in early life and becomes progressively more marked In the early stages it is manifested by night blindness (nyctalopia) and by concentric contraction of the fields of vision The progressive diminution of vision rarely results in complete blindness

SECONDARY RETINITIS—(*a*) RETINITIS SECONDARY TO RENAL DISEASE.—According to Gowers there are three fairly well differentiated types of retinal change in nephritis (1) degenerative, (2) hemorrhagic (3) inflammatory

In the degenerative type widespread evidence of degeneration appears throughout the retina without any change in the disk The toxic character of this type of alteration is permanent and the retinal elements suffer an almost direct selective destruction In the hemorrhagic type there is only slight evidence of inflammation and the extravasations may be flame shaped and extend over a considerable part of the retina or linear and remain closely confined to the region of blood vessels These lesions are usually associated with evidence of marked arteriosclerosis in the fundus In the inflammatory form there are marked retinal changes characterized by edema areas of exudate and hemorrhage engorgement, dilatation and tortuosity of the blood vessels and an obscuration of the margins of the disk with an actual papilledema which may amount to four or five diopters of swelling These alterations produce an appearance of the disk which is practically identical with that found in increased intracranial pressure.

Although retinal changes occur in the course of both acute and chronic nephritis they are more commonly associated with interstitial nephritis In all conditions suspected of having a renal basis the eyegrounds should be carefully examined as there is often no apparent relationship between the extent of renal involvement and the manifestations in the fundus Retinitis may also appear as a symptom of the general toxemia of pregnancy This type of disturbance usually clears up after delivery

(*b*) RETINITIS SECONDARY TO SYPHILIS.—The retinitis secondary to syphilis has been described as occurring in acquired syphilis but it more usually accompanies the inherited type. The primary inflammation seems to be in the choroid while the retinal changes appear to be secondary manifestations with extensive accumulations of black and brownish pigment between the retinal elements The process usually results in a considerable thinning of the retina and the choroid which materially increases the translucency of the retina so that the choroidal vessels are easily seen through it The accumulations of pigment may be excessive

(*c*) RETINITIS SECONDARY TO HEMAL DISTURBANCES —The retinal changes associated with anemia, malaria leukemia and other general diseases such as diabetes purpura chronic lead poisoning and so forth are principally the results of alterations in the constituents of the blood

In primary and secondary anemia leukemia purpura and at times in metabolic disturbances such as diabetes there is a marked tendency to the occurrence of hemorrhages throughout the body When these occur in the retina they are frequently followed by thickenings which result in scarring and thus disturb the function of the visual elements

(*d*) RETINITIS SECONDARY TO DEGENERATION OF THE CENTRAL NERVOUS SYSTEM.—Amaurotic family idiocy is manifested by progressive loss of sight, resulting in complete blindness and by increasing idiocy The more common type appears in infancy and is usually limited to Russian or Polish Jews In early stages the macular region is found to be definitely pale and atrophic as the condition progresses a cherry red spot appears in the center of the macula. This lesion is associated with widespread degeneration of the entire nervous system which finally causes death

The less common type of amaurotic family idiocy appears in adolescence and is much less severe It does not always result in complete blindness or dementia.

In both types of the disease not only the visual fibers but also the light fibers of the retina are affected and the reaction of the pupils to light accommodation and convergence is disturbed Localized mono homonymous losses of vision (scotomata)

terfere with the conduction of olfactory stimuli Meningeal thickening neoplasms which arise from the floor of the anterior cranial fossa or in the frontal lobes and press on one or both olfactory tracts abscesses hemorrhages areas of softening near the olfactory pathways or any general increase in intracranial pressure may reduce or destroy the sense of smell Laceration of one or both tracts the result of fracture of the floor of the anterior cranial fossa, may produce unilateral or bilateral hyposmia or anosmia

Alterations in the mucous membrane or changes in the nerve endings frequently produce a reduction in the sense of smell in persons who are engaged in the handling of wine of cognac in those who smoke to excess and in individuals addicted to cocaine by inhalation Senile changes in the mucous membrane also reduce the acuity of the sense of smell

Parosmia a perversion of the sense of smell may be a symptom of generalized cerebral disease or it may be an indication of local functional disturbance in the olfactory lobe Such perversions are usually of an unpleasant character Hallucinations of smell frequently occur as the result of disorders of the olfactory cortex They take place frequently in the aura of approaching convulsive seizures and constitute a variety of attack known as the hippocampal convulsive state They occur frequently in the insane

Neoplasms arising in the uncus produce a definite syndrome characterized by extreme olfactory hallucination—usually unpleasant rarely pleasant—and by generalized convulsive seizures or localized tremors and twitchings which have been ascribed to pressure on the red nucleus There is frequently also a homolateral exophthalmos with marked venous engorgement due to pressure on the cavernous sinus and occasionally the oculomotor nerves which lie in the wall of the sinus are involved Pressure on the brain stem may in addition evoke other signs of involvement of the central nervous system These manifestations are usually accompanied by the general signs of increased intracranial pressure

Functional—Hysteric anosmia is often associated with similar disturbances in the other special senses and also in general body sense Its distribution is usually unilateral and all of the disturbances both motor and sensory almost invariably affect the same side of the body Hyperosmia—increased acuity of smell—is a variable and indefinite condition which is usually a symptom of hysteria

HENRY ALSOP RILEY

THE VISUAL APPARATUS

Strictly speaking the peripheral portion of the optic apparatus is an intrinsic part of the brain and is not homologous with the peripheral cerebral or spinal nerve

The visual receptors in the retina and the central processes which pass from them to the deeper layers of the retina are the only homologs of the peripheral nerves in the optic apparatus

The visual structures from the retina to the thalamic centers represent the derivatives from an evagination of the primitive neural tube.

Extraneural Factors in Visual Defects—Extraneural disturbances in vision may result from pathologic changes in the various media of the eye Disorders of vision produced by such causes may be identified by proper methods of examination

Retinal Factors in Visual Defects—Retinitis may be a disease of the retina itself or the expression of some degenerative systemic or neural disease which expresses itself by changes in the retina These alterations may result in all kinds of visual disturbance

PRIMARY RETINITIS.—In primary or simple retinitis the evidence of inflammation is limited to swelling of the retinal element distention of the blood vessels and occasional hemorrhages This condition is considered by some authorities to be the first stage of the more advanced forms but by others it is thought to be a definite type which may not undergo any further development Overuse of the eyes uncorrected errors of refraction poor illumination exposure to cold or to excessive light may produce this type of retinitis

RETINITIS PIGMENTOSA may appear as a definite and specific disease *sui generis* not associated with syphilis It usually is hereditary and is often found in the offspring of consanguineous parents It is frequently ac

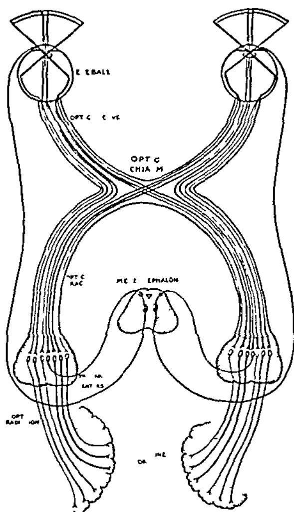

Fig 192—The visual pathway This diagram indicates the reversal of the visual and retinal fields the course of the fibers which arise from the various portions of the retina, and the path of the light reflex Red indicates the temporal fibers Blue indicates the nasal fibers Green indicates the macular fibers Black indicates the light fibers The uncrossed course of the temporal fibers, the crossed course of the nasal fibers and the partially crossed and partially uncrossed course of the macular fibers are indicated The primary visual centers consisting of the pulvinar of the thalamus and the lateral geniculate body are indicated together with the course of the optic radiation to the calcarine cortex The switching of the light reflex stimulus from the primary visual centers to the tectum of the midbrain and its connection with the efferent oculomotor neuron governing the sphincter iridis is also shown

result from local destruction of the visual elements They are appreciated by the patient as dark spots in the field of vision

Neural Factors in Visual Defects.—Neural causes of visual defects are of two types those which interfere with the visual pathways and those which disturb the cortical perceptive system The disturbances in vision which result from localized processes affecting the visual pathways manifest themselves clinically according to the particular anatomic part of the apparatus which they involve In considering the defects of vision which result from local lesions it is essential to remember the anatomic arrangement of the fibers which constitute the various parts of the visual pathway from the eyeball to the cortical centers In differential diagnosis the fact that the optic nerve and tract contain both light and sight fibers is of importance Both types of fibers remain commingled as far caudad as the primary visual centers consisting of the pulvinar and the lateral geniculate body Emerging from these nuclei the visual fibers form the optic radiation (radiation of Gratiolet), while the light fibers pass to the superior colliculus and form a part of the reflex arc which controls the retinal illumination It is this arrangement which renders possible the pupillary reactions of Wernicke A lesion affecting the visual pathway between the chiasm and the primary visual centers produces a contralateral homonymous hemianopsia through the interruption of the fibers arising from the temporal retina of the homolateral eye and the nasal retina of the contralateral eye This disturbance affects equally the visual and the light reflex fibers and a narrow beam of light falling upon the parts of the retina rendered blind by the lesion will not result in a light reflex If however the cause of the disturbance affects the visual pathway caudal to the primary visual centers at which point the light and sight fibers separate the patient will present an homonymous hemianopsia but the light reflex from the affected portion of the retina will be retained These reactions are difficult to demonstrate but are of considerable localizing value when present

Disturbance of Vision Due to Local Factors.—LESIONS OF THE OPTIC NERVE.—The conduction of impulses over the fibers of the optic nerve may be interfered with by local injury or disease involving the nerve within the orbit, in the optic foramen or between the optic foramen and the optic chiasm Laceration of the nerve may result from fracture of the base of the skull involving the walls of the orbit, the anterior cranial fossa or the most anterior portion of the middle cranial fossa Neoplasms arising in the orbital cavity from the contents of the orbit or from the periosteum or bone of the wall of the orbit or optic foramen may compress the optic nerve. Tumors arising in the caudal portion of the orbital gyrus of the frontal lobe may by impinging directly on one or both optic nerves, interfere with vision As a result of the pressure exerted directly on the nerve there is usually evident a primary atrophy in the nerve head and a reduction in vision commensurate with the atrophy while papilledema appears in the fundus Optic atrophy may result from primary tumors of the optic nerve (gliomata) tumors of the nerve sheath (neurofibromata and sarcomata) and from involvement by metastatic neoplasms Compression of the optic nerves may also result from acute or chronic inflammation in the periosteum or walls of the optic foramen Periostitis or osteitis is usually caused by chronic infections such as syphilis and tuberculosis Osteitis deformans and leontiasis ossea may produce sufficient overgrowth of the bone forming the optic foramen to compress the optic nerve and thus produce partial or complete loss of function

Inflammation of the contents of the orbit either hematogenous or by direct extension from the eyelid or accessory nasal sinuses may produce an optic neuritis with diminution or loss of vision in one eye Involvement of the optic nerve by local toxic or inflammatory processes usually manifests itself as an increasing central scotoma, the more vulnerable macular fibers being the first to be disturbed A frequent source of this type of involvement is an inflammation of the ethmoid cells

LESIONS OF THE OPTIC CHIASMA may result from disorders of the hypophysis the hypencephalon the bony tissues of the sella turcica the blood vessels or the meninges in its vicinity The inflammatory processes

which may affect the chiasma are usually direct extensions from an inflammation of the sphenoidal sinus or from localized meningitic processes Lesions affecting the central portion of the chiasma involve the fibers which cross from the nasal half of each retina to the opposite side. This results in a loss of function in the nasal halves of the retina of both eyes (bitemporal hemianopsia) The lesion which most often produces this visual disturbance is an hypophyseal neoplasm In many instances the involvement of the chiasm may be asymmetric, the neoplasm extending more to one side and may involve *one entire optic nerve producing an amaurosis* in the eye on that side and temporal hemianopsia in the other eye A relatively unusual type of involvement of the chiasma is an aneurysm or varicose dilatation of one or both carotid arteries compressing the chiasma from one or both sides An involvement of this kind impinging upon the lateral aspects of the chiasma interrupts the uncrossed fibers from the temporal half of each retina and produces a binasal hemianopsia

Lesions of the Optic Tract—The causative factors producing disturbances in the optic tracts are similar to those already mentioned namely injuries softening from vascular lesions neoplasms from the base of the skull or from the meninges localized meningitic processes or intracerebral neoplasms which press on the optic tract in its course toward the primary visual end stations the lateral geniculate body and the pulvinar of the thalamus Involvement of the tract in this locality produces a contralateral homonymous hemianopsia with corresponding loss of the light reflex

Lesions of the Primary Visual End Stations—The primary visual end stations in the thalamus and methalamus consist of the lateral geniculate body and the pulvinar of the thalamus Lesions of these structures are usually due to inflammatory processes vascular disease (embolism thrombosis hemorrhage) or neoplasms These disorders produce a contralateral homonymous hemianopsia usually accompanied by other disturbances such as partial or complete contralateral hemianesthesia or hemiplegia Vertical gaze may also be paralyzed by a disturbance in the subthalamic aberrant pyramidal bundle which supplies the nuclei of the third nerve From the primary end stations the visual pathway passes through the retrolenticular portion of the internal capsule and the corona radiata to the calcarine cortex

The optic radiation in the occipital lobe of the hemisphere may be involved by neoplasms arising from the brain itself the meninges overlying the brain or from the skull by vascular disease (hemorrhage embolism or thrombosis) by diffuse or local inflammation (encephalitides brain abscess) and by degenerative or sclerotic processes These disorders produce an homonymous hemianopsia *the light reflex from the affected* retinal fields being preserved Lesions in the temporal lobe which affect only a portion of the optic tract may produce sector deformities in the visual fields

Lesions of the Calcarine Cortex—Lesions of the cuneus produce a contralateral homonymous hemianopsia Bilateral disease of the cunei may cause complete blindness This involvement of both occipital lobes may result from degenerative sclerotic inflammatory, neoplastic or vascular disorders which are bilaterally symmetric from pressure by new growths originating in the falx cerebri between the occipital lobes or from trauma

Transient hemianopsia usually of the homonymous types is not uncommon in the ophthalmic type of migraine It may be associated with the scintillating scotomata which are often found in this disease. These disturbances probably depend upon transient interruptions of the circulation

Disease of the meninges or bone overlying the lateral aspects of the occipital lobes such as inflammation or neoplasms injury producing a laceration of this part of the brain as well as degeneration or sclerotic processes and vascular accidents inflammations and intrinsic new growths of the occipital lobe may interfere with the higher associative functions of this part of the brain although the perception of the primary visual qualities of form color etc is intact This condition is called mind blindness The higher psychic elaboration of the primary visual constituents is lost and although the patient is still able to see he cannot appreciate the meaning and significance of objects He is no longer able to

DIFFUSE NEURITIS involving the entire optic nerve causes marked amblyopia or blindness It is often associated with acute myelitis and develops in the course of infectious diseases particularly influenza and syphilis and in conjunction with scarlet fever malaria yellow fever and erysipelas Diffuse optic neuritis may also accompany epidemic encephalitis It may become so severe that a papilledema of four or five diopters of swelling results This is indistinguishable locally from the optic neuritis with papilledema which is evoked by increased intracranial pressure. The cause of this encephalitic papilledema is thought to be a leptomeningitis which occludes the foramina of exit of the cerebrospinal fluid and thus produces an internal hydrocephalus

ASSOCIATED DEGENERATIVE CONDITIONS OF THE CENTRAL NERVOUS SYSTEM —OPTIC NEURITIS OR OPTIC ATROPHY may appear in the course of multiple sclerosis It is a very common evidence of this disease and is usually confined to the temporal halves of the disks which are markedly pale It frequently appears also in tabes dorsalis general paresis Friedreich s and Marie s ataxias

MYASTHENIA GRAVIS may produce a concentric constriction usually more or less transient of the visual fields. This may progress during the active course of the attack and then regress as the other symptoms of the disease disappear More often however myasthenia gravis produces a transient diplopia or ptosis from involvement of the oculomotor nerve

Postneuritic secondary or inflammatory optic atrophy usually follows papillitis or neuritis retinitis or pigmentary degeneration of the retina embolism of the central artery glaucoma or trauma The disk has a dense white or grayish color with more or less irregularity and obscuration of the margin The minute vessels disappear completely and the lamina cribrosa is hidden by the organized exudate. The retinal arteries are narrow show a white line and the veins are enlarged and tortuous After injury to the nerve atrophy may not appear for several weeks although vision is immediately diminished or lost A surprising amount of vision may remain after optic neuritis or optic atrophy In differentiating between a papillitis and a papilledema the degree of retention of vision may be of some aid it is always much greater in the latter than in the former condition although the appearance of the disk may seem to be almost identical

HYSTERIC AMBLYOPIA may be unilateral or bilateral The narrowing of the visual fields increases characteristically during examination The extent of the visual fields varies greatly from time to time and the color fields may be inverted It is usually accompanied by other evidences of the hysteric condition

PAPILLEDEMA is usually the result of an increase in intracranial pressure caused by intracranial neoplasms or internal hydrocephalus Intracranial neoplasms may arise from the cerebral tissue itself from the meninges or from the skull The presence of this addition to the normal intracranial contents increases the pressure within the skull and presses the tissue fluid into the various exits from the intracranial space The perineural sheaths of the optic nerves participate in this general distention and papilledema develops. In the early stages there is usually only an increase in the diameter of the veins As the pressure continues to increase however the veins become tortuous and the margins of the disks indistinct Radial lines appear which extend from the center of the papilla over the edge of the disk into the retina and the retina itself begins to participate in the edema The edema increases and the papilla becomes raised above the level of the surrounding retina There is a consequent obliteration of the normal physiologic cup the vessels pass across the disk and then dip over the edge to reappear as they traverse the retina The degree of swelling of the disk is measured by determining the lens in the ophthalmoscope with which the details of the retina can be most distinctly seen and then carrying out the same procedure focusing upon the summit of the papilla The actual swelling is computed by subtracting the two lens numbers the result being expressed in diopters each one equaling ⅓ mm Hemorrhages and patches of localized exudate become evident at this stage scattered throughout the retina If the cause for the increased intracranial pressure be removed recession may

recognize objects by name and there is no understanding of their uses The meaning of written and printed words is affected also

General Causes of Disturbance of Visual Function—The general factors bringing about disturbance of vision are the exogenous and endogenous toxemias and the degenerative conditions associated with disease of the central nervous system

Exogenous Toxins—The excessive use of tobacco may produce a gradual progressive diminution in the central fields of vision This is first evidenced by the inability to recognize red and green (a central scotoma for red and green) If the intemperate use of tobacco continues a complete optic atrophy with total loss of sight (unilateral or bilateral) may result in exceptional cases Similar involvement of the optic nerve may follow poisoning by the heavy metals particularly lead and by methyl alcohol and also by quinine in individuals who are hypersensitive to this drug Hemeralopia (day blindness) in which the patient sees better in a dim light is not uncommon in these amblyopias of exogenous origin

Endogenous Toxins—Diminution of vision is sometimes associated with severe or repeated infection of the respiratory tract, as well as with syphilis tuberculosis diabetes, typhoid fever, erysipelas influenza, pneumonia tonsillitis, malaria, beriberi, the toxemia of pregnancy and extensive cutaneous burns

Results of Both Endogenous and Exogenous Intoxications—The result of endogenous and exogenous intoxications is an optic neuritis of three types axial interstitial or peripheral and diffuse Axial neuritis (neuritis of the papillomacular bundle) affects the optic nerve between the eyeball and the optic chiasma It may be acute or chronic The acute type appears in young adults particularly in females It is usually manifested by a sudden cloudiness or diminution of vision with frontal headache and orbital pain which is increased by pressure on or movement of the eyeballs The loss of vision is rapid and usually reaches its maximum in a short time With the loss of sight the headache diminishes Usually no change can be seen by ophthalmoscopic examination The pupil of the affected eye is larger than the other and as a rule contracts on direct stimulation, but quickly dilates despite continued stimulation After the acute stage there is gradual recovery of sight at the periphery, although varying degrees of central scotoma may persist The permanent visual defect may be unilateral or bilateral, may affect only color, or may be limited to central or paracentral scotoma *The chronic form* is more common and is usually associated with chronic alcoholism and nicotine poisoning The condition often begins with red green scotoma In the earliest stages it may be recognized by the difference between the appearance of red and green in the peripheral and central fields of vision Acuity of vision gradually diminishes The fundus may be entirely normal or may appear hyperemic or mildly neuritic with some temporal pallor The prognosis depends on the severity of the involvement The characteristic lesion is a degeneration of the papillomacular bundle This may in severe cases become complete with a unilateral or bilateral optic atrophy

An hereditary form of axial neuritis is described which seems to affect males and is transmitted by unaffected females (von Leber s atrophy) It progresses acutely or subacutely Its incidence is manifested by a central scotoma which affects color vision before perception of form and gradually increases in size Nyctalopia (night blindness) is a common symptom Total blindness results in about 33 per cent of cases The fundus shows an optic atrophy which is most marked in the temporal half of the disk This disease is rare

Interstitial or peripheral neuritis in contrast to axial neuritis, involves the periphery of the optic nerve before the papillomacular bundle is involved and results in a concentric limitation of the field of vision for white instead of producing a central scotoma for colors Central vision usually remains sharp even for color Ophthalmoscopic examination reveals a simple or neuritic atrophy Very occasionally the evidences of papilledema appear This type of neuritis usually follows systemic infections such as measles diphtheria influenza typhoid fever syphilis diabetes the meningitides disease of the nasal sinuses and metallic poisoning (lead and arsenic)

take place with organization of the patches of exudate and of the hemorrhages The edge of the disk never, as a rule, returns completely to normal but remains blurred because new connective tissue has formed by the organization of the inflammatory exudate The end result of a papillitis may be a return to normal optic atrophy with the retention of a considerable degree of visual acuity but with concentric contraction of the visual field or blindness from the postneuritic atrophy Papilledema may also be associated with echinococcus cysts, cysticercus cellulosae brain abscess lues tuberculosis, hydrocephalus, sinus thrombosis nephritis lead encephalopathy, leukemia, epidemic encephalitis and pachymeningitis hemorrhagica.

Chromatopsia is the ability to recognize colors Achromatopsia or color blindness, may appear as an hereditary or acquired defect in vision In the hereditary form it may occur as a loss of the ability to distinguish red and green the individual being able to recognize the blue yellow combinations (partial achromatopsia) or it may involve all colors (complete achromatopsia) It usually affects both eyes Acquired achromatopsia may follow extensive disease of the retina or of the optic nerve

Visual perversions may appear without apparent change in the retina or the optic nerve The most frequent is red vision (erythropsia) which appears after cataract extraction The excessive use of santonin as a vermifuge may disturb the color vision The first bluish tinge is later replaced by a yellowish discoloration (xanthopsia) which renders blue objects greenish and violet objects indistinct No satisfactory explanation of these visual disorders has been found

Henry Alsop Riley

THE OCULOMOTOR APPARATUS (THIRD, FOURTH AND SIXTH NERVES)

Lesions of the Oculomotor Nuclei and the Efferent Fibers of the Oculomotor Nerves—Nuclear lesions of the oculomotor nerves result from the acute encephalitides associated with infectious diseases such as measles scarlet fever chickenpox smallpox, or influenza with acute epidemic encephalitis and polioencephalitis and with chronic inflammatory or degenerative diseases as chronic anterior poliomyelitis chronic nuclear encephalitis progressive nuclear degeneration, ascending spinal paralysis, amyotrophic lateral sclerosis, multiple sclerosis syringobulbia tabes and cerebrospinal syphilis The hemorrhagic polioencephalitis of Wernicke a rapidly developing disease, involves almost selectively the nuclei of the oculomotor nerves It usually spares the internal muscles of the eye It is characterized by headache vertigo vomiting and progressive involvement of the oculomotor nerves A much less well defined group of diseases including paralytic vertigo, exophthalmic goiter pseudoparalytic myasthenia, myasthenia gravis, and ophthalmoplegic migraine may evoke oculomotor palsies of various types

Disturbances of the oculomotor apparatus are frequent in severe migraine (so called 'ophthalmoplegic migraine") These interferences with function appear after the acute attack as paretic or paralytic sequelae usually involving the third cerebral nerve although infrequently the fourth or sixth nerve may be affected This condition is analogous to weakness sometimes found in one or both extremities of one side or the other after convulsive attacks but is considered to be the result of organic pathologic conditions in the vicinity of the nerves

The nuclei may also be involved in vascular disease hemorrhage thrombosis or embolism of the small vessels which supply the oculomotor trochlear and abducens nuclei With these forms of vascular disturbance the pyramidal tract is frequently involved Involvement of the pyramidal tract and the homolateral oculomotor nerve produces the superior alternating type of hemiplegia, while a disturbance of the pyramidal tract and the homolateral abducens nerve results in the middle alternating hemiplegia

The oculomotor and trochlear nuclei may be affected by pressure exerted by neoplasms arising in the vicinity The usual sites of origin are the collicular plate the pineal gland the tegmentum of the mesencephalon the caudal portion of the thalamus or the interpeduncular region The abducens nucleus may be involved by neoplasms arising in the pons the cerebellopontile angle the

posterior longitudinal fasciculus usually appear as interruptions in the conjugated movements of the two eyes together, the assumption of bizarre attitudes (skew deviation) or paralyses of conjugate gaze.

Inflammation degeneration injury, vascular accidents, and destructive neoplastic activity involving the posterior longitudinal fasciculus may result in a destruction of the fibers linking the oculomotor trochlear and abducens nuclei in the conjugated movements of the eyes or may cause interference in conjugate gaze by affecting the fiber tracts descending from suprasegmental centers to their nuclei

Disturbances in the vestibular and cerebellar control of the eyeballs occasioned by lesions of the posterior longitudinal fasciculus appear as abnormal ocular movements called *nystagmus* This is an oscillatory movement of the eyes which is of three types vestibular cerebellar and congenital In *vestibular nystagmus* the movement of the eyes is divided into a slow and a rapid phase The slow phase is a drifting away of the eyes from the point of fixation because of vestibular influence while the rapid phase is the voluntary return of the eyes to the point of fixation This type of nystagmus is most easily seen in extreme lateral gaze but may sometimes be demonstrated in vertical gaze (vertical nystagmus) *Rotary nystagmus* is due to abnormal activity of the oblique muscles *Cerebellar nystagmus* which usually accompanies all movements of the eyeballs or fixation of the eyes is a true asynergia of gaze which results in unbalanced activity of the muscular apparatus due to disturbed cerebellar control In *congenital nystagmus* the eye movements are in wild disorder quite extensive irregular and follow no definite pattern Nystagmus may also result from extensive retinal disease

The nystagmus due to imbalance of the ocular muscles is most commonly seen in multiple sclerosis but also develops in myasthenia gravis Friedreich s ataxia alcoholism individuals with congenital mental defects and in miners who must work in a poor light with their heads in abnormal positions It may be produced by mechanical irritation of the semicircular canals rotation and stimulation by electricity or by the injection of cold or hot water into the external auditory meatus

Disturbances in Conjugate Movements —Supranuclear disease of the oculomotor pathways causes disturbances of the conjugated movements of the two eyes Lesions producing interference with conjugate gaze may be situated in the oculogyric centers in the lower part of the intermediate precentral region of the cortex, along the fiber tracts conducting these impulses or in the brain stem centers for vertical or lateral gaze or for convergence or divergence In the disturbances of lateral gaze if the lesion be irritative the action of the affected muscles is increased and the patient looks away from the side of the lesion if however the involvement causes a paralysis of gaze the unopposed action of the antagonistic muscle groups results in the gaze being directed toward the side of the lesion Disturbance of lateral or vertical gaze may result from lesions of the aberrant pyramidal system Paralysis of vertical gaze is often associated with disease of the colliculi or of the pineal gland It is uncertain whether the paralysis of vertical gaze which is present often in pineal tumor is the result of pressure by the neoplasm upon the superior colliculi the oculomotor nuclei or a hypothetic center for vertical ocular movements situated in close proximity to the oculomotor nuclei It may also result from an involvement in the subthalamus of the aberrant pyramidal bundle controlling vertical movements

Paralysis of conjugate movements has been said to occur in *exophthalmic goiter* as a manifestation probably of the general toxemia In hyperthyroidism the exophthalmos may be so extreme as to produce a complete mechanical external ophthalmoplegia due to stretching of the muscles The reactions of the pupils to light and accommodation are usually not affected

Hysteric ptosis may simulate disease of the third nerve On passive elevation of the lid however there is no evidence of association of other ocular palsies which almost invariably accompany the ptosis of the organic lesions In hysteria any attempt to raise the lid with the finger evokes resistance which is never present in paralytic ptosis Hysteric ptosis is also accompanied usually by other hysteric stigmata

Exophthalmos is usually found in exophthalmic goiter and is accompanied by other ocular manifestations the sign of von Graefe i.e. slow and imperfect following of the movement of the eyeball by the eyelid the sign of Stellwag a widening of the palpebral fissure, and the sign of Moebius a weakness in the power of convergence Exophthalmos frequently accompanies pronounced myopia It is frequently found unilaterally in association with arteriovenous aneurysm of the cavernous sinus and with disease of the contents of the orbit or the bony tissue forming its walls If the exophthalmos be the result of systemic disease it is usually bilateral if it results from local abnormalities it is usually unilateral It may be so marked as to interfere with proper closure of the eye (lagophthalmos) and result in a keratitis the consequences of which may be serious

Enophthalmos is due to disease of (1) the oculopupillary center in the medulla (2) the ciliospinal center in the spinal cord or (3) the preganglionic fibers which originate in the ciliospinal center pass to the vegetative nervous system and reach the ciliary ganglion It may also follow disease within the orbit or loss of orbital tissue It is almost always unilateral

HENRY ALSOP RILEY

THE TRIGEMINAL NERVE

It has for a long time been a question for debate whether the sense of taste belongs to the trigeminal or to the facial nerve but the greater weight of evidence seems to indicate that it is an essential function of the seventh cerebral nerve The distribution of the taste fibers is merely taken over by the trigeminal nerve A discussion of the disturbances in taste is therefore included in the consideration of the seventh cerebral nerve

Diminution in Sensibility of the Trigeminal Nerve (*Hypesthesia or Anesthesia*) —The trigeminal nerve supplies sensation to the skin of the face the anterior half of the scalp the mucous membrane of the lips mouth tongue and pharynx the accessory spaces of the nose the teeth portions of the dura mater and the cornea and conjunctiva of the eye Disturbances in sensation may be partial (hypesthesia) or complete (anesthesia) If complete they may include all types of sensibility or be merely a dissociation of sensation certain types being affected while others remain uninvolved The disturbance may also be either peripheral in type and corresponds to the distribution of the three branches of the trigeminal nerve (the ophthalmic maxillary and mandibular divisions) or segmental and limited to areas corresponding to the circumoral arrangement of the trigeminal dermatomes described by Dejerine Careful plotting of the area of disturbed sensation will indicate the peripheral or segmental character of the sensory loss

Peripheral Disturbances—An interference with the conduction of impulses by the fibers of the trigeminal nerve results in a reduction in superficial sensibility (touch pain and temperature) which may be partial or complete according to the severity of the lesion If only one of the branches of the nerve is involved the disturbance is limited to all or a part of the distribution of the branch If the root of the nerve is affected the result may be a uniform diminution of sensation over the area supplied by the entire nerve or it may present an uneven distribution The branches of the trigeminal nerve may be affected by inflammatory processes in the deeper tissues of the face or mouth by inflammatory hyperplastic or neoplastic processes affecting the bones of the skull and involving the nerves in their course through the various foramina The root of the nerve may be involved by meningitic processes by neoplasms arising from the bones of the cranial fossae the meningeal envelopes and from the pons cerebellum or acoustic nerve Neoplasms may also originate in the nerve itself or in the nerve sheath (von Recklinghausen s disease) and produce hypesthesia or anesthesia of any division or of the entire nerve according to the site of development

The divisions of the nerve may be lacerated by direct penetrating wounds or fracture of the base of the skull passing through the foramina or by tears of the dura implicating the nerve The ophthalmic division on account of its location is also exposed to damage by aneurysm of the internal carotid

posterior longitudinal fasciculus usually appear as interruptions in the conjugated movements of the two eyes together, the *assumption of bizarre attitudes* (skew deviation) or paralyses of conjugate gaze.

Inflammation, degeneration injury, vascular *accidents*, and *destructive neoplastic* activity involving the posterior longitudinal fasciculus may result in a destruction of the fibers linking the oculomotor *trochlear* and abducens nuclei in the conjugated movements of the eyes or may cause interference in conjugate gaze by affecting the fiber tracts descending from suprasegmental centers to their nuclei

Disturbances in the vestibular and cerebellar control of the eyeballs occasioned by lesions of the posterior longitudinal fasciculus appear as abnormal ocular movements called *nystagmus* This is an oscillatory movement of the eyes which is of three types vestibular cerebellar and congenital In *vestibular nystagmus* the movement of the eyes is divided into a slow and a rapid phase The slow phase is a drifting away of the eyes from the point of fixation because of vestibular influence while the rapid phase is the voluntary return of the eyes to the point of fixation *This type of nystagmus is* most easily seen in extreme lateral gaze but may sometimes be demonstrated in vertical gaze (vertical nystagmus) *Rotary nystagmus* is due to abnormal activity of the oblique muscles *Cerebellar nystagmus* which usually accompanies all movements of the eyeballs or fixation of the eyes, is a true asynergia of gaze which results in unbalanced activity of the muscular apparatus due to disturbed cerebellar control In *congenital nystagmus* the eye movements are in wild disorder quite extensive irregular and follow no definite pattern Nystagmus may also result from extensive retinal disease

The nystagmus *due to imbalance of the* ocular muscles is most commonly seen in multiple sclerosis but also develops in myasthenia gravis Friedreich s ataxia alcoholism individuals with congenital mental defects and in miners who must work in a poor light with their heads in abnormal positions It may be produced by mechanical irritation of the semicircular canals rotation and stimulation by electricity or by the injection of cold or hot water into the external auditory meatus

Disturbances in Conjugate Movements —*Supranuclear disease of the oculomotor* pathways causes disturbances of the conjugated movements of the two eyes *Lesions producing interference with conjugate gaze* may be situated in the oculogyric centers in the lower part of the intermediate *precentral region of the cortex, along the* fiber tracts conducting these impulses or in the brain stem centers for vertical or lateral gaze or for convergence or divergence In the disturbances of lateral gaze if the lesion be irritative, the action of the affected muscles is increased and the patient looks away from the side of the lesion if however, the involvement causes a paralysis of gaze the unopposed action of the antagonistic muscle groups results in the gaze being directed toward the side of the lesion *Disturbance of lateral or vertical gaze may result from lesions of the aberrant pyramidal system Paralysis of vertical gaze is often associated* with disease of the colliculi or of the pineal gland It is uncertain whether the paralysis of vertical gaze which is present often in pineal tumor is the result of pressure by the *neoplasm upon the superior colliculi the* oculomotor nuclei or a hypothetic center *for vertical ocular movements situated in* close proximity to the oculomotor nuclei It *may also result from an involvement in the* subthalamus of the aberrant pyramidal bundle controlling vertical movements

Paralysis of conjugate movements has been said to occur in *exophthalmic goiter* as a manifestation probably of the general toxemia In hyperthyroidism the exophthalmos may be so extreme as to produce a complete mechanical external ophthalmoplegia due to *stretching of the muscles The reactions of* the pupils to light and accommodation are usually not affected

Hysteric ptosis may simulate disease of the third nerve On passive elevation of the lid however there is no evidence of association of other ocular palsies which almost invariably accompany the ptosis of the organic lesions In hysteria any attempt to raise the lid with the finger evokes resistance which *is never present in paralytic ptosis* Hysteric ptosis is also accompanied usually by other *hysteric stigmata*

affects all types of sensibility is frequently complete extends with precision to the mid line and may be associated with functional anosmia ageusia and amaurosis and with other hysteric stigmata such as loss of corneal and pharyngeal reflexes The character and distribution of the changed sensations are found to be profoundly affected by suggestion

Motor disturbances of the trigeminal nerve may be irritative or paralytic

Irritative —The irritative type of disturbance is characterized by local or general spasms of the muscles of mastication It may be produced by irritative lesions in the part of the cortex which controls the masticatory muscles The hyperkinetic symptoms may constitute the manifestation of a jacksonian convulsive state Violent convulsive movements of the jaws are also seen in generalized convulsize seizures biting of the tongue being one of the most characteristic manifestations Spasm of the masticatory muscles may be an expression of more widespread irritation of the central nervous system It may be the initial symptom of tetanus or lockjaw If limited to the jaws it is called *trismus* Spasm of the masticatory muscles constitutes one of the outstanding features of *hydrophobia* It occurs in the chattering associated with chills Masticatory spasm may result from reflex irritation arising in the mouth jaws or teeth It is present also in strychnine poisoning

Other hyperkinetic masticatory manifestations appear in paralysis agitans and epidemic encephalitis In paralysis agitans the typical tremor may be located in the muscles of the jaw and cause a constant or inconstant rhythmic tremor In many of the sequelae of encephalitis there is a similar involvement Not only syndromes similar to that of pseudobulbar palsy but also irritative phenomena have been observed such as grinding champing and chattering movements This involvement of the masticatory apparatus in the chronic forms of epidemic encephalitis seems to be caused by inflammatory and degenerative lesions in the substantia nigra

Paralytic disturbances may be peripheral or central

Peripheral —Paresis or paralysis of the masticatory muscles may be a manifestation of a local neuritis involving the motor portion of the trigeminal nerve or much more rarely it may be a part of a multiple neuritis This neuritis may be due to any one of the numerous causes which can affect the peripheral nerves Peripheral disturbances of the motor portion of the trigeminal nerve may also follow inflammation of the portio minor between its origin in the brain stem and its distribution to the muscles of mastication On account of its close relation to the mandibular division lesions often involve this division of the nerve also The motor nerve may be compressed by neoplasms arising from the brain stem the neighboring cranial nerve the meninges or the skull by aneurysms of the vessels at the base of the skull thrombosis of the sinuses osteomyelitis of the cranial bones or injured by penetrating wounds fractures of the base of the skull etc The existence of a unilateral peripheral paralysis may be demonstrated by the loss of voluntary contraction of the masticatory muscles by the relaxed condition of the mylohyoid and digastric muscles in the floor of the mouth on the affected side and by the deviation of the jaw toward the paralyzed side and by the inability to move the jaw toward the unaffected side The jaw jerk is lost muscle atrophy and the reaction of degeneration appear after the acute phase is passed Unilateral paralysis disturbs but little the movements of mastication

Bilateral involvement of the peripheral nerves supplying the muscles of mastication may be the result of any one of the factors mentioned above if it affects the nerves bilaterally The result is a complete paralysis of the lower jaw which hangs open

Central —Unilateral or bilateral paralysis of the masticatory apparatus may follow nuclear involvement by acute or subacute inflammatory processes such as nonspecific or epidemic encephalitis polioencephalitis ascending paralysis progressive nuclear amyotrophy or chronic tuberculous or syphilitic conditions Neoplasms of the brain stem may involve the masticatory nuclei unilaterally or bilaterally In bilateral nuclear lesions the jaw falls and all movements are abolished The jaw jerk is lost atrophy takes place in the muscles and there is a reaction of degeneration in the muscles

artery, arteriovenous aneurysm or thrombosis of the cavernous sinus and by neo plasms which arise in the hypophysis

Segmental Disturbances —Disturbances in sensation corresponding to the segmental distribution of the trigeminal nerve are much less common than those of the peripheral type They depend upon intra axial disease and may result from vascular lesions such as hemorrhage thrombosis, or embolism from neoplasms in the medulla oblongata and the pons Varolii from conditions such as syringobulbia and multiple sclerosis and from inflammations such as epidemic en cephalitis In these types of disease, if the lesion progresses from below upward the disturbances will first affect the most aboral segments and gradually extend to the more circumoral dermatomes

Dissociative Disturbances —Pathologic processes within the neuraxis particularly syringobulbia may dissociate the various types of sensibility mediated by the fifth nerve Lesions which involve the descending root of the fifth nerve affect the pain and temperature fibers especially whereas lesions in the caput of the nucleus of the trigeminal nerve disturb the more discriminative types of sensibility It is possible also to involve separately the secondary fibers entering the spinal or medullary fillets the former carrying pain and temperature sensations the latter the discriminative sensibilities

Central Disturbances —The ability to lo calize points stimulated in the area supplied by the trigeminal nerve to distinguish the distance separating two simultaneously made contacts and the ability to recognize the character of objects touching the surface may be lost due to central lesions while the primary sense qualities are retained Conversely the ability to appreciate deep pressure and to localize stimulating points may survive a loss of superficial sensibility These deep types of sensation have been ascribed to the seventh cerebral nerve The course by which these stimuli reach the neuraxis is still unknown

Trophic Disturbances —Trophic changes in the mucous membrane the result of dis turbances in the trigeminal nerve may dis turb the sense of smell and also the sense of taste Trophic ulceration of the cornea may follow lesions or operative procedures on the ophthalmic division or the gasserian gang lion producing permanent opacity and dis turbance of vision Such trophic alterations favor the spreading of infection with result ing ophthalmia Interference with the glandular effector fibers of the fifth nerve may materially reduce and change the sal ivary and lacrimal secretions

Involvement of the cells of the gasserian ganglion by a virus may produce a *herpes zoster* in the distribution of any of the three divisions of the nerve This is characterized by burning and itching followed shortly by the development of groups of small vesicles on a reddened base which in time ulcerate It is usually associated with marked discom fort pain and tingling and is often followed by actual hypesthesia

Increased Sensibility (*Hyperesthesia*) —Pain may be produced and referred to the peripheral distribution of the nerve by lesions which irritate the root fibers The principal pathologic processes which produce such results are neoplasms inflammations and glioses Pressure of neoplasms originat ing from the brain stem the cerebellum or the cerebellopontile angle may irritate the nerve and produce pain which is referred to part or all of the trigeminal distribu tion

The most common condition characterized by pain in the trigeminal distribution is the so called *trigeminal* or *facial neuralgia* a full description of which will be found in the section on neuralgias page 1486

Trigeminal neuralgia may be associated with spasmodic reflex contraction of the muscles supplied by the seventh nerve It is then called *tic douloureux*

Perverted Sensibility (*Paresthesia*) — Irritative lesions of the peripheral branches or the central connections of the trigeminal nerve may sometimes pervert sensation and produce a feeling of tingling numbness or formication These symptoms are frequently produced by the irritation caused by gliosis either in the brain stem or thalamus and often prove to be the prodromal manifesta tions of hypesthesia and anesthesia

Hysteric Alterations in Sensibility — Hysteric disturbances are typically nonan atomic and do not follow any physiologic or morphologic laws in their manifestations *Hysteric hypesthesia* or *anesthesia* usually

sure neuritis Herpes zoster involving the geniculate ganglion may be sufficiently intense to involve the motor fibers of the facial nerve Blows by sharp or dull instruments resulting in direct injury or pressure may cause palsy of the nerve after its exit from the stylomastoid foramen Stab wounds and injuries from the application of obstetric forceps also act in this way Inflammatory processes in the parotid or face or mouth cavity often favor if they do not directly produce facial paralysis

Symptoms—The *paralysis* comes on rapidly in the course of a few hours without premonitory symptoms That due to local inflammation however may be preceded by the symptoms of the primary disease At times there is pain in the face or neck usually behind and below the ear for a short time before the paralysis appears and for a week or two afterward This has been attributed to a simultaneous involvement of the local sensory nerves (trigeminal cervical and occipital) Well marked paralysis affects all the muscles supplied by the facial nerve. The disturbance may be first noticed by friends on account of the distortion of the face or because of inability to whistle puff out the cheeks or close the eye The appearance of the face is characteristic The unaffected muscles draw the *mouth* toward the normal side and elevate its corner The wrinkles of the forehead and the nasolabial fold on the affected side are flattened out The eye is more widely open than the other and the lower lid slightly everted so that the mucous membrane is visible There is a slight deviation of the nose toward the sound side Voluntary movements—showing the teeth attempts to whistle closing the eyes—are possible only on the normal side and greatly increase the asymmetry As the lips cannot be tightly closed and the corner of the mouth droops on the paralyzed side saliva may escape from the corner of the mouth

The strength of the muscles may be tested in doubtful cases by attempting to open the tightly closed eyes or to draw back the corners of the pursed mouth by inserting the tips of the fingers into the mouth If the patient attempts to resist his own inflation of the cheeks the cheek of the paralyzed side is distended because of failure of the buccinator

The *eye* on the affected side cannot be closed nor the eyebrow elevated In attempts to close the eye the palpebral fissure remains open because of paralysis of the orbicularis palpebrarum the upper eyelid is lowered on account of relaxation of the levator palpebrae superioris and the eyeball turns upward until the cornea is hidden Since winking and the lid closure reflex are absent foreign bodies are apt to lodge on the cornea or conjunctiva and produce inflammation *Articulation* may be affected in that the labial sounds are defectively formed Relaxation of the lower lid allows the tears to escape on the cheek rather than through the lacrimal duct. Common sensation is not affected although taste may be imperfect or absent on the anterior two thirds of the same side of the tongue The secretion of saliva on the paralyzed side is usually diminished The hearing may be modified so that high notes are not accurately perceived while low notes are more readily heard than on the normal side

Herpes zoster of the auricle or external auditory canal is occasionally a symptom The electric excitability is normal at first but shortly response to faradic stimulation is lost and if the process be severe partial or complete reaction of degeneration develops during the first two weeks

Diagnosis—Fully developed facial palsy is recognized at a glance In order to discover the cause it is important to determine if possible the site of the nervous lesion whether it is in the tracts leading from the cerebral cortex to the facial nucleus in the facial nucleus itself or in the pathway from the nucleus to the periphery

Supranuclear lesions characteristically do not affect the superior facial branches which supply the orbicularis palpebrarum and the muscles of the forehead or involve them but slightly because they are innervated from both hemispheres neither do they alter the electric reaction nor the reflex excitability of the facial muscles they are frequently associated with hemiplegia of the same side rarely with that of the opposite side *Lesions of the nucleus or motor root* within the substance of the pons produce complete paralysis of the same side of the face but no disturbance of taste a change in the electric reactions loss of reflex excitability in the

Involvement of the trigeminal motor control may appear as the result of disease of the cerebral hemispheres These disturbances manifest the usual results of supranuclear lesions In pseudobulbar palsy there may be bilateral or unilateral involvement of the muscles of mastication Unilateral interference with these muscles makes difficult the approximation of the jaws on the side of the paralyzed muscles The lower jaw tends to deviate toward the side of the paralyzed muscles on account of the unopposed action of the unaffected pterygoid muscles The jaw cannot be protruded easily and there is lateral movement only toward the paralyzed side In bilateral disease the jaws cannot be approximated or protruded there is no atrophy and no reaction of degeneration if the lesion is supranuclear The jaw jerk usually is exaggerated

There may also be asymmetry of the soft palate the paralyzed side being somewhat lower because of involvement of the levator palati and azygos uvulae muscles

Progressive Facial Hemiatrophy—This condition was formerly attributed to nuclear trigeminal disease but it is more probable that the atrophy is due to an underlying involvement of the vegetative nervous system Since the fibers of the vegetative nervous system in this region are distributed by the small divisions of the trigeminal nerve trophic disturbances due to interference with the vegetative nervous system supply may correspond to the territories of the various branches of the trigeminal nerve The condition is characterized by a progressive atrophy of the bones cartilages and soft tissues of the involved portions of the face while the masticatory and facial muscles show no signs of the reaction of degeneration It is usually more intense in the middle and interior divisions Conditions which may cause it are injuries to the head and face infection exposure to cold erysipelas and osteitis of the jaw The atrophy results almost regularly after involvement of the cervical sympathetic ganglia The disease may be progressive for years or may come to a standstill at any stage in its development It does not seem to be definitely modified by any type of treatment

Henry Alsop Riley

Seventh to Twelfth Nerves

THE FACIAL NERVE

Paralysis—*Etiology*—Facial paralysis shows no special age or sex relationship although it but rarely occurs in childhood In some instances there seems to be a congenital origin *Facial palsy* may result from lesions situated anywhere from the cortical facial center in the lower rolandic region to the division of the nerve trunk in the parotid gland Lesions of the nerve trunk are the most frequent cause and produce so called peripheral or Bell s palsy

Supranuclear and *nuclear facial palsy* may result from tumors internal capsular hemorrhage, or thrombosis and encephalitic processes Congenital facial paralysis is usually bilateral and combined with partial or total oculomotor paralysis

Peripheral facial palsy may accompany gout diabetes mellitus tonsillitis puerperal infections and diphtheria The facial nerve may be affected in multiple neuritis especially in the alcoholic form and there is a type of syphilitic neuritis of the seventh nerve which occurs in the early stages of this disease Meningitis syphilis tuberculosis or suppurative processes may involve the nerve at the base of the skull Tumors of the acoustic nerve endotheliomata arising from the meninges and aneurysms and fractures of the base of the skull are other agents which may cause lesions of this part of the nerve In the fallopian canal it is involved by diseases of the middle ear and caries of the petrous portion of the temporal bone Fractures of the base of the skull may produce paralysis immediately after the interval of a few days because of inflammatory processes or later on account of the pressure of the callus Operations on the mastoid have at times directly injured the nerve By far the most frequent cause of facial paralysis is the neuritis accompanying exposure to cold or local chilling This may be brought about by application of ice to the side of the neck or face exposure to the draught from an open window or electric fan or washing the hair The exact mechanism of this process is unknown but the long course of the nerve through an unyielding bony canal in which there are a large number of lymphatics is believed to favor pres

Tumors of the trunk of the auditory nerve are more common than growth of any of the other cranial nerves Those occupying the cerebellopontine angle evoke symptoms which render diagnosis easy in many instances. The symptoms are those of internal hydrocephalus (headache vomiting and choked disks) and local manifestations such as impaired hearing and loss of function of the auditory nerve hemiasynergy cerebellar ataxia paresis of basilar cranial nerves especially the seventh sixth, fifth and possibly the ninth and tenth and nystagmus increased by looking toward the affected side

Diseases of the Vestibular Portion of the Auditory Nerve—*Meniere's Disease Acute Labyrinthitis*—Meniere's disease is an acute disturbance of the labyrinth due either to inflammation or to hemorrhage which is caused by various acute infectious diseases but especially by syphilis or arteriosclerosis *Entire destruction of the labyrinth* evokes *characteristic symptoms*—intense dizziness vomiting profound disturbance of equilibrium with a sensation of rotation of the body around its long axis and marked nystagmus The patient is not able to stand and lies upon the sound side. Turning on the back or other side causes intense vertigo These symptoms are pronounced for four or five days and then gradually subside but the nystagmus persists for a longer period and quick turning of the head may produce vertigo The disturbance of equilibrium eventually passes away but tinnitus and impaired hearing or deafness persist

Meniere's disease is a symptom-complex rather than a disease entity It is a labyrinthine imbalance and may be precipitated by a peripheral or central stimulus.

The peripheral stimulus is frequently a eustachian obstruction or an increased intracranial pressure Changes in the blood volume or in the vestibular fluid volume are presumably also causative factors

The causes of central stimuli are more vague and are believed to be similar to those causing neuralgia of the trigeminal nerve

The treatment of Meniere's syndrome is primarily directed to insure the patency of the eustachian tubes In the presence of general increased intracranial pressure or a local collection of fluid in the posterior fossa a spinal puncture will frequently be of value.

The researches of Fürstenberg Lashmet and Lathrop have led them to believe that Meniere's syndrome is due to a retention of sodium in the body These authors have outlined a treatment which has been found very beneficial in many instances of this disease Their treatment is as follows

1 Protein unrestricted or forced

2 Calories as indicated

3 Low salt content

4 Medication—Ammonium chloride, 3 Gm with each meal in capsules (6 capsules each containing 0.5 Gm taken during the meal), three days on and two days off The capsules should not be replaced by the enteric-coated pills because these sometimes pass through the gastro intestinal tract without being absorbed The ammonium chloride can be given in this dosage for an indefinite time without injurious effects

5 Water intake unrestricted although excessive *quantities of liquid should not be* taken

6 Vegetables and fruit daily except those listed below in groups A and B

7 Butter cream honey jellies jams sugar and candy permitted as desired

Foods to be Avoided

Group A all salt meats and fish or bread crackers and butter prepared with salt Carrots clams condensed milk raisins caviar cowpeas olives spinach cheese endive oysters

Foods to Be Taken no more than Twice Weekly

Group B lima beans beets buttermilk cantaloupe cauliflower celery chard dried cocoanut dried currants dates figs horse radish kohlrabi limes muskmelon peanuts, peaches mustard pumpkin radishes rutabagas strawberries turnips, turnip tops watercress.

Note all foods to be prepared and served without salt

Chronic labyrinthitis is usually secondary to disease of the middle ear Tinnitus and some degree of deafness usually precede the attacks of vertigo which vary in severity When severe enough to cause the patient to fall to the ground suddenly with a sensation that external objects are revolving about him they may be accompanied or followed by vomiting and nystagmus occurs

affected muscles and frequently *in addition* paralysis of the abducens nerve because of its close anatomic relationship with the pons

If the nerve is affected between its origin in the pons and the geniculate ganglion the symptoms are similar to those of nuclear origin except that the sixth nerve *is not* usually affected The eighth nerve *may* be involved Taste in the anterior portion of the tongue is normal Often the *secretion* of tears on the affected side is *diminished*

If the facial nerve *becomes involved* after leaving the stylomastoid *foramen*, complete paralysis of the *entire side* of the face ensues

The Nervus Intermedius of Wrisberg —The afferent fibers *of the nervus intermedius* convey *sensations* of taste through the glossopharyngeal *nucleus* to the brain, the *efferent* fibers join the submaxillary ganglion and *transmit* secretory impulses to the *submaxillary* and sublingual glands R Hunt *has* described instances of inflammation *of the* geniculate ganglion analogous *to* that of the posterior root ganglia in herpes *zoster* The *symptoms* of inflammation of the geniculate ganglion are the eruption of herpetic vesicles in the external auditory canal and pain in the auricle If the inflammation be so *severe as to implicate* the motor fibers of the facial nerve weakness of the facial muscles results and taste is lost over the *anterior* portion of the tongue When the auditory nerve is involved tinnitus, vertigo, diminution of hearing and possibly nausea and vomiting ensue

Hubert S Howe

AUDITORY NERVE

Paralysis —*Diseases of the Cochlear Portion of the Nerve* —Unilateral deafness *may* be produced by lesions of the temporal lobe Memory of words heard seems to be located in the *first temporal convolution* on the left side Very severe injuries to this area produce *word deafness* a condition of failure to understand spoken words although sounds are heard Injury of the auditory areas of both sides produces complete deafness Nuclear disease of the auditory nerve is practically unknown The termination of the nerve is often affected in labyrinthine disease The nerve trunk is frequently the seat of tumors and may be involved in tumors of the bone or meninges or by inflammation in the surrounding tissues Infiltration of the auditory *nerve* has been frequently observed in *leukemia* Toxic neuritis probably develops more frequently in the auditory than in any other cranial nerve It occurs in meningitis, *scarlatina*, and typhoid fever Implication of the auditory nerve is also found in tabes multiple sclerosis and other diseases Hemorrhages and inflammations may affect the labyrinths either one alone or both simultaneously This is especially *common in syphilis* but may take place in the *infectious* diseases (typhoid scarlatina mumps influenza, malaria and meningitis)

Diagnosis—Loss of function of the cochlear portion of the acoustic nerve impairs hearing As *disturbances of the middle ear* also produce the same effect nerve deafness must be distinguished from it by the reduction of hearing through bone conduction and defective perception of the higher notes on the scale The integrity of bone conduction is determined by Schwabach s *Rinne's* and Weber s tests

Schwabach s test is carried out by comparing the time during which a vibratory tuning fork is audible when applied to the mastoid process of the side affected with that on the normal side or of a normal individual In the impairment of hearing which accompanies a nerve lesion the period of audible bone conduction is shortened while in deafness referable to the middle ear this is normal or prolonged In performing the *Rinne test a vibrating tuning fork is placed* upon the mastoid process when the sound is no longer perceptible the fork is held opposite the external auditory meatus An individual with normal hearing then hears the sound again This is described as a positive result (positive Rinne) In diseases of the middle ear the sound conduction through the air is reduced and consequently the sound is not heard when the fork is opposite the ear (negative Rinne) In nerve deafness the test is positive as a rule unless there is a marked defect of hearing The *Weber test* is carried out by placing a vibrating tuning fork on the vertex of the skull In a normal individual the *sound is heard* with equal intensity in both ears If one ear is artificially occluded the sound is heard loudest in the ear in which the air conduction is thus interrupted This lateralization of sound occurs also on the side of the impaired hearing in individuals with diseases of the middle or external ear (sound conducting apparatus) This is referred *to as a* positive Weber sign A person with nerve deafness lateralizes the sound to the normal side ("negative Weber) The perception of the notes of the scale are tested by Galton s whistle Deafness for the higher notes of the scale is evidence of nerve deafness rather than of disease of the middle or outer ear

The symptoms of the various types of laryngeal palsy are most clearly indicated in Table 1 which is taken from Gowers

TABLE 1—LARYNGEAL PALSY

Symptoms	Signs	Lesion
No voice no cough stridor only on deep inspiration	Both cords moderately abducted and motionless	Total bilateral palsy
Voice low pitched and hoarse, no cough stridor absent or slight on deep breathing	One cord moderately abducted and motionless the other moving freely and even beyond the middle line in phonation	Total unilateral palsy
Voice little changed cough normal inspiration difficult and long with loud stridor	Both cords near together and during inspiration not separated but even drawn closer together	Total abductor palsy
Inconclusive little affection of voice or cough.	One cord near the middle line not moving during inspiration the other normal	Unilateral abductor palsy
No voice perfect cough no stridor or dyspnea	Cords normal in position and moving normally in respiration but not brought together on an attempt at phonation	Adductor palsy

In *complete bilateral recurrent laryngeal paralysis* the symptoms are complete aphonia lack of closure of the glottis in coughing and difficulty in breathing due not alone to insufficient width of the glottis but also to the fact that the vocal cords are drawn inward closer together on inspiration with consequent inspiratory stridor and severe dyspnea In some instances *central* or *peripheral injuries* of the vagus affect only the fibers of the recurrent laryngeal which supply only the posterior crico arytenoid muscles (abductors) This produces narrowing of the glottis to a mere fissure so that inspiration is stridulous while the voice is not seriously interfered with Isolated paralysis of the *superior laryngeal nerves* is very infrequent and is produced mainly by injuries or operations on the neck The diminished sensation which results in the pharynx and larynx causes a tendency to allow food to enter the larynx and paralysis of the cricothyroid muscles causes defective approximation of the cricoid and thyroid cartilages in phonation which results in hoarseness and lowering of the voice and rapid fatigue on intonation

HUBERT S HOWE.

THE SPINAL ACCESSORY NERVE

Paralysis—*Etiology*—The nuclei or roots of the spinal accessory nerve may be involved in the diseases of the upper cervical region of the cord (poliomyelitis progressive muscular atrophy, myelitis gliosis or tumor) The chief causes of peripheral paralysis are caries of the upper cervical vertebrae new growths meningitic exudations and lesions of the meninges or of the bone in the region of the jugular foramen In the neck the nerve may be injured by operations for the removal of cervical glands in the resection of cervical ribs by the pressure of tumors and rarely by primary inflammation of the nerve Lesions of the base of the skull also frequently affect the vagus and occasionally the hypoglossal

Symptoms—The symptoms of paralysis of the accessory portion of the eleventh nerve are entirely motor producing complete paralysis of the sternomastoid and incomplete paralysis of the trapezius Inaction of the sternomastoid is shown by inability to turn the head completely toward the opposite side In bilateral paralysis of the sternomastoid muscles the head tends to fall backward and in the horizontal position it cannot be raised forward without assistance Paralysis of the trapezius muscle is made manifest by an alteration of the outline of the neck and drooping of the shoulder The scapula on the paralyzed side is displaced downward and outward and rotated outward so that its inner border is inclined from below upward and outward instead of being parallel to the spine Elevation of the shoulder on the affected side is imperfect and the scapula cannot be actively approximated to the midline

HUBERT S HOWE

simultaneously, when less severe the patient reels but can prevent falling by grasping some stationary object The giddiness may persist for hours or pass off in a few minutes The attack is usually followed by nausea and headache, which last for some hours Between attacks there is some degree of deafness and tinnitus The symptoms may be unilateral or bilateral One ear is usually more severely affected than the other

The disease is not always progressive although the symptoms may recur from time to time for long periods

As a rule there is little difficulty in the diagnosis of this malady when the symptoms are severe but when the aural symptoms are not marked it may be confused with *petit mal* The absence of complete loss of consciousness and the presence of deafness and tinnitus however, suggest labyrinthitis rather than epilepsy

HUBERT S HOWE

THE GLOSSOPHARYNGEAL VAGUS AND ACCESSORY NERVES

Glossopharyngeal Paralysis—Isolated paralysis of the ninth nerve has not been observed for the nerve is so intimately associated with the spinal accessory and vagus that it is not affected alone Symptoms of glossopharyngeal palsy would include anesthesia of the upper portion of the pharynx loss of taste over the posterior third of the tongue *difficulty in swallowing and abolition* of the pharyngeal reflex

Vagus Paralysis—*Etiology*—The medullary nuclei may be involved in bulbar palsy medullary tumors syringomyelia epidemic encephalitis lues and multiple sclerosis The *intracranial portion* may be affected by growths or inflammatory processes in the meninges aneurysms diseases of the bones of the base of the skull and intracranial hemorrhages Operations on the neck may injure the vagus especially ligation of the carotid or the removal of glands or tumors The vagus is occasionally the seat of neuritis which has been attributed to the spine in such infectious diseases as typhoid pneumonia influenza and especially diphtheria Of the chemical poisons alcohol has the most important action on the vagus but lead and arsenic may also have some effect The *recurrent laryngeal branch* is especially prone to injury and is frequently damaged in removal of the thyroid or in ligation of the inferior thyroid artery It may be involved in atheroma or *aneurysms of the aorta* dilatation of the left auricle in mitral stenosis, tumors or enlarged glands of the mediastinum or neck and in tuberculosis and other affections of the lungs

Symptoms—Total vagus paralysis is seen most frequently in processes which involve the nerve trunk within the skull If one vagus alone be involved there is unilateral paralysis of the palate pharynx and larynx Frequently also there are evidences of involvement of other cranial nerves particularly of the glossopharyngeal the superior root of the spinal accessory, and the hypoglossal nerve The soft palate does not move *on the affected side and is* arched lower than on the normal side The voice assumes a nasal quality and the pharyngeal paralysis may produce a slight difficulty in swallowing There *is absence of the palatal and* pharyngeal reflex on the affected side The corresponding vocal cord is in the cadaveric position and does not move with either phonation or respiration *Disturbances of* cardiac rate or rhythm are not constant in unilateral vagus paralysis there may be slowing of the rate or alteration of the rhythm but these as a rule are not permanent Symptoms referable to the abdominal branches (*vomiting anorexia pains* etc) have been described but are too inconstant and unreliable to be of value in diagnosis

The most frequent and important symptom is *laryngeal paralysis* which may occur as the only result of lesions of the vagus itself or of the recurrent laryngeal In unilateral paralysis of the recurrent laryngeal the affected vocal cord is in the cadaveric position midway between abduction and adduction It does not move on either phonation or respiration During phonation which is carried out fairly well the healthy cord is moved across the midline and approximated to the paralyzed one There is some hoarseness but the quality of the voice is not greatly altered Respiration is not impeded except on very deep inspiration when there is some stridor

The symptoms of the various types of laryngeal palsy are most clearly indicated in Table I which is taken from Gowers

TABLE I—LARYNGEAL PALSY

Symptoms	Signs	Lesion
No voice no cough stridor only on deep inspiration	Both cords moderately abducted and motionless	Total bilateral palsy
Voice low pitched and hoarse no cough stridor absent or slight on deep breathing	One cord moderately abducted and motionless the other moving freely and even beyond the middle line in phonation	Total unilateral palsy
Voice little changed cough normal inspiration difficult and long with loud stridor	Both cords near together and during inspiration not separated but even drawn closer together	Total abductor palsy
Inconclusive little affection of voice or cough.	One cord near the middle line not moving during inspiration the other normal	Unilateral abductor palsy
No voice perfect cough no stridor or dyspnea	Cords normal in position and moving normally in respiration but not brought together on an attempt at phonation	Adductor palsy

In *complete bilateral recurrent laryngeal paralysis* the symptoms are complete aphonia lack of closure of the glottis in coughing and difficulty in breathing due not alone to insufficient width of the glottis but also to the fact that the vocal cords are drawn inward closer together on inspiration with consequent inspiratory stridor and severe dyspnea In some instances *central* or *peripheral injuries* of the vagus affect only the fibers of the recurrent laryngeal which supply only the posterior crico arytenoid muscles (abductors) This produces narrowing of the glottis to a mere fissure so that inspiration is stridulous while the voice is not seriously interfered with Isolated paralysis of the *superior laryngeal nerves* is very infrequent and is produced mainly by injuries or operations on the neck The diminished sensation which results in the pharynx and larynx causes a tendency to allow food to enter the larynx and paralysis of the cricothyroid muscles causes defective approximation of the cricoid and thyroid cartilages in phonation which results in hoarseness and lowering of the voice and rapid fatigue on intonation

HUBERT S HOWE.

THE SPINAL ACCESSORY NERVE

Paralysis.—*Etiology*—The nuclei or roots of the spinal accessory nerve may be involved in the diseases of the upper cervical region of the cord (poliomyelitis progressive muscular atrophy, myelitis gliosis or tumor) The chief causes of peripheral paralysis are caries of the upper cervical vertebrae new growths meningitic exudations and lesions of the meninges or of the bone in the region of the jugular foramen In the neck the nerve may be injured by operations for the removal of cervical glands in the resection of cervical ribs by the pressure of tumors and rarely by primary inflammation of the nerve Lesions of the base of the skull also frequently affect the vagus and occasionally the hypoglossal

Symptoms—The symptoms of paralysis of the accessory portion of the eleventh nerve are entirely motor producing complete paralysis of the sternomastoid and incomplete paralysis of the trapezius Inaction of the sternomastoid is shown by inability to turn the head completely toward the opposite side In bilateral paralysis of the sternomastoid muscles the head tends to fall backward and in the horizontal position it cannot be raised forward without assistance Paralysis of the trapezius muscle is made manifest by an alteration of the outline of the neck and drooping of the shoulder The scapula on the paralyzed side is displaced downward and outward and rotated outward so that its inner border is inclined from below upward and outward instead of being parallel to the spine Elevation of the shoulder on the affected side is imperfect and the scapula cannot be actively approximated to the midline

HUBERT S HOWE.

HYPOGLOSSAL NERVE

Paralysis of the tongue in cerebral disorders is a common result of lesions producing hemiplegia The nucleus is involved in bulbar palsy and in syringobulbia, and may be affected by tabes and diseases of the medulla oblongata As the hypoglossal nuclei are placed close together in the medulla both are involved, as a rule in medullary lesions, although instances of unilateral nuclear diseases have been recorded Paralysis of the hypoglossal caused by lesions of the nerve is produced mainly in the posterior cranial fossa (tumors of the brain or meninges basilar meningitis hemorrhages or *aneurysms of* the vertebral artery) The nerve may also be injured by fracture of the base of the skull and by various changes in the bone It is rarely injured outside of the skull, but may be severed by penetrating wounds or involved in deep abscesses or tumors or in dislocation or caries of the first cervical vertebra Cortical or supranuclear lesions produce paralysis of the opposite side of the tongue On protrusion the tongue deviates toward the paralyzed side because of the action of the unaffected genioglossus muscle and the inaction of the paralyzed one In supranuclear lesions there is no atrophy of the tongue Nuclear disease usually affects both nuclei but unequally The tongue cannot be protruded and atrophies so that fibrillary tremors develop in the wasting muscles The roots of the hypoglossal and pyramidal tracts for the opposite side of the body are involved rarely by a single lesion This produces a crossed paralysis of the tongue and limbs

Speech is not much affected by unilateral paralysis of the tongue but is much disturbed in bilateral paralysis as are swallowing and proper mastication

DISEASES OF THE SPINAL NERVES

Hiccup —*Definition* —An intermittent clonic contraction of the *diaphragm often* associated with clonic contractions of the accessory muscles of *respiration*

The condition may occur at any age Sex plays no part It is due to a great variety of causes which irritate either the afferent pathway to the centers in the upper cervical part of the spinal cord the *centers themselves*, or their efferent pathway to the muscles

The afferent pathway may be irritated by swallowing very hot or irritating substances and by disorders of the esophagus or of the stomach such as gastritis and gastric dilatation Various intestinal disorders may initiate an attack, such as obstruction ileus strangulated hernia acute appendicitis acute pancreatitis and typhoid fever Peritonitis may be the cause Postoperative hiccup is *often very severe refractory to* treatment and so weakening as to endanger life The centers may be affected by tumors or meningomyelitis due to such infections as syphilis or epidemic encephalitis An epidemic variety of hiccup was reported in Paris in 1920 and also in New York A distinguished physician and his chauffeur were seriously ill within two weeks of each other In some cases no signs of epidemic encephalitis coexisted in these cases in others, the hiccup was a clonic part of that disease The attacks did not last over a week

Tumors and inflammatory disease of the mediastinum such as caseous glands enlargement of the heart and adherent pericardium are occasional causes

Uremia and alcoholism—acute or chronic —are toxic causes

Cancer metastases to the liver may be a cause

Finally the condition may be psychogenic in origin In these cases it often lasts for weeks but stops while the patient eats

Treatment —Pressure upon the phrenic

nerve between the heads of the sternocleido mastoids drinking cold water holding the breath or a sudden fright may be tried and will stop a mild attack Gastric lavage will often give relief when irritation of the gastric mucous membrane is present By hypo dermic 1/8 grain apomorphine or 1/100 grain *of hyoscine hydrobromate may be given* and repeated after three hours Morphine rarely succeeds Benzyl benzoate (1/2 drachm of a 20 per cent solution) sometimes stops an attack Inhalations of nitroglycerin or chloroform have been used Application of an ice bag to the neck ethyl chloride sprayed on the epigastrium repeated trac tion of the tongue pressure upon the eye balls mechanical dilatation of the esophagus by a small bougie and pressure upon the ribs near the origin of the diaphragm should all be tried in difficult and refractory cases

The treatment of hiccup by inhalational therapy of 5 to 10 per cent carbon dioxide in oxygen is of real importance in patients with pneumonia and in postoperative condi tions Inhalation of carbon dioxide should be pursued until the patient has had an absence of hiccup for a one minute period When it recurs as it often does inhalation of carbon dioxide should be begun again If no results are obtained with 5 per cent 10 per cent carbon dioxide in oxygen may be used It is at times necessary to give carbon dioxide until the patient becomes dizzy It must be recognized that long continued ad ministration of these high concentrations of CO_2 may cause unconsciousness and convul sions

Cervical rib is a developmental anomaly consisting of a more or less completely de veloped rib lying above the first thoracic rib and in relation to the seventh cervical vertebra

The various forms of cervical ribs may exist in two or more members of a family They usually do not produce symptoms or signs until the third decade Women are said to be more frequently affected than men

The *anatomic relations explain the dis* orders which these developmental anomalies cause The extra rib lies beneath the seventh and eighth cervical roots of the brachial plexus and in close relation to the subclavian artery

The ribs may be bilaterally symmetric or asymmetric but one side may produce a visible prominence They may very often be felt X ray examination establishes their presence Though ribs may be found on both sides but one side may produce symptoms

The relation of these various anomalies *to the subclavian artery and its branches is* of importance The extra rib either lies upon the first thoracic rib or upon the fibrous band of the cervical rib The transversalis colli or suprascapular artery may lie upon the cervical rib

The sympathetic system sends fibers from the first thoracic and inferior cervical gang lia to the plexus As the signs and symptoms indicate these may also be affected by pres sure of the extra rib or its fibrous continua tion

The cause of the appearance of signs and symptoms is sudden and severe or long lasting and oft repeated compression of the nerve roots as in carrying very heavy weights upon the shoulders continual irrita tion of the root by respiration the effort of childbirth and the drooping of the shoulder after adolescence Other causes such as periostitis have been described An unusual number of cervical rib cases appeared among troops in the B E F the pressure of rifles carried at the slope the straps of 90 pound packs or in gunners the carrying of heavy shells on the shoulder excited symp toms which would otherwise have never ap peared

Signs and Symptoms—These are motor sensory and vasomotor The motor manifes tations are weakness atrophy and various degrees of reaction of degeneration These are usually found in the muscles supplied by C 8 and D 1 but muscles supplied by the entire plexus may be affected Occasion ally after carrying heavy weights an iso lated paralysis of the serratus magnus mus cle may occur

The objective sensory changes may cor respond to the radicular limitations of the motor changes but more often they are *more limited in* extent or quite absent Sub jectively the patient has pain (neuralgia) or paresthesia or both in the forearm and hand

The vasomotor signs are cyanosis cold ness or edema due to pressure upon the

sympathetic fibers in the plexus These changes may become very severe and present the picture of early Raynaud's disease Paralysis of the cervical sympathetic (Dejerine Horner *syndrome*) *is occasionally* seen

There may be visible arterial pulsation due to pressure upward on the subclavian or one of its branches Thrombosis may occur in the artery distal to the rib The pulses may be unequal

Congenital syringomyelia is not infrequently associated with cervical ribs A developmental defect has occurred in both *the bony and nervous structures*

The *diagnosis* is best made by x ray examination though occasionally a fibrous *band alone may be present may not show* in the x ray film and may cause as serious *disorders as the bony ribs themselves*

The differential diagnosis from the various diseases causing pain paresthesia, weakness, muscle atrophy and vasomotor disorders is usually not difficult even without x ray examination Brachial neuralgia is not complicated by motor signs and symptoms The pain radiates from and through the shoulder as well as down the arm Brachial neuritis has a more widespread and uniform distribution of signs and symptoms Progressive muscular atrophy is not complicated by pain or other sensory disorders Syringomyelia presents a more difficult problem particularly when the vasomotor trophic disorders of this disease are mildly present The systematic examination of the reflexes throughout, and of sensation for the syringomyelic dissociation should make the differentiation simple Of course when both cervical ribs and syringomyelia are present the need for differentiation exacts most careful sensory examination and search for signs referable to tract changes in the spinal cord

Spinal cord tumors sufficiently large to cause the signs and symptoms of cervical rib produce other signs and symptoms Pain in cardiac disease such as that radiating down the left arm is unassociated with vaso*motor* and motor disorders

Treatment—Elevation of the shoulder and rest constitute the best initial treat*ment* Removal of the extra rib though a serious undertaking has resulted in cure or marked improvement in many cases The sensory disorders are often relieved at once The atrophy disappears much more slowly Massage and electric stimulation are indicated after operation Recently it has been shown that many cases can be cured by section of the scalene muscle without interference with the extra rib

Radiculitis—*Definition*—*An inflammation* of a spinal root

The spinal root on emerging from the *spinal cord is not fused into one structure*, but is divided into rootlets Each of these is covered by a layer of the arachnoid con*tinuous with the pia These cuffs* of endothelial cells extend outward to the point of fusion of the anterior and posterior roots *They thus form little* troughs in which infection can most easily find a resting place Outside of the arachnoid lies the dura which extends outward and is continuous with the perineural sheaths of the nerves The root may be defined as the emerging fibers from the point of their emergence from the spinal cord to the point of their fusion into the anterior and posterior roots

Etiology—Radiculitis is almost always dependent upon the occurrence of a meningitis and may therefore result from any of its causes Among these are syphilis tuberculosis acute coccal varieties and more rarely the exanthemata The symptomatology of *meningitis* is essentially that of *radiculitis plus signs and symptoms due to increased amount and pressure of spinal fluid* The symptomatology of meningitis usually given is in reality that of encephalomyelomeningitis a combination of the symptoms of infection of the brain and spinal cord and those of infection of the meninges Included in the latter are those of *radiculitis* Posterior spinal radiculitis is herpes zoster It is characterized by spinal root pain—often agonizing—which may last weeks months or ever after X ray to the affected spinal root area is very often dramatically curative It should be given at once Periapical abscess of a tooth may cause radiculitis *and allergic* reactions may give rise to fluctuating nerve root symptoms and signs A more frequent cause is trauma *to the spine caused by* extrusion of a nucleus pulposus on to a spinal root the slipped intervertebral disc may impinge on *both the spinal cord* and on one

or two spinal roots The ligamentum subflavum hypertrophied by injury or chronic infection from the gut or pelvis may produce the same symptoms and signs In Bellevue Neurological Service instances have occurred where two levels ' usually cervical and lumbar were easily demonstrated due to the simultaneous presence of two compressing slipped discs in the same person Not infrequently only radicular signs and symptoms are found Radicular syndromes dependent upon epidemic encephalitis, extramedullary tumors cancer metastases Pott s disease or other forms of spondylitis are not infrequent They are rarely simple but complicated by other signs and symptoms elsewhere in the body Tabes dorsalis at its onset is but a polyradiculitis The radicular signs and symptoms due to increased spinal fluid pressure in tumors of the brain are considered under that subject Telangiectasis may give rise to acute or fluctuating radicular cauda equina symptoms

The disease may be acute subacute or chronic

Symptoms.—The signs and symptoms of radiculitis are sensory reflex motor vasomotor trophic and glandular

(1) Sensory —The most striking and frequent sensory symptom is pain (neuralgia) It may be extremely severe and lancinating or dull and aching It occurs in the area of distribution of the roots involved It is often referred to as inside ' The points of emergence of the nerve trunks are not tender Pressure upon muscles does not increase the pain Coughing sneezing or yawning increases the pain by the increase in spinal fluid pressure. Movements which stretch the roots also increase the pain

Sensations of pins and needles formication heat and cold also occur in areas of root distribution

Objectively there are sensory losses of various kinds touch pain heat and cold always in a radicular distribution The entire root distribution may not be completely affected nor are the areas of several roots always completely affected Patchy involvement therefore results In oculomotor paralysis from syphilitic basal meningitis partial lesions due to involvement of some rootlets only are almost the rule

(2) The reflexes both deep and superficial are occasionally exaggerated at the onset Later they are diminished or absent Babinski s sign and other similar signs as well as clonus are usually absent The spinal cord is seldom affected

(3) Motor disorders are not so common as sensory disorders They consist of paresis or paralysis and atrophy of the muscles supplied by a root. The electric reactions may show various degrees of reaction of degeneration—rarely complete Simple diminution of reaction to faradic and galvanic current is frequent In lesions of the eighth cervical and first thoracic roots there may appear the syndrome of cervical sympathetic paralysis

(4) Trophic disorders occur in the chronic varieties. The skin may become more hairy or smoother Glossy skin may result The nails become rigid and curved There may be hyperostoses on the bones supplied by the affected roots Perforating ulcers may occur Cyanosis coldness paleness and various disorders of sweating may occur The spinal fluid changes are those of the cause. Slipped disc most often gives rise to increased spinal fluid protein *i.e* more than 45 mg

Diagnosis—The diagnosis is made by elimination of evidence of myositis on one hand and neuritis on the other In the first one finds tonic reflex spasm of muscle local muscular tenderness no sensory changes normal reflexes and no chemical alteration of the spinal fluid In neuritis there is nearly always local muscular weakness local reflex change and motor and sensory signs of the neural type There is no evidence of increase of pain by root stretching or by increased spinal fluid pressure from coughing yawning and sneezing

Prognosis and Treatment—The prognosis depends entirely on the effectiveness of the treatment of the primary cause For slipped disc surgical intervention may be necessary X ray therapy should be used for the pain of herpes zoster Massive intramuscular injections of thiamine chloride (100 or 200 mg daily or on alternate days) for two months or more in all forms of radiculitis is good treatment whatever else be done The pain of diabetic neuritis is often the result of diabetic radiculitis—treat the diabetes cor

rectly use thiamine as described and give all necessary analgesic drugs—phenacetin aspirin, and even codeine Paravertebral injections of alcohol have become popular and, one notices are often done previous to correct diagnosis Remember never do anything to a patient you would not have done to your self for the same ailment Remember, too that these injections are in the realm of 'blind surgery 80 per cent alcohol is potent and its employer must be both expert and optimistic. Paravertebral injection of saline solution is not hurtful and may be used both diagnostically, to determine further therapeutic action, and as treatment in its own right The writer has cured many cases of severe sciatic pain by injecting 200 cc of saline through the sacrococcygeal joint, a procedure which may be repeated two or three times

PARALYSIS AGITANS

(Shaking Palsy Parkinson s Disease)

Definition—Paralysis agitans is a slowly progressive organic affection of the central nervous system beginning in the fifth or sixth decade of life and resulting in a characteristic rhythmical tremor of resting muscles, associated with stiffness and slowness of movement It was first described by James Parkinson in 1817 and is one of the classical forms of disorder of executive nervous function with preservation of the pyramidal tract and lower motor neurons hence called *extrapyramidal disease* Conditions exhibiting the same type of rigidity with or without the same type of resting tremor are termed Parkinsonism

Etiology—The specific cause is entirely unknown Since the disease occurs in later life there is commonly associated arteriosclerosis, but the characteristic disorder and pathology are independent of this Arteriosclerosis may result in a similar but not identical clinical condition Trauma may shortly precede the first symptoms The onset is more commonly precipitated by an emotional crisis or physical exhaustion, and there is no reason to believe that the precipitant effect of trauma is other than through the effect of these factors in drawing attention to the previously unnoticed insidious onset. It is remarkable that focal vascular lesions tumors and all variety of experimental lesions in animals fail to produce the characteristic syndrome which must therefore require a very selective type of damage to nervous structure

The incidence is slightly higher in men than in women and is not limited to any particular race or continent or any type of occupation So called 'juvenile forms" are open to strong suspicion of being the result of epidemic encephalitis The occurrence of more than one case in one family is an extreme rarity

Morbid Anatomy—The nervous system presents no change that is obvious to the naked eye except that on the cut surface through the midbrain the dark pigmentation of the substantia nigra is less striking than usual Only careful histologic study will reveal a loss of many of the cells of the substantia nigra and a similar outfall of the larger cells of the globus pallidus the remainder being pale, some shrunken There is no evidence of inflammation or of vascular change and no constant lesion has been found in any other part of the nervous system or in the muscles

In the closely related postencephalitic parkinsonism the loss of cells in the substantia nigra is more complete the changes elsewhere less definite and small foci of round celled infiltration may be present Some however (Tretiakoff, Cobb and Benda) consider the two conditions identical The evidence for a distinct juvenile pallidal form (Hunt) is slender

Symptoms—The tremor or slowness of movement and set facial expression are commonly not noticed by the patient until his attention is drawn to them by others so slow and insidious is the onset. Any one of these symptoms may be the first to ap

pear soon followed by the others Most commonly the rhythmical tremor of the fingers of one or the other hand is first noticed as the limb rests after some excitement or exertion In weeks or months the tremor becomes more constantly present whenever the limb is at rest The patient now becomes aware of a general slowing and loss of freedom of movement The lower limb on the affected side drags if he attempts to run The tremor and slowness gradually appear in the other limbs. He begins to feel a difficulty in writing in dressing himself in maintaining balance in turning around quickly or in rising from a chair all gradually resulting in great disability Once confined to bed the patient slowly develops greater rigidity and owing to limitation of coughing is liable to terminal bronchopneumonia

There is no disorder of sensation The relative immobilization of joints usually results in arthritic changes The shoulder joints in particular may become painfully limited In the earlier stages awkward postures may be long maintained without apparent difficulty but later the difficulty in turning may result in great discomfort in bed.

The sphincters are not affected nor is swallowing or digestion The mind remains clear The occurrence of confusion is usually the effect of drugs used in treatment Speech becomes slurred and indistinct only in later stages when movements of the tongue jaw and larynx are slowed and incomplete At this stage in paralysis agitans food is incompletely chewed and saliva tends to collect in the mouth and drool over the lips

Bouts of reactive nervous depression and anxiety are common During these the symptoms are more prominent lessening again with return of mental calm Sudden exacerbation of symptoms should thus indicate the transient effect of anxiety and not an extension in the organic pathology

Physical Signs —The general appearance of the patient is so characteristic that to the practised eye it is alone sufficient to establish the diagnosis beyond doubt All manifestations of the disease can be traced to two abnormalities tremor and rigidity

Parkinsonian Tremor—This is a fairly regular rhythmical alternating contraction of opposing muscular groups at the rate of 2 to 5 a second It is best seen in the fingers and thumb which beat against each other as if rolling a pellet (pill rolling) There is irregular fluctuation in the amplitude of the movement, so that from time to time it lessens in the fingers and appears instead at the wrist, or elbow then again in the fingers In the limbs it is most prominent in distal joints The same rhythm actuates the ankle or knee with similar gentle fluctuation It can be seen in the lips during momentary relaxation or in the eyelids when lightly closed (blepharoclonus) or in the relaxed tongue or palate It rarely actuates the trunk musculature or extra-ocular muscles

Parkinsonian tremor is seen at rest or in relative relaxation It is damped by movement or strong contraction and reappears only after an interval thus differing radically from the behavior of intention cerebellar or hysterical tremor When severe in degree it may occur in sleep

Parkinsonian Rigidity—In the affected limbs all muscles at each joint offer a soft plastic resistance to passive or active movement This has no sudden give as has spasticity and is usually a little more intense in the flexors than in the extensors resulting in a continued slightly flexed posture of the limbs In early stages it is most easily felt by gently extending and flexing the patient s fingers or wrist Commonly rhythmical fluctuations in the relaxing resistance are felt (cogwheel phenomenon) corresponding to the beats of the tremor When no tremor is present the cogwheel relaxation indicates its imminence The rigidity is more widespread than the tremor and its affection of the spine and neck results in the stooped posture with slightly flexed upper limb and hip joints that is an obvious feature of the fully developed disease Only in very late stages is the rigidity intense

Power of muscular contraction is retained to the end and can be tested by the patient s ability to resist a passive opposing movement Voluntary movement nevertheless becomes slow and weak owing to the rigidity Thus paralysis refers only to impairment of movement not of power of contraction of muscles The *reflexes* are accordingly not altered though the tendon jerks may be submerged by the rigidity that is

already activating the muscles The plantar responses remain flexor

Parkinsonian rigidity affects the facial musculature, slowing expression and impairing or abolishing the smaller natural movements and spontaneous blinking This unnatural stillness combined with increased tone in the levators of the eyelids gives rise to the staring *'parkinsonian mask'* As in the limbs, the rigidity may at first be one-sided, and is likely to be mistaken for facial weakness until a full voluntary effort or more violent emotion show slower but nevertheless full power of contraction on the affected side The eyelids once tightly closed are slow to open, and similar slowness of movement and tremulous relaxation is seen in the tongue Small steps in walking, also due to limitation of movement and slowness in compensatory movement give rise to difficulty in maintaining balance, especially in turning where a few rapid steps backward (retropulsion') may occur In his hurried steps (festination) the patient may literally chase his center of gravity The struggle against rigidity is apparent in all types of movement and many small movements virtually disappear This may occur at a *stage when rigidity is very slight* so that absence of swinging of an affected arm may be a confirmatory sign when there is doubt about the presence of palpable rigidity

There is no change in sensation or in the special senses. The cerebrospinal fluid is unaltered in pressure or contents

Diagnosis —The fully developed syndrome of paralysis agitans is unmistakable In early stages of development however it must be differentiated from *multiple sclerosis* where the tremor is of intention or cerebellar type and thus increased by movement, and usually accompanied by nystagmus and where any stiffness in muscles is in the nature of spasticity with reflex changes *Hysteria* may also be manifested by rhythmical tremor which however tends to be localized, not affecting the lips and tongue for instance and increased by attempted use of the part

There is a form of fine rhythmic tremor of the outstretched fingers lessened during movement which is a family characteristic ('familial tremor") This appears in the second or third decade and then remains constant A similar tremor (*senile tremor*) may appear in the hands in the fifth or sixth decade This is increased by movement and sometimes associated with a tremor of the head Both these tremors lack the postural changes and rigidity of parkinsonism and follow a benign course

More difficulty attaches to clear differentiation from *other varieties of parkinsonism* *Postencephalitic parkinsonism* (see Epidemic Encephalitis, p 63) has the same type of tremor and rigidity, the same facies and slowness in movement but differs in its onset at any age from childhood upwards its tendency to become arrested and even remit after some months, and its usual association with defect in convergence of the eyes and in reaction of the pupils to accommodation Even when these criteria are lacking the rigidity is greater and the tremor slightly faster and more intense than the gentle undulation of true paralysis agitans Because of this greater intensity of ridigity the postencephalitic has usually greater difficulty in speech, in disposing of salivary flow, and frequently suffers from attacks of spasmodic deviation of the eyes (oculogyric crises) and spasmodic torticollis, or torsion *spasms of the trunk* The original acute stage of encephalitis is frequently unrecognized or forgotten, and the absence of such history is therefore not a useful criterion

Arteriosclerosis is not uncommonly the cause of parkinsonism in elderly subjects The tremor is lacking however and the fixed expression slowness in movement, and gait in short steps are the sole representatives of the syndrome Disturbances in the sphincters and progressive memory disorder are commonly associated due to the damage to the basal ganglia being part only of a general cerebrovascular degenerative process

Syphilitic parkinsonism is seen in the rare occurrence of the characteristic tremor in a tabetic (Wilson and Cobb) It is possibly only a coincidental relationship of the two disorders

Progressive lenticular degeneration (hepato lenticular degeneration Wilson s disease) is an extremely rare familial disease which also exhibits slowly progressive tremor and rigidity The onset is in adolescence with a regular fine tremor of the hands mild rigidity of parkinsonian type and a very

characteristic slowing of expression and vacuous smile A golden pigmentation of the outer edge of the cornea is pathognomonic Cirrhosis of the liver is present but ascertained only at autopsy

Slowness in movement and fixed expression may result from damage to the basal ganglia as part of generalized cerebral disease such as general paresis myoclonic epilepsy or resulting from very severe intoxications by manganese or carbon monoxide but are not sufficiently distinct to merit consideration as separate clinical entities

Prognosis —The course of paralysis agitans is so slowly progressive that the patient may continue to live as long as twenty years and may succeed in carrying on an occupation especially of intellectual kind for several years after the onset The total duration depends largely upon nursing care after the first five years

Postencephalitic parkinsonism runs a variable course some cases showing steady progression to a bedridden state in five to ten years In most the course is arrested at some stage and the patient adjusts himself to his disability for many years A very few mild cases have recovered or changed in type

Treatment —The treatment is essentially symptomatic No known form of therapy will alter the course of the disease Much can be done in adjusting the patient s life to his disability and in view of the deleterious effects of stress anxiety and fatigue there should be careful planning to avoid these Within the limits of fatigue regular exercise is beneficial Regular passive movements and very light massage lessen stiffness and discomfort Electrical treatment is seldom helpful and often increases rigidity

Where anxiety and depression are present simple *psychotherapy* can often achieve remarkable improvement As in other kinds of chronic disease optimism and bright surroundings greatly assist the patient to make the most of his reduced capacity

The effect of any therapy is difficult to assess owing to the strong suggestive effects of any new treatment in these patients The solanaceous (hyoscine stramonium hyocyamine atropine) group of drugs has a remarkable effect in lessening the rigidity without however materially altering the tremor To secure this effect the drug has to be given in full dosage large enough to cause its physiologic side effects—dryness of the mouth and impairment of accommodation of vision The most generally useful is *stramonium* then *hyoscine* and it is considered best to change from one to the other every six months Some physicians (see Vollmer) consider that better results are obtained by combinations of these drugs There is a wide individual variation in tolerance Pilocarpine gr $\frac{1}{10}$ may be added to the morning dose if dryness of the mouth is a complaint and spectacles fitted to allow accommodation Very many patients have taken such dosage for years without ill effect After the age of fifty drugs of this group are less well tolerated and toxic confusion delirium insomnia or restlessness are likely to result In true paralysis agitans therefore a simple sedative tonic with phenobarbital at night usually is more satisfactory

Attempts to abolish the tremor by various *surgical procedures* have been made The induction of spasticity by cortical or high spinal operation abolishes the tremor but only when in such degree that it is of itself a disability

ACUTE CHOREA

(*St Vitus Dance Sydenham's Chorea*)

Definition —Acute chorea is an acute *infectious disease characterized by involuntary*, coarse muscular twitchings psychic changes and a propensity to endocarditis and polyarthritis It was first described by Thomas Sydenham in 1686 It is usually seen in children but in rare instances occurs in adults It is commoner in cities than in the country

Etiology —A nonhemolytic *Streptococcus* is generally believed to be its exciting agent Toxins from this organism or some unascertained source act upon the brain, particularly its basal ganglia to produce the characteristic *symptom complex of a non* epidemic encephalitis *Fright* or *trauma* may precipitate or exaggerate an attack and *emotional shock* seems to play a noteworthy role in the production of relapses when a *locus minoris resistentiae* has been established In children *mimicking* may produce a habit spasm but not true chorea

Age —In the decade between five and fifteen *years of age the susceptibility* to acute chorea is greatest Rarely the disease is seen in infants or even at birth but 80 per cent of all cases occur during childhood Adults are rarely affected except during pregnancy The senile type of chorea is usually a symptom of some other organic disease of the brain

Sex —Girls are about two and one half *times as susceptible as boys*

Season —The highest incidence occurs during the months from December to April

Heredity —A certain vulnerability to the disease expressed in a type of constitution may be heritable The Negro race and full blooded American Indians seem relatively immune

Pregnancy predisposes to acute chorea and *favors a relapse in previously choreic* individuals The younger primiparae are most liable

Acute Infections —Various acute infectious diseases (particularly measles and scarlet fever) may modify and coincide with acute chorea although they play no directly causative role

Rheumatism per se is not really a cause of chorea it is rather part of a multiple symptom complex (rheumatism, endocarditis, chorea) In the series of choreics reported by Jones and Bland 72 per cent showed some evidence of rheumatic fever rheumatic heart disease complicating 54 per cent (40 per cent, in Hedley s report) The actual causative agent is possibly a streptococcus which is responsible for the rheumatism endocarditis or chorea *alone or to* gether Teeth tonsils and paranasal sinuses are suspected as portals of entry

Morbid Anatomy —The lesion is a low grade *meningo encephalitis* with at least some striatal (caudate?) localization The involuntary movements are presumed to be attempts by the cerebral cortex to compensate for failure of subcortical mechanisms

Cerebral *congestion common to all acute* infectious processes is found *Hyperemia* and *thromboses* may be more or less uniformly scattered through the brain and meninges Small nodules occur in connection with the vessels particularly in the gray matter of the cortex and basal ganglia Freeman stresses the absence of those exudative and destructive changes in the locus niger *which are typical of epidemic encephalitis*

The electroencephalogram shows generalized abnormalities dysrhythmias that are nonspecific among encephalopathies decrease in alpha rhythms and presence of continuous slow wave activity of increased amplitude (Usher and Jasper)

The cerebrospinal fluid may be normal or show a mild pleocytosis increased tension *and glucose content and diminished* calcium Eosinophils tend to be increased in the blood The sedimentation rate may be raised The serum calcium is lowered Warner found 9 66 mg per cent, compared with 10 14 after recovery

Symptoms —The *onset* of the disease may be gradual or comparatively rapid It is frequently accompanied by insomnia headache anorexia and constipation and occasionally by vomiting Fever is usually of low grade or absent. The severity of the disease varies greatly

There are three *cardinal symptoms* spontaneous *movements ataxias* and weakness to which may well be added a fourth psychic changes The patient typically makes involuntary but conscious muscular jerks and twitches He cannot coordinate

movements normally and is unable to hold a muscle or muscle group in steady contraction he tends to overreach the mark (dysmetria) in pointing tests and suffers some loss of muscular power Generally these signs vary in degree on the two sides of the body There is also a noticeable psychic alteration frequently dulled perception and diminished attention occasionally a tendency to hypomania.

The typical *twitching movements* are rather quick and of moderately wide excursion Each begins suddenly and passes rapidly and often resembles a gesticulation or grimace They are not rhythmic one or several movements in one direction are followed by movements in the opposite direction but no two are of the same extent The rapidity of choreic movement is greater than that of athetosis and less than that of a tic The movements generally cease during sleep but not in severe cases In the most severe conditions they entirely prevent sleep Sensory stimuli may increase them It is common during the examination when the disturbance is mild for choreic movements to be absent at first later when the novelty of the procedure wears off and the patient s attention lessens the involuntary activities gradually appear as though breaking through inhibition

Ataxia of the extremities produces a stumbling gait Dysmetria and asynergia appear in attempts to perform complicated acts such as piano playing Hypotonia is generally well marked being evidenced by signs like the choreic posture of the hand (flexion at the wrist and hyperextension at the metacarpophalangeal joints) The inability to maintain a tonic muscular contraction is quite typical and is readily demonstrated by the hand grip which will relax suddenly and involuntarily

Weakness may be evidence of disturbance in the pyramidal tract The other motor signs can be referred to lesions in the extra-pyramidal basal ganglial and cerebellar systems Very marked weakness produces the paralytic type of chorea and not the common spasmodic type Varying degrees of involvement of different systems explain the dissimilar symptom-complexes In each individual the symptoms remain fairly constant in type throughout the course of the disease Extrapyramidal signs are characteristic of chorea, but pyramidal signs apparently do occur Extension of the great toe (Babinski sign) is far less common than flexion the deep reflexes are characteristically diminished but occasionally increased Dana describes a *tonic reflex* evoked by tapping the patellar tendon the foot flies up and remains up unusually long or a second reinforcing jerk occurs In most cases the tendon reflexes and muscle tone differ appreciably on opposite sides of the body

Acute chorea can affect any number of muscles or muscle groups Beginning usually in the hands and arms symptoms spread to the face and later to the legs Facial muscles alone may be involved or the tongue continue choreic jerking after other muscles function normally Motor disturbances are commonly unequal on opposite sides and a pure hemichorea may occur

Speech is involved in about 25 per cent of patients The abnormality is not a paralysis but a disorder of articulation It may amount to hesitancy incoherence or even transitory mutism

The *pupils* are often dilated although they react normally as a rule Oppenheim mentions hippus as a symptom. There are no trophic changes nor endocrine sequelae The electric excitability of nerves and muscles is normal or slightly increased The sensory findings are negative except that occasionally there are pains and tenderness in the limbs

Most choreic patients suffer *psychic alterations* of some degree Before the typical motor signs appear the disposition frequently becomes irritable later the dulness inattention carelessness and loss of memory may be so pronounced as to suggest mental deficiency Mild emotional disturbances are usual and violent hysteric outbursts occasional. In the rarer severe conditions exhaustive psychoses (*chorea insaniens*) may develop with mild movements great mental excitement delirium visual hallucinations and delusions Pregnant women are especially prone to the more serious mental complications

Special attention should be given the heart, joints and nasopharynx In a *sinusitis pharyngitis tonsillitis* or *dental caries* foci of infection are often found *Articular in*

flammation usually precedes the chorea *Cardiac complications* on the other hand are more likely to appear after it is established or during its involution tachycardia whether functional or organic commonly occurs simultaneously

Duration and Termination —The duration of acute chorea formerly reckoned at from one to six months has been shortened to a quarter or one fifth that length by the use of fever therapy It is not yet certain whether this treatment will reduce the frequency of recurrences Hitherto these have followed 15 to 50 per cent of initial attacks

Disappearance of symptoms is gradual Personality changes, such as neurasthenic or schizoid traits may tend to persist Very exceptionally acute chorea becomes chronic or is succeeded by a tic

Outside of pregnancy a fatal termination is rare (1 2 per cent) and due most often to cardiac complications It may ensue without them in a maniacal state (*chorea gravis*) Willson and Preece report a mortality in the chorea of pregnancy varying from 19 per cent for cases without previous history of chorea or rheumatism down to 6 8 per cent for those with a history of both

Diagnosis —Sydenham's acute chorea is a disease entity to be differentiated from choreas dependent on conditions unrelated to rheumatism The following diseases may present some diagnostic difficulty

Hysteria protean in its manifestations may readily simulate chorea The history of the disease and general appearance of the patient the lack of organic signs should suggest hysteria This condition is more common at puberty begins more suddenly evokes more purposeful and more closely localized rhythmic movements is interrupted by intervals free from movements and is usually associated with anesthesia and analgesia

Tic or *habit spasm,* is still more localized abrupt, momentary contractions affect single muscles or groups of physiogically related muscles Such movements are coordinated and purposeful and remain the same in repetition Choreic movements are more like aimless wiggling vary constantly and affect different muscles Tic is more subject to the will

Choreic and choreo athetoid twitchings are occasional sequelae of attacks of *epidemic encephalitis* Differentiation of chorea from encephalitis demands familiarity with the latter s changing peculiarities in different epidemics It has no rheumatic or cardiac association its transient and migratory pareses and its epidemic character should be of value in making the differential diagnosis

Severely paretic examples of Sydenham s chorea can readily be confused with *acute anterior poliomyelitis* especially during an epidemic of the latter Choreic movements if detected make the diagnosis

Rarely is *senile chorea* a Sydenham s Most cases are related to such gross organic lesions of the brain as occur in posthemiplegic chorea and Huntington s chorea The movements of chorea are less active in senility than in childhood

Posthemiplegic hemichorea may be confined to an arm or leg and depends on the cerebral process that gave rise to the hemiplegia *Little s disease* cerebral hemiplegia or diplegia may be associated with some choreiform movements Its appearance at or shortly after birth is evidence that the condition is not Sydenham s chorea and its typical spasticity and pronounced pyramidal tract signs are characteristic *Congenital athetosis* is marked by similarly distinguishing cerebral signs Each individual movement of athetosis begins and develops more slowly than in chorea

Huntington s chorea can be distinguished by the heredity the past history the onset in late adult life the chronicity the greater breadth of movements and the dementia

Paramyoclonus multiplex is practically always bilateral and is seen in the sudden contraction of a single muscle or muscle bundle with fibrillary twitching Muscles are not involved in groups The face so generally affected in Sydenham s chorea practically always escapes

Friedreich s ataxia occasionally suggests chorea by producing abrupt movements in the face and extremities The gait is however more staggering and reeling and the subsequent course makes the diagnosis certain

Dystonia musculorum deformans in its early stages has been confused with chorea The twitching is more athetoid and the

pathognomonic torsion spasm as well as the evolution differentiates it

Various *intoxications* and *multiple sclerosis* with rhythmic tremblings are in rare instances confused with chorea

Treatment.—Several weeks rest in bed benefits most cases and is quite essential for the more severe Rest is aimed particularly at reduction of sensory stimulation Application of a cold pack once or twice daily or a warm bath at night for the milder cases is recommended Phenobarbital 0 016 to 0 1 Gm., may be given several times daily for a few weeks in mild cases Chloral hydrate 0.5 to 1 Gm with sodium bromide in equal or greater amount can be given by mouth (or rectally with starch) occasionally over a shorter period Sodium amytal 0 4 to 0.8 Gm. by mouth or rectum can be used for relief of great motor restlessness excitement and insomnia Hyoscine hydrobromide in 0 4 to 0 6 mg doses is valuable for subcutaneous administration in severe conditions Morphine and even chloroform inhalations may be needed to control intense paroxysms.

Repeated lumbar punctures with moderate drainage apparently prove beneficial during the rest treatment especially when the disease is severe

Salicylates given to tolerance are sometimes valuable Calcium and parathyroid may be useful Nirvanol (phenyl-ethyl hydantoin) is unsafe The classic treatment of chorea with Fowler s solution of arsenic is largely outmoded and probably useless Sulfanilamide has given some good results but further experimenting with other sulfonamides is needed Favorable effects of thiamine niacine pyridoxine and others also need further study

Fever therapy has proved successful Sutton and Dodge give a triple typhoid vaccine containing 1000 million typhoid and 750 million each of paratyphoid A and B per cubic centimeter intravenously The initial dose is 0 05 or 0 1 cc followed by increasing doses once or twice daily with occasional resting days until all choreic signs disappear A febrile reaction of 104° to 106° F is sought and the vaccine doses are run up to around 5 cc Subacute carditis does not contraindicate fever therapy Fever induced mechanically by the Kettering hypertherm short wave diathermy etc is equally satisfactory From about 5 to 20 heatings are given each of two and a half hours duration at 105° to 106° F

Carious teeth and infected tonsils which constitute especially dangerous foci of infection should be carefully examined and treated Particular attention is due the heart which is often the seat of endocarditis Dilatation is a common abnormality Direct therapy is necessary for whatever cardiac complications are present

In convalescence anemia and malnutrition can be combated by administration of cod liver oil with malt iron and arsenic tonics Ample food should be given somewhat more stimulating in character than the simple milk and vegetable regime suitable to the acuter stages Massage and passive movements are often beneficial Electricity should be avoided In a survey of pediatric after-care Irving found that supervised activity did not lengthen the course of the disease and that choreic convalescence was not hindered by association with other patients Outdoor exercise work and play rather favored complete return to good health

SPASM TIC AND TORTICOLLIS

A *spasm* is a sudden involuntary rigid contraction due to muscular action When persistent it is called tonic when characterized by alternate contraction and relaxation clonic Spasm is usually attended by pain

It interferes with function and produces involuntary movements as well as distortion

The type known as *reflex spasm* is evoked by some exciting stimulus such as a local lesion in the skeletal motor, or sensory domain

A tic is a recurrent spasmodic involuntary muscular action confined to a few muscles or muscle groups without the presence of a peripheral irritative cause Presumably a tic is cortical in origin.

Pain, often present with reflex spasms and even a symptom of certain tics is the particular feature of the so-called *tic douloureux* which is, properly speaking not a tic It is a special type of reflex spasm of the face associated with paroxysmal facial pain of great intensity and dependent upon changes in the corresponding fifth cranial nerve A reflex spasm may persist after the excitant is relieved This is often true in blepharospasm which is a clonic tonic spasm of the orbicularis palpebrarum muscle usually beginning in some period of ocular irritation but persisting as a habit after its subsidence

Local hysteric spasms have no physical excitant but are evoked by a psychic stimulus Like a tic in this regard they are separated from tic only somewhat arbitrarily They are less constant in localization than a tic and are chiefly recognizable by the fact that they vary greatly in extent and degree in the same patient from time to time and are associated with hysterically emotional even convulsive states Disappearance of a spasm during sleep is not a sign that it is necessarily hysteric Reflex spasms and other organic spasms may be absent then also Persistence of the spasm during sleep however, is sure evidence that the condition is organic in nature and not hysteric

A so called *habit spasm* is a persistently repeated involuntary clonic motion which when sufficiently severe is a tic A very common type is the ordinary facial tic which produces a frown a sidewise twitch of the mouth or similar movement.

A tic is radically different from the movement in chorea since in the latter condition no one movement is repeated regularly again and again Tics while often psychogenic have in individual cases an accompanying physical reflex element In such instances the boundary lines between these types of spasms all but disappear It is conspicuous that tics occur in patients prone to psychasthenic reaction, and that those sometimes associated with acute psychasthenia are transient Such tics can best be ignored in therapy, for they disappear when the psychasthenia is treated

A type of spasm which is being more and more widely recognized depends on lesions in the midbrain and basal ganglia It can be labeled *central spasm* Unusual states of clonus with clonic or tonic movements must all be studied with such changes in mind The prevalence of encephalitis has made this clear In individual cases it is necessary to look for other signs of previous encephalitis, or to consider whether infection or trauma of any kind has altered the integrity of these basic centers of motor control

Torticollis is a tonic or tonic clonic spasm of the neck muscles which causes wryneck. It is usually considered a distinct disease but is, more correctly one of the types of spasm just described The torticollis which accompanies cervical Pott s disease is a reflex spasm which is increased in later stages by the mechanical misalignment Another reflex torticollis is the so called "labyrinthine" type This follows irritation of the semicircular canals on one side At times torticollis is a habit phenomenon, really an example of tic Still other types are central in origin, that is, they follow organic changes in the region of the basal ganglia

Treatment—The treatment appropriate for torticollis and for all other local spasms depends entirely on their etiology It varies therefore from the cure of tuberculous spondylitis to the removal of psychic abnormalities Spasm of central origin may be helped by midbrain sedatives such as hyoscine Torticollis may occasionally be improved by surgical division of the spinal accessory nerve or by division of the combined trunks of the three upper cervical segments

THOMAS K DAVIS.

DYSTONIA MUSCULORUM

(*Tortipelvis*)

Dystonia as a general term indicates a state of abnormal tonus of muscle but *dystonia musculorum* describes a clinical en

ity It is a rare chronic disease characterized by irregular, involuntary, clonic contortions of the trunk and proximal muscles of the extremities and characterized as well by constantly shifting tonus in the affected muscles The face is usually not involved

The disease affects both sexes and usually begins near the end of the first decade of life It results from certain progressive lesions in the lenticular nucleus. While it is possible to conclude that the changes are degenerative their exact cause is not yet clear

While the patient is sitting quietly or lying down the symptoms are almost entirely in abeyance but they begin as soon as voluntary movements are initiated The abnormality is most conspicuous in walking and the contortions bend the body and twist it forward and sideways in a most bizarre manner They seem focused at the pelvis

The muscles remain free from trophic changes The normal reflexes persist abnormal responses referable to lesions of the pyramidal tract are absent and sensation is unimpaired The mentality remains normal

No therapy has produced important or lasting benefit

THOMAS K. DAVIS

THE CONVULSIVE STATES

A convulsive reaction is a phenomenon common to all animals possessed of an integrated neuromuscular system Given an adequate stimulus—say the injection of a convulsant drug—every animal will have a convulsion However the amount of stimulus required varies for different species of animals and among men for different individuals Two conditions underlie the phenomenon of convulsions first a constitutional tendency towards this reaction and second an appropriate stimulus Probably in each person subject to seizures both of these conditions are present The proportion of the two varies from person to person and every degree of gradation exists but for practical purposes clinical convulsive states may be divided into two groups first those in which an inborn hereditary tendency seems the predominant though not the exclusive factor These may be called *genetic* (essential or idiopathic) *seizures* In the second group some post conceptual environmental condition seems the predominant though not the exclusive factor These may be called *acquired* (symptomatic) *seizures* They include jacksonian, traumatic and organic epilepsy tetany, eclampsia and syncope

WILLIAM G LENNOX

EPILEPSY

The most important (and most feared) of the convulsive states is epilepsy

Definition—The word means seizure Defined clinically the syndrome consists of recurrent paroxysms of (1) impairment of consciousness or of other psychic functions (2) involuntary muscle movement and (3) disturbance of the autonomic nervous system These recurring symptoms are concurrent with a dysrhythmic discharge of the neuronal cells of the brain recordable by means of the electroencephalograph Defined physiologically epilepsy is a symptomatic paroxysmal cerebral dysrhythmia

Incidence—Epilepsy occurs in about 0.5 per cent of the population or in approximately 600 000 persons in the United States The onset of seizures is predominantly in early childhood and in adolescence yet about 30 per cent of private and clinic patients begin to have seizures after the age of twenty Males and females are equally affected though the onset of seizures is earlier in females than in males due possibly to a greater hereditary factor The number of children in the family or their order of birth is not influential Statistics for judging the relative frequency of seizures among racial and economic groups are inadequate

Etiology—Of the two main causes of epilepsy the genetic and the acquired the former is the most important Of patients who are subject to seizures approximately three fourths give no history or on examination present no evidence of significant brain or bodily injury Among the near relatives of unselected epileptics both epilepsy and cerebral dysrhythmia occur approximately five times more frequently than in the general population Among identical twins only one of which has epilepsy and evidence of brain injury the normal twin nevertheless possesses an hereditary dys

rhythmia of brain waves In a given patient the relative importance of this genetic factor is greater if evidence of brain injury is lacking if there is a family history of epilepsy or migraine and most important of all if one or both parents have cortical dysrhythmia on electroencephalographic examination The practical aspects of genetics will be discussed under Prevention The acquired (symptomatic) causes of epilepsy are multiple, although evidence of such a cause is found in less than one fourth of patients A genetic factor must play a part in acquired epilepsy for these patients have three times as many relatives with epilepsy as persons in the general population Following are the disorders in which seizures occur more frequently than in the general population

1 Congenital defects of the central nervous system cerebral aplasia cerebromacular degeneration congenital mental defect, and tuberous sclerosis

2 Pathologic changes in the brain developing after birth the various types of encephalitis and of meningitis multiple sclerosis general paresis cerebral abscess, toxoplasmosis parasitic cysts tumors hemorrhage, trauma, gliosis scars porencephalic cyst chronic arachnoiditis, arteriosclerosis and senile degeneration

3 General conditions or diseases uremia toxemia of pregnancy, alcoholic intoxication cerebral edema, pernicious anemia polycythemia hemorrhage asphyxia carbon monoxide poisoning oxygen intoxication, protein shock anaphylaxis Raynaud s disease acute fever in children angioneurotic edema Stokes Adams syndrome orthostatic hypotension syncope carotid sinus reflex migraine craniofacial hemiatrophy tetany, insulin or electric shock, hyperventilation and hysteria

4 Convulsant drugs cocaine strychnine magnesium sulfate picrotoxin absinthe thujone camphor, caffeine ergot nicotine lead epinephrine and sulfathiazole

The incidence of epilepsy in these disease conditions varies widely but except for convulsant drugs and brain tumor does not exceed 10 or 15 per cent This is about the proportion of persons in the population who have some degree of cortical dysrhythmia Whether those who develop seizures are recruited from among those who had a pre existing dysrhythmia awaits investigation Diabetes and schizophrenia are the only conditions with a reported negative correlation with epilepsy

In a group of nearly 2000 clinic and private patients whose records were tabulated by Lennox the following conditions were believed to be the principal cause of seizures brain trauma 5 7 per cent, congenital defect or birth injury, 5 6 per cent brain infections 4 2 per cent, brain tumor 2 6 per cent cerebral circulatory defect 1 9 per cent, extracerebral causes 0 9 per cent In 77 6 per cent of the patients the principal cause of seizures could not be demonstrated although if electroencephalographic examinations had been possible almost all of these would have displayed a cerebral dysrhythmia

Morbid Anatomy—Since the time of Hippocrates physicians have recognized that the brain is the seat of epilepsy and have searched for characteristic pathologic changes—but in vain At autopsy neuropathology is often encountered even when unsuspected in life Atrophies gliosis arachnoiditis are most common but morbid changes when found seem to be either a result of seizures or an acquired condition which is but a contributory factor in seizures The morbid anatomy if any of the sixty acquired causes mentioned under Etiology will be found in other sections of the volume The book by Penfield and Erickson deals especially with the important subjects of trauma and tumors

Pathologic Physiology and Chemistry—The underlying phenomenon of genetic (essential) epilepsy is a dysrhythmia of the electrical potentials of the brain which is a hereditary trait and which is the resultant of chemicophysical peculiarities of the discharging cells of the brain Structural abnormalities of the brain either genetic or acquired seem to be only contributory Seizure discharges arise from live functioning neurones and not from dead neurones the supporting structures of the brain or from foreign bodies embedded in it Pursued to its lair the peculiar chemistry of epilepsy is the chemical structure of the gene which comes to be expressed in the chemical structure or the chemical reaction of the neuronal cells of the brain This pathochemistry in

turn finds expression in the rate and voltage of the electrical pulsations of the brain Before grappling with the chemistry of epilepsy we may first summarize its electrophysiology The following condensed statement is culled from the writings of Dr and Mrs Gibbs and Lennox

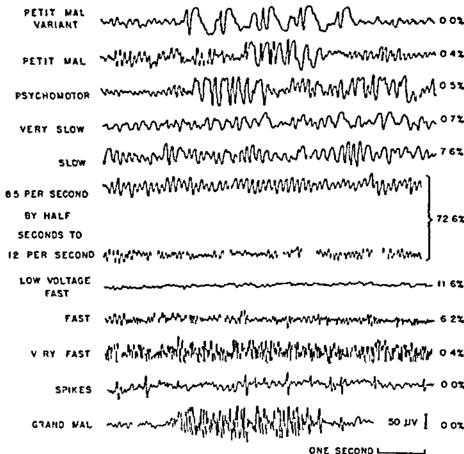

Fig 193—Classification of electroencephalograms used by the Gibbs The upper three and the bottom two tracings contain "seizure discharges" These together with very fast or very slow rhythms are classed as definitely abnormal Tracings moderately slow or fast are classed as slightly abnormal Others including low voltage fast tracings are termed normal Tracings showing dominant frequencies of 9 9½ 10 10½ 11 and 11½ per second are omitted The figures at the right of each tracing indicate the percentage of 1 000 adult controls who were classed as having that type of record In the lower right hand corner is the deflection made by a current of 50 microvolts and the time occupied by one second Tracings are reduced 2½ times

The Electroencephalograph—Proof of Hughlings Jackson s definition of epilepsy as a sudden excessive and unruly discharge of neuronal cells had to await the patient labor of Hans Berger who in 1929 published the first electroencephalograms

During the epileptic seizure the patient s electrical potentials increase greatly in amplitude and become either faster or slower The three main types of seizures are distinguished by different wave patterns fast in *grand mal* slow in psychomotor seizures and alternately fast and slow in *petit mal* The last named the three a second alternate dart and dome formation is distinctive perhaps pathognomonic for *petit mal* The electrical perturbations which accompany seizures may like the seizures themselves be a mixture of two different patterns In the period between seizures approximately 90 per cent of epileptic patients display disturbances of brain waves which may be called asymptomatic dysrhythmia Samples

of these various wave patterns are shown in Fig 193 a condensation of the Gibbs classification of electroencephalograms The various abnormalities occurred more often in the epileptics than in the controls as follows paroxysmal discharges of high voltage fast slow, or alternately fast and slow waves (seizure discharges)—34 times more often, a dominant frequency which was either very slow or very fast—19 times more often and a frequency which was only slightly slow or fast—twice as often Eighty six per cent of patients with *petit mal* 36 per cent of those with psychomotor seizures and 2 per cent of those with *grand mal* display in their routine electroencephalographic record the pattern of seizure discharge which corresponds with their clinical seizures In a given patient the degree of dysrhythmia varies greatly from time to time but is usually at a maximum as a convulsive seizure approaches Although ordinarily widespread over the cortex dysrhythmia may be most pronounced or even confined to one area, such a focus indicating the site of a cortical lesion The degree of abnormality varies spontaneously but is also influenced by brain activity and by alterations in the chemistry of the body Mental concentration sensory stimulations opening or closing the eyes sleep variations in the pH carbon dioxide oxygen sugar and other elements of the blood alter the frequency of abnormal as well as of normal waves However the different types of dysrhythmia may not all be affected alike The alternate dart and dome dysrhythmia of petit mal is most easily influenced by an altered chemical environment Severity of symptoms and of the cortical dysrhythmia do not necessarily run parallel Indeed 2 per cent of the normal control group and 10 per cent of the normal adult relatives of epileptics had grossly abnormal records

Abnormal brain waves may be inherited or acquired The pattern of the electroencephalogram is an hereditary trait and in the great majority of patients their cerebral dysrhythmia is a transmitted and not an acquired condition a conclusion supported by the experience with twins which was mentioned under Etiology Decision as to whether a given dysrhythmia is transmitted or acquired calls for electroencephalograms of parents or other near relatives and a search for evidence of acquired pathology or metabolic disturbance of the brain Obviously, the use of the electroencephalograph is of great potential value in tracing the transmission of epilepsy and in the detection of individuals who may be predisposed Because dysrhythmia is encountered in an unusual proportion of certain nonepileptic groups such as criminals behavior problem children and psychotic persons the local war against seizures may become a general war against cerebral dysrhythmia without regard to what the associated dysfunction of mind or of action may be

The Chemicophysiology of Epilepsy—As previously stated a disturbance of the electrophysicochemical make up or reaction of the neuronal cell and its antecedent gene underlies the disordered electrical pulsations of epilepsy Detection of molecular abnormalities in these submicroscopic fragments of the body is beyond present means of examination Indirect information can be gained from analysis of body fluids the value of the observations being in inverse proportion to the distance of the fluids from the brain

Analysis of the blood entering and leaving the brain at the same time that the functional electrical activity is being recorded provides the most direct information yet available about the metabolism of brain cells which are discharging abnormally Using this method of study Lennox Gibbs and Gibbs have observed that the carbon dioxide of both the arterial and the internal jugular blood tends to be unusually high in patients subject to *grand mal* and unusually low in those subject to *petit mal* Alterations in the carbon dioxide tension and in the pH of blood passing through the brain have a profound effect on the abnormal electrical activity of the brain *petit mal* activity being accentuated by low and *grand mal* by high tensions of carbon dioxide Perhaps most intriguing is the observation that the brains of patients subject to *petit mal* tend to have a lower respiratory quotient and to consume less glucose per unit of oxygen consumed than normal individuals Spiegal has reported a parallel relationship between various procedures which promote convulsions and an increased permeability of the brain tissue of

animals The ratio of potassium within the nerve cell to that of sodium without is influential in nervous discharge and is related to the activity of the adrenal cortex and to the sympathetic nervous system and the emotions McQuarrie and his associates speculated that the increased urinary excretion of potassium which they observed at the time of seizures might represent leakage of potassium from cells of the brain

The reviews by Lennox and Cobb and by Goldstein and MacFarland demonstrate the many efforts which have been made to find significant abnormalities by laboratory procedures Epileptics tend to have low basal metabolic rates slow startle responses and a slow peripheral blood flow but on the whole the findings of these many studies have been negative or only coincidental Most observers agree however that the physiology of epileptics like their brain waves seems to be unstable with unduly great hour to hour or day to day fluctuations

More rewarding has been the study of conditions which tend to produce or prevent seizures in persons already subject to them These observations do not ferret out the etiology of seizures but they demonstrate methods of altering the seizure threshold and thus contribute to the therapy of epilepsy Various conditions influence seizures especially *petit mal* 1 Acidosis induced by starvation a ketogenic diet ingestion of acids or acid forming salts breathing air containing a high concentration of carbon dioxide and the formation of excess lactic acid through vigorous muscular work tend to inhibit seizures Alkalosis induced by overventilation or by ingestion of alkali tends to precipitate seizures 2 Dehydration as shown by Temple Fay tends to inhibit seizures and water intoxication has long been recognized as a convulsant McQuarrie observed that the convulsant effect of water drinking was accentuated by the simultaneous injection of pitressin but that convulsions did not result if a saline solution replaced the water 3 An increased tension of oxygen or hyperglycemia tends to prevent seizures and anoxemia or hypoglycemia tends to induce them 4 Various drugs tend to inhibit seizures and others to cause them The mechanism of their action has been little studied The anticonvulsant action of dilantin deserves especial attention because this drug has little or no hypnotic effect it causes hirsutism and hyperplasia of the gums and its value seems to be greatest in certain types of seizures

Symptoms —The symptoms which were mentioned under Definition may occur in varying proportions in different patients and in the same patients at different times A seizure may be a transient impairment of consciousness so slight as to be unrecognizable or a convulsion of demoniacal fury

Aura —About one half of patients experience premonitory symptoms of a seizure These are various consisting perhaps of a sensation of dizziness or of discomfort in the abdomen or in patients having a localized cortical lesion a numbness or spasm of an extremity The aura which corresponds to the first gust before a storm may be too brief to permit the patient to sit or lie down

Grand Mal —The outstanding phenomenon is excessive tonic and clonic activity The patient loses consciousness his muscles become rigid respiration is suspended and if not supported he falls Because of the apnea his face becomes livid and the veins engorged As the cyanosis deepens the pupils dilate and become insensitive to light normal reflexes are abolished blood pressure rises perspiration and saliva flow The asphyxia and accumulation of carbon dioxide in the blood presumably sets reverse forces in action and after less than a minute the rigid tonic contractions are replaced by shock like clonic jerks air enters the lungs and frothy saliva possibly mixed with blood is blown from the lips by the oxygen starved lungs The patient s body bathed in ill smelling perspiration then lies limp and exhausted A convulsion if severe is followed by heavy sleep and by headache vomiting muscular soreness and depression of spirits Convulsive attacks occur at variable intervals some patients having only one or two a year others many a day Eight per cent of patients have experienced *status epilepticus* a condition in which one convulsion succeeds another with no intervening periods of consciousness

In general convulsive movements which are one sided or localized are more common

of these various wave patterns are shown in Fig 193 a condensation of the Gibbs' classification of electroencephalograms The various abnormalities occurred more often in the epileptics than in the controls as follows paroxysmal discharges of high voltage fast, slow, or alternately fast and slow waves (seizure discharges)—34 times more often a dominant frequency which was either very slow or very fast—19 times more often, and a frequency which was only slightly slow or fast—twice as often Eighty six per cent of patients with *petit mal* 36 per cent of those with psychomotor seizures, and 2 per cent of those with *grand mal* display in their routine electroencephalographic record the pattern of seizure discharge which corresponds with their clinical seizures In a given patient the degree of dysrhythmia varies greatly from time to time but is usually at a maximum as a convulsive seizure approaches Although ordinarily widespread over the cortex dysrhythmia may be most pronounced or even confined to one area, such a focus indicating the site of a cortical lesion The degree of abnormality varies spontaneously but is also influenced by brain activity and by alterations in the chemistry of the body Mental concentration sensory stimulations opening or closing the eyes sleep variations in the pH carbon dioxide, oxygen sugar and other elements of the blood alter the frequency of abnormal as well as of normal waves However the different types of dysrhythmia may not all be affected alike The alternate dart and dome dysrhythmia of petit mal is most easily influenced by an altered chemical environment Severity of symptoms and of the cortical dysrhythmia do not necessarily run parallel Indeed 2 per cent of the normal control group and 10 per cent of the normal adult relatives of epileptics had grossly abnormal records

Abnormal brain waves may be inherited or acquired The pattern of the electroencephalogram is an hereditary trait and in the great majority of patients their cerebral dysrhythmia is a transmitted and not an acquired condition a conclusion supported by the experience with twins which was mentioned under Etiology Decision as to whether a given dysrhythmia is transmitted or acquired calls for electroencephalograms of parents or other near relatives and a search for evidence of acquired pathology or metabolic disturbance of the brain Obviously, the use of the electroencephalograph is of great potential value in tracing the transmission of epilepsy and in the detection of individuals who may be predisposed Because dysrhythmia is encountered in an unusual proportion of certain nonepileptic groups, such as criminals behavior problem children and psychotic persons the local war against seizures may become a general war against cerebral dysrhythmia without regard to what the associated dysfunction of mind or of action may be

The Chemicophysiology of Epilepsy—As previously stated a disturbance of the electrophysicochemical make up or reaction of the neuronal cell and its antecedent gene underlies the disordered electrical pulsations of epilepsy Detection of molecular abnormalities in these submicroscopic fragments of the body is beyond present means of examination Indirect information can be gained from analysis of body fluids, the value of the observations being in inverse proportion to the distance of the fluids from the brain

Analysis of the blood entering and leaving the brain at the same time that the functional electrical activity is being recorded provides the most direct information yet available about the metabolism of brain cells which are discharging abnormally Using this method of study Lennox Gibbs and Gibbs have observed that the carbon dioxide of both the arterial and the internal jugular blood tends to be unusually high in patients subject to *grand mal* and unusually low in those subject to *petit mal* Alterations in the carbon dioxide tension and in the pH of blood passing through the brain have a profound effect on the abnormal electrical activity of the brain *petit mal* activity being accentuated by low and *grand mal* by high tensions of carbon dioxide Perhaps most intriguing is the observation that the brains of patients subject to *petit mal* tend to have a lower respiratory quotient and to consume less glucose per unit of oxygen consumed than normal individuals Spiegal has reported a parallel relationship between various procedures which promote convulsions and an increased permeability of the brain tissue of

in acquired than in genetic epilepsy In seizures of focal origin the head and eyes may turn to one side, that opposite the lesion, or jerking of the limbs may be one sided

A nearly pure type of acquired epilepsy is the variety called jacksonian named after Hughlings Jackson the English neurologist In this type convulsive movements or abnormal sensations begin in the small muscles of the hand foot or face and slowly spread the patient being a helpless witness The 'march' may end spontaneously or be arrested by squeezing the part or it may spread to the rest of the body and loss of consciousness and a generalized convulsion ensue The area of the cortex which corresponds to the portion of the body first involved is called the 'trigger zone

Petit Mal—Loss or impairment of consciousness is the predominant symptom This comes without warning starts and stops abruptly lasts but a few seconds and is without after symptoms Usually there are rhythmic motions of eyelids or of the head at the rate of three a second synchronous with the spike of the EEG This form of seizure occurs usually in genetic epilepsy and is most common in females and during adolescence It is the form most frequently recurring the most innocuous and yet the most resistant to drug therapy The term pykno epilepsy is sometimes used

Psychic Equivalent Seizures—These are variously spoken of as psychic psychic variants or psychomotor seizures Amnesia is the predominant symptom The person is out of contact with his environment but activity is not suspended He may perform purposeful acts but is not subject to command and after the period of confusion is over has no recollection of what took place and may not know that a seizure has occurred The seizures are longer than *petit mal* lasting from a few seconds to minutes or hours The patient may make chewing motions and his body may rotate or become slightly rigid but muscular movements if present are tonic and not clonic as in *petit mal* In prolonged episodes the patient may act as though intoxicated and may become violent especially if restraint is attempted Psychomotor attacks are more frequent in men than in women and in adults than in children

Borderland Phenomena—The portion of the brain involved in a seizure discharge determines the display of symptoms which follows Some seizures are bizarre indeed such as running fits vasovagal attacks in which there may be only pallor nausea, or other visceral phenomena sleep attacks or narcolepsy, and migraine headaches which are sometimes spoken of as sensory epilepsy

Diagnosis—The real problem in the diagnosis of epilepsy is the detection and separation of the genetic from the half hundred acquired causes of seizures The accumulation of evidence must precede this sifting process

A clear description of the seizure when obtainable usually gives a clue as to whether the seizure is hysterical tetanic syncopal jacksonian or if epileptic like whether it is *grand mal petit mal* or psychomotor

The patient's *family history* is to be searched for instances of convulsions spasms faints fits spells dizziness, lapses of consciousness migraine feeblemindedness or psychosis The patient should be asked about the circumstances of his birth any head injury which resulted in unconsciousness infections such as meningitis encephalitis whooping cough or pneumonia and symptoms such as enuresis sleep-walking night terorrs unexplained faintings dreamy periods and headaches The use of alcohol with the time relationship if any, to seizures and the function of the gastrointestinal tract and relationship of constipation to seizures should be determined With women patients one must know the menstrual history and the relationship of seizures to menstruation and pregnancy There must be a detailed account of seizures and of previous examinations and treatments

The survey of the patient should include first a *general physical examination* with particular attention to the posture the general physique and the circulatory system The neurologic examination should be painstaking and include inspection of the eye grounds and mapping of the visual fields Detection of an early brain tumor requires a keen eye for small signs Following is the proportion of certain signs encountered in a group of 1500 clinic and private patients

definite nystagmus, 2.5 per cent lefthandedness 7 1 per cent, some peculiarity of speech, 22.8 per cent reduced coordination of movements 4.3 per cent, paralysis of an extremity, 0 6 per cent, and a positive Babinski sign 5 6 per cent

Of *laboratory examinations* much the most important is the electroencephalogram A tracing which shows outbursts of high voltage fast slow, or alternately fast and slow waves is almost certain evidence either *of epilepsy or of a strong predisposition to it, and weighs heavily against a diagnosis of* hysteria Routine examinations should include urine and blood roentgen ray films of the skull and if a lesion of the brain is suspected lumbar puncture with note of spinal fluid pressure concentration of protein number of cells and the Wassermann and gold sol reactions A pneumoencephalogram and sometimes exploratory operation is needed if other evidence suggests a localized brain lesion In suggestive cases other tests such as measurement of the basal metabolism the blood sugar curve or Roentgen rays of the digestive tract, may be indicated Determination of the intelligence quotient and of traits of personality are often necessary for proper treatment Usually careful search will discover not one but several causes and sometimes more than one disorder such as a hybrid *form of epilepsy and hysteria* of epilepsy and migraine or of tetany and epilepsy

Prognosis —The many factors involved *in epilepsy and the lack of statistical evi*dence from noninstitutional patients prevents accurate forecasting Doubts about the future refer to length of life relief from seizures maintenance of mentality and of social usefulness

Life expectancy is somewhat reduced for most patients because of the chances of external injury from unexpected loss of consciousness or of internal injury from frequently repeated and severe convulsions The brain injuries of acquired epilepsy if not operable bring additional dangers Prognosis regarding seizures is more hopeful if the patient has not suffered brain injury if cortical dysrhythmia is not too severe if mentality is normal if seizures began late are infrequent or of the *petit mal* type if intelligence and finances permit adequate treatment and if seizures are controlled by drug therapy Fortunately, increasing age seems to exert a healing influence

Mental Deterioration —Impaired mentality when it occurs is the most distressing aspect of epilepsy Fortunately contrary to common lay and medical opinion serious deterioration is unusual Of 1905 private and clinic patients examined 67 per cent were found to be mentally normal 23 per cent slightly deteriorated and 10 per cent *definitely deteriorated* Of 1638 *patients who were mentally normal at birth* 75 *per* cent were normal when seen by the examining neurologist and only 7 per cent definitely deteriorated The proportion of mentally normal was 54 per cent in patients with a history of brain injury The proportion of mentally normal decreases somewhat with the passage of years and with the total number of attacks suffered Yet of patients who had been afflicted twenty five years or longer 46 per cent were mentally normal Psychomotor seizures *grand mal* and *petit mal* are harmful in the order named Mental deterioration when present may be due to one or more of the following causes heredity brain damage suffered prior to the onset of seizures the effect of the seizures themselves or of the underlying brain dysrhythmia over medication and psychologic traumas Pa*tients may show unpleasant traits such as* egotism rigidity, moodiness perseveration elements in the so-called epileptic personality Such traits are rare in mentally nor*mal patients who have received intelligent* treatment Whether the life of the epileptic can be happy and useful depends largely on his social and psychological background and treatment

Prevention.—Eugenics is the principal prophylaxis against genetic epilepsy Sensibly to reduce epilepsy in succeeding generations eugenics would need to be applied not only to persons subject to genetic seizures but also to the much larger number of normal persons with hereditary cerebral dysrhythmia especially of the seizure discharge' type Approximately half of the near relatives of epileptic patients have disturbed brain rhythms and in about 90 per cent of patients one or both parents have some degree of dysrhythmia If an epileptic, or a normal person who has cortical dys

in acquired than in genetic epilepsy In seizures of focal origin the head and eyes may turn to one side that opposite the lesion, or jerking of the limbs may be one sided

A nearly pure type of acquired epilepsy is the variety called jacksonian named after Hughlings Jackson the English neurologist In this type convulsive movements or abnormal sensations begin in the small muscles of the hand, foot or face and slowly spread the patient being a helpless witness The march' may end spontaneously or be arrested by squeezing the part, or it may spread to the rest of the body and loss of consciousness and a generalized convulsion ensue The area of the cortex which corresponds to the portion of the body first involved is called the trigger zone"

Petit Mal—Loss or impairment of consciousness is the predominant symptom This comes without warning starts and stops abruptly lasts but a few seconds and is without after symptoms Usually there are rhythmic motions of eyelids or of the head at the rate of three a second synchronous with the spike of the EEG This form of seizure occurs usually in genetic epilepsy, and is most common in females and during adolescence It is the form most frequently recurring the most innocuous and yet the most resistant to drug therapy The term pykno epilepsy is sometimes used

Psychic Equivalent Seizures—These are variously spoken of as psychic psychic variants or psychomotor seizures Amnesia is the predominant symptom The person is out of contact with his environment, but activity is not suspended He may perform purposeful acts but is not subject to command and after the period of confusion is over has no recollection of what took place and may not know that a seizure has occurred The seizures are longer than *petit mal* lasting from a few seconds to minutes or hours The patient may make chewing motions and his body may rotate or become slightly rigid but muscular movements if present are tonic and not clonic as in *petit mal* In prolonged episodes, the patient may act as though intoxicated and may become violent especially if restraint is attempted Psychomotor attacks are more frequent in men than in women and in adults than in children

obedience to instructions the daily measured output of urine should not exceed the volume of fluid allowed not counting that contained in solid food Patients experience chronic thirst so that in spite of its simplicity, the procedure is not popular

Ketosis or dehydration should be continued only if trial demonstrates an actual reduction in the number or severity of seizures Patients with frequent severe seizures or with definite underlying cerebral pathology *are least likely to be helped*

Anticonvulsant Drugs—Three drugs are of proved usefulness bromides phenobarbital and phenytoin sodium This is the order of their discovery and the inverse order of their effectiveness in controlling seizures Ten to 20 grains (0 6 to 1.2 Gm) of sodium or potassium bromide are given three times a day usually in a watery solution Long-continued and heavy medication may result in an acneform eruption or in somnolence and *mental sluggishness* The chloride intake should be kept steady since that ion if excessive may displace the bromide. For accurate treatment the bromide content of the blood should be measured Phenobarbital, at an increased price is sold also under the trade name of luminal The daily dose for adults is from 1½ to 3 grains (0 1 to 0 2 Gm) although double this amount may be taken The occasional patient with an idiosyncrasy for the drug will *have a diffuse macular rash within a few* days after beginning its use The amount which can be taken is usually limited by somnolence Soluble phenobarbital is used for intravenous injection

Phenytoin Sodium—Putnam and Merritt in 1938 first demonstrated in patients the anticonvulsant action of sodium diphenyl hydantoinate The official name is phenytoin sodium the trade name in America is dilantin sodium The original claims of the Boston workers have been confirmed and phenytoin sodium is recognized as the drug of choice for the majority of patients suffering from seizures both because of its *relative effectiveness and its lack of hypnotic* effect However its administration requires vigilance and experience It is most effective for the psychomotor type of seizures for which other drugs are of little use and relatively ineffective for petit mal The effective dose may approximate the dose at which side effects appear Therefore the physician beginning with 1½ grains (0 1 Gm) three times a day for adults and one-*half* that amount for children *will gradually* increase the amount until seizures are controlled or toxic symptoms appear The maximum amount which adults can tolerate is 9 grains (0 6 Gm) a day Most prominent of the toxic symptoms are incoordination (shown by tremor nystagmus or instability *of movements*) *gastric discomfort or cutaneous* rash Some patients especially children have annoying hyperplasia of the gums Symptoms rarely encountered are hirsutism loss of weight fatigue excessive activity or psychotic manifestations Some of these symptoms are inconsequential others call for a reduction in the dose or even abandonment of this form of therapy Obviously this is a medicine to be avoided by concerns which treat patients by mail *and by the physician who is unable or unwilling* to learn by reading and experience. If phenytoin sodium is not fully effective, phenobarbital may be added the full dose of phenytoin being continued Many patients discouraged by the defeatist attitude of the profession have turned to mail order concerns The basis for these epilepsy 'cures is phenobarbital or bromides The cost of phenobarbital purchased in this way is nearly ten times the cost of that bought *at a drugstore*

Care During Convulsions—During a convulsion the principal effort is to avoid injury Some soft substance should be inserted between the teeth to prevent biting of the tongue and clothing about the neck should be loosened Efforts to cut short the attack are useless After the convulsion is over the patient should be allowed to sleep or remain quiet until he feels normal again. In the presence of *status epilepticus* soluble phenobarbital *may be given parenterally* in 3 to 5 grain (0 2 to 0.3 Gm) doses, repeated after twelve hours if necessary Oversedation with its prolonged hang-over effect is however to be avoided A shorter acting drug is paraldehyde one to three drachms (4 to 12 cc) given parenterally When other means fail and exhausting convulsions threaten life resort may be had to etherization A cleansing enema can do no

rhythmia marries he should choose a person whose brain waves are normal thereby greatly reducing the existing chance (about one in forty) that each child will be epileptic In advising about marriage, the physician must remember that the patient and his spouse may have desirable genetic traits which may outweigh his tendency to seizures Furthermore like many other conditions epilepsy *per se* is not inherited, but only the predisposition If precipitating acquired factors can be avoided the predisposition may lie dormant

Public responsibility for the prevention of acquired epilepsy concerns the reduction of infectious diseases which involve the brain brain injuries which result from traffic or industrial accidents and war Individual prophylaxis involves the avoidance of asphyxia or injury at birth later brain trauma or emotional upsets There is also the possibility of treating dysrhythmia before seizures begin especially if a history of infantile convulsions or other suspicious symptoms are present

Treatment *Remedial*—Since the causes of seizures are multiple treatment must be individual and many sided The intelligent and interested family physician who has the confidence of the patient is in the best position to carry out a rounded program the steps of which are (1) correction of observed abnormalities, (2) raising the seizure threshold and (3) the maintenance of mental health and social usefulness

Correction of Abnormalities—The repair of encephalopathies requires the services of a skilled neuro surgeon The most hopeful situations are superficially located or encapsulated tumors or localized cortical scars Penfield reports worthwhile reduction of seizures in about two thirds of patients in which excision of cerebral scars was undertaken after first determining the trigger point' by means of electrical stimulation The necessity of an excision extensive enough to control seizures must be weighed against the possibility of a residual hemiplegia or aphasia Apparently a mere trephine opening or the separation of adhesions between the brain and meninges is of little avail Enucleation of a circumscribed tumor may be both life and seizure saving General surgery may be useful in removing infected or malformed organs or tissues which may be contributory elements in seizures

The correction of abnormalities in the digestive, endocrine circulatory and other systems requires the procedures of general medicine Poor posture should receive specific attention by the use of exercises to strengthen the abdominal muscles and instructions in correct standing Constipation requires the use of fruits and vegetables in the diet, regularity in bowel habits, exercise and possibly mild catharsis

A low metabolic rate may be brought to normal by the use of thyroid Hyoglycemia if present and if due to excessive insulin production calls for a low carbohydrate intake but if severe enough to be accompanied by symptoms of hypoglycemia surgical intervention may be necessary Disturbances of the sympathetic nervous system which so many patients exhibit can sometimes be helped through physical training and improvement of the general physique Though an emotional disturbance is only a contributing cause, its elimination may greatly improve the patient s lot The difficulty usually is near the surface financial or domestic worries, feelings of incompetency fear unfulfilled ambitions conflicts between parental and personal desires These situations should be exposed and righted

Raising the Seizure Threshold—Diet, dehydration and drugs are three practical methods of increasing a patient s resistance to seizures Patients should eat what the other members of the family eat if their diet is sensible and well balanced The exception to this rule is the use of the ketogenic diet in children This diet is expensive and distasteful and long continued use calls for fortitude and intelligent cooperation on the part of patient and family Out of 267 children treated by Helmholtz 47 per cent were improved The book by Talbot gives details of this form of treatment

Dehydration—Dehydration secured by reduction of fluid intake was first advocated by Fay In order to produce a net loss of tissue fluids the total fluid intake must be reduced to 20 ounces or less a day not counting the water content of solid food The check on effectiveness is a decrease in body weight with the total caloric intake remaining the same As a rough check on

ings or laryngospasm and the characteristic carpopedal spasm with pronation of hands and feet. Chovstek s and Trousseau s signs and the Erb electrical reaction are positive the roentgen ray may show a beginning healing of rachitis, the serum calcium is low and the phosphorus high

Treatment consists of administration of calcium chloride 15 to 30 grains (1-2 Gm) four to six times a day or viosterol 15 to 20 minims (1-2 cc) twice a day with exposure to the sun or ultraviolet light

WILLIAM G LENNOX

ECLAMPSIA

Toxemia is an important complication of pregnancy occurring in about one tenth of pregnancies and accounting for about one fourth of maternal deaths The term is used to cover various conditions acute yellow atrophy of the liver nephritis hypertension of pregnancy, pernicious vomiting mild and severe preeclampsia and eclampsia itself

Symptoms.—Convulsions are the distinguishing feature of eclampsia Eclampsia occurs in about 0.2 per cent of pregnancies in about 1 per cent of maternity cases in hospitals and in about 2 per cent of patients with some form of toxemia of pregnancy It is unusually common in primiparous patients in twin pregnancies and in the presence of hydramnios

Etiology —A discussion of causes must include two conditions first the so-called toxemia and second the eclampsia which would seem to be only a superadded symptom There is an ominously large number of explanations for toxemia uremia bacterial auto intoxication biological reactions toxic substances from the fetus or the placenta endocrine disturbances mammary toxemia dietary alterations physicochemical changes Each of these theories has had its proponents

As for the eclampsia presumably patients with toxemia who become eclamptic have a tendency toward convulsive reactions If so they should have a cerebral dysrhythmia which antedates the pregnancy also eclampsia and epilepsy should appear with unusual frequency in the same person or in an unusual number of relatives especially in identical twins These questions have been insufficiently studied

Morbid Anatomy —The immediate cause of death is often pulmonary infection Pathologic examination has disclosed lesions of the brain heart uterus liver and kidney, those last named being most constant The liver damage greatest in the periphery of the lobules consists of hemorrhage necrosis and fatty degeneration In the kidneys the glomeruli are increased in size and ischemia is present due to swelling of capillary walls the tubules exhibit albuminous degeneration Lesions in these and other organs and tissue are probably due to a spasm of terminal arterioles which occurs throughout the body (Irving and Weiss et al) Bartholomew and Kracke in studying 1000 placentas found acute infarcts in all of those from eclamptic or preeclamptic patients They suppose the infarcts are from cholesterol induced arterial disease and the eclampsia from the absorption of split protein products from the infarcted areas

Pathologic Physiology and Chemistry —The pathologic lesions described could be the cause of toxemia and symptoms but are themselves undoubtedly caused by physiological derangements of the organism Many and varied alterations of blood chemistry have been described of which acidosis and increase of uric acid are the most constant but both these effects might be the result of starvation ketosis The edema may be related to an excess of sodium intake in salt or in sodium bicarbonate to anemia vitamin lack decrease in plasma protein or more importantly a hormonal inbalance. The immediate cause of edema Dieckmann believes is a change in the permeability of capillaries In recent years new evidence has come from study of the sex hormones Smith and Smith found a high prolan and a low estrogenic content in the placentas of preeclamptic patients as well as a high concentration of prolan in the serum They believe the toxemia of pregnancy is associated with a progressive deficiency of progestin and destruction of estrogen Weiss and associates believe that the placenta is the source of the trouble that is a normal hormonal constituent of pregnancy in abnormal amounts or in normal amounts acting on a vascular sys

harm In children the use of a hot bath is irrational but if the child is feverish, a cold sponge bath is indicated

MAINTENANCE OF MENTAL HEALTH AND USEFULNESS —The prevention of physical and mental stagnation requires the institution of active measures There must be regular and sufficient time for eating and sleeping vigorous exercise, and, if possible, participation in interesting and worthwhile work Seizures come most frequently when body and mind are idle Driving an automobile and certain dangerous occupations are taboo but the risks inherent in many sports and occupations are less to be feared than psychologic invalidism Children should, if possible, continue in school

Many patients suffer more from the fear of seizures than from the seizures themselves The patient and those about him should look on seizures, not as a catastrophe but as a temporarily disabling condition like migraine, or dysmenorrhea or an impediment of speech The physician can point to the fact that the great majority of patients with seizures are leading fairly normal lives and that many, in spite of epilepsy, have attained distinction Patients need to be protected from discouragement from the horror of school authorities or employers who wish to discharge them forthwith and from the overprotection of relatives The public needs to be educated away from the idea that epilepsy is a hopeless mentally deteriorating disease Not always, or often, can the physician stop seizures, but *almost always* he can inspire new courage and build morale Furthermore joined with others, he can educate patients and the public to a more just and hopeful attitude about epilepsy Enlistment of the support of patients and their friends and relatives is possible through the Laymen's League Against Epilepsy

INSTITUTIONAL CARE —Many persons with epilepsy need to be segregated from the general population and provided for in hostels or hospitals At present eleven of the states provide well equipped buildings and commodious grounds equipped to care for an aggregate of 18 000 of the approximately 60 000 patients in institutions These colonies are havens of refuge for persons who are hopelessly deteriorated or who cannot be kept at home without unduly sacrificing the needs of other members of the family There is great need for private but moderate priced care of patients who *should not* be sent to state institutions

WILLIAM G LENNOX

SPASMOPHILIA

In children with seizures acquired and genetic factors may seem inextricably mixed The earlier in life seizures begin the greater seems to be the factor of inheritance and developmental defects of the brain and birth injuries are additional loads which cause an immature and inadequately insulated nervous system to break into a convulsion In children, even more than in adults, a combination of causes may be responsible Peterman assigned one cause for seizures in each one of 911 children ten years of age or under Various causes were acute infections 35 2 per cent epilepsy and unknown 25 3 per cent, cerebral birth injury 16 4 per cent, spasmophilia or tetany 8 7 per cent, miscellaneous 8 3 per cent and meningitis encephalitis, and whooping cough 6 1 per cent Spasmophilia was reported *only* in children during their first three years or in 12 per cent of a group of 659 children of that age A convulsion in early childhood *especially* if repeated must be regarded with some uneasiness Thom gathered information about 8823 children in a laboring population During their first five years approximately 7 per cent had one or more seizures Of this group 12 per cent and of the total goup 0 8 per cent later became epileptic a ratio of 15 to 1

Spasmophilia is a term used for childhood tetany The subject of tetany is fully discussed elsewhere Undoubtedly the diagnosis of spasmophilia is often made on insufficient grounds as suggested by the frequency with which children with this diagnosis later become epileptic

The etiology is much the same as that of tetany Affected children are often rachitic In babies symptoms are often precipitated by lack of respiratory control especially in the presence of respiratory infections

Symptoms are irritability facial twitch

ings or laryngospasm and the characteristic carpopedal spasm with pronation of hands and feet Chovstek s and Trousseau's signs and the Erb electrical reaction are positive, the roentgen ray may show a beginning healing of rachitis the serum calcium is low and the phosphorus high

Treatment consists of administration of calcium chloride 15 to 30 grains (1–2 Gm) four to six times a day or viosterol 15 to 20 minims (1–2 cc) twice a day with exposure to the sun or ultraviolet light

WILLIAM G LENNOX

ECLAMPSIA

Toxemia is an important complication of pregnancy, occurring in about one tenth of pregnancies and accounting for about one-fourth of maternal deaths The term is used to cover various conditions acute yellow atrophy of the liver, nephritis hypertension of pregnancy, pernicious vomiting mild and severe preeclampsia and eclampsia itself

Symptoms.—Convulsions are the distinguishing feature of eclampsia Eclampsia occurs in about 0.2 per cent of pregnancies in about 1 per cent of maternity cases in hospitals and in about 2 per cent of patients with some form of toxemia of pregnancy It is unusually common in primiparous patients in twin pregnancies and in the presence of hydramnios

Etiology.—A discussion of causes must include two conditions first the so called toxemia and second the eclampsia which would seem to be only a superadded symptom There is an ominously large number of explanations for toxemia uremia bacterial auto intoxication biological reactions toxic substances from the fetus or the placenta endocrine disturbances mammary toxemia dietary alterations physicochemical changes Each of these theories has had its proponents

As for the eclampsia presumably patients with toxemia who become eclamptic have a tendency toward convulsive reactions If so they should have a cerebral dysrhythmia which antedates the pregnancy also eclampsia and epilepsy should appear with unusual frequency in the same person or in an unusual number of relatives, especially in identical twins These questions have been insufficiently studied

Morbid Anatomy.—The immediate cause of death is often pulmonary infection Pathologic examination has disclosed lesions of the brain heart uterus liver and kidney, those last named being most constant The liver damage greatest in the periphery of the lobules consists of hemorrhage necrosis and fatty degeneration In the kidneys, the glomeruli are increased in size and ischemia is present due to swelling of capillary walls, the tubules exhibit albuminous degeneration Lesions in these and other organs and tissue are probably due to a spasm of terminal arterioles which occurs throughout the body (Irving and Weiss et al) Bartholomew and Kracke in studying 1000 placentas found acute infarcts in all of those from eclamptic or preeclamptic patients They suppose the infarcts are from cholesterol induced arterial disease and the eclampsia from the absorption of split protein products from the infarcted areas

Pathologic Physiology and Chemistry.—The pathologic lesions described could be the cause of toxemia and symptoms but are themselves undoubtedly caused by physiological derangements of the organism Many and varied alterations of blood chemistry have been described of which acidosis and increase of uric acid are the most constant but both these effects might be the result of starvation ketosis The edema may be related to an excess of sodium intake in salt or in sodium bicarbonate to anemia vitamin lack decrease in plasma protein or, more importantly a hormonal imbalance. The immediate cause of edema Dieckmann believes is a change in the permeability of capillaries In recent years new evidence has come from study of the sex hormones Smith and Smith found a high prolan and a low estrogenic content in the placentas of preeclamptic patients as well as a high concentration of prolan in the serum They believe the toxemia of pregnancy is associated with a progressive deficiency of progestin and destruction of estrogen Weiss and associates believe that the placenta is the source of the trouble that is a normal hormonal constituent of pregnancy in abnormal amounts or in normal amounts acting on a vascular sys

tem with a congenital or acquired irritability

Symptoms —Symptoms of toxemia which usually precede the appearance of eclampsia are albuminuria, hypertension edema visual disturbance, nausea and vomiting and headache The convulsion unlike the epileptic seizure has a gradual onset with twitching of the small muscles of the face and slow extension to the rest of the body The convulsions are severe, bilateral tonic clonic and not distinguishable from the *grand mal* of epilepsy Apparently *petit mal* or psychomotor seizures are not a part of the eclamptic syndrome Usually convulsions are few in number but may be multiple similar to a *status epilepticus*

Diagnosis —In approximately one half of the cases the convulsions occur before labor and in one fourth they occur either during or after This consideration together with a *history of symptoms of toxemia makes the* diagnosis simple Confusion may arise when convulsions occur in an epileptic at or near labor

Prognosis —Maternal mortality ranges between 10 and 25 per cent with the lower figures in recent years and child mortality *around 40 per cent Maternal mortality is* higher with antepartum eclampsia and with unskilled treatment. The maternal prognosis is best in young women

Treatment —Observation throughout pregnancy should detect the toxemia in its early stages when treatment can be most *effectively applied* The use of progesterone and estrogen is logical but too expensive at present When eclampsia sets in active treatment and constant nursing care is necessary The decreased mortality of recent years is attributed to the substitution of conservative delaying tactics for the formerly popular method of immediate emptying of the uterus During the period of convulsions the primary objectives are adequate sedation and increased urinary output For the first morphia is the drug of choice Plass advocates giving morphine only hypodermically in doses of ¼ grain (0 016 Gm) repeated at intervals until the respiratory rate is reduced to twelve per minute This may require from 1 to 1½ grains (0 065 to 0 1 Gm) This sedation may be supplemented by chloral hydrate 30 grains (2 Gm.) in 100 cc of milk For the promotion of urinary excretion, intravenous injections of 500 cc of a 10 to 25 per cent solution of dextrose are most effective or 20 cc of a 10 per cent magnesium sulfate solution may be given intravenously using no more than five injections in twenty four hours From 200 to 400 cc of blood may be withdrawn for the sake of reducing blood pressure. Bryant and Flemming had only two deaths in 120 patients with the use of veratrum viride magnesium and glucose solutions intravenously and sedatives for extreme restlessness Veratrum viride is a powerful *vasodilator and must be used with caution* giving 10 minims (0 6 cc) immediately and repeating it every 10 to 15 minutes until the pulse rate is below sixty or blood pressure is below 120 systolic thereafter, until the patient is conscious 3 to 10 minims (0.2 to 0 6 cc) doses are given if the pulse rate exceeds *eighty or the blood pressure exceeds 150* systolic Whatever drug therapy is used gentle handling rest and quiet are of primary importance The patient should not be rushed to a distant hospital If comatose she must be fed by nasal tube with carbohydrates and a minimum of protein When the *convulsions are over and the patient* has regained consciousness and strength, she should be delivered as a means of preserving the life of the fetus If the fetus is dead haste is less urgent because fetal death has a favorable influence on the course of the eclampsia

William G Lennox

SYNCOPE

Fainting is considered here because of the frequency with which it is confused with epilepsy It is a common symptom Although especially frequent during adolescence and among females it may occur at any age Approximately one *adult in 200 faints* on the occasion of acting as a blood donor The syncope is directly due to cerebral anemia The underlying factors are variable The first is a certain constitutional susceptibility evidenced by a family history of fainting Contributory are conditions which place a strain on the sympathetic nervous system fatigue hunger standing immobile, pain migraine headache and emotional shock

such as the sight of blood or of others fainting The experimental studies of Weiss suggest that there is first a dilatation of veins and a pooling of blood in them increase in heart rate decrease in pulse pressure loss of consciousness a fall of the body to the prone position with reestablishment of an adequate supply of blood to the heart and restoration of consciousness. Fainting may however occur when the person is lying down it may be accompanied by cyanosis and jerking of extremities and be followed by vomiting features which suggest epilepsy especially if the electroencephalogram is abnormal Attacks which are at first syncopal may later become epileptic Usually however the tendency to faint disappears with the passing years The various disorders of circulation with which fainting may be associated are discussed elsewhere A person who has fainted should be allowed to lie quietly and recover spontaneously For prevention the cause or causes must be ascertained and appropriate treatment instituted For patients with orthostatic hypotension or vasomotor instability building a vigorous physique avoidance of fatigue smoking and drugs like sodium nitrite which interfere with normal vascular responses often prove helpful

MIGRAINE

Definition.—Migraine is a periodic cephalalgia characterized by the absence of any local lesions which might cause headache and peculiar as regards the visual and oculoplegic symptoms and psychic phenomena which may accompany it. All migraine except that of the abdominal type may be considered headache, but all headache is not migraine Migraine is characteristically periodic but in the majority of instances the attacks occur irregularly with no definite interval between the crises The term ophthalmic migraine' is somewhat superfluous because it is merely a separate name for the periodic headache associated with such visual disturbances as transient scintillating scotomata

Etiology—Migraine can be shown to be hereditary in every instance if heterozygous inheritance is carefully considered There is also a kinship between migraine and epilepsy and Buchanan s statistics seem to indicate that an individual with migraine is more likely to produce epileptic offspring than is an individual with epilepsy

In the old conceptions migraine was explained on the basis of injury excessive work or exhausting disease but new ideas have relegated such factors to secondary place Excesses of work and the ill effect of exhausting disease can be fully corrected without relieving the migrainous constitutional syndrome As Miller and Raulston point out there is evidence to support the theory that migraine is allergic in nature and therefore in some measure comparable to hay fever asthma and urticaria Patients with migraine frequently have periods of relative immunity during which nervous strain such as ordinarily brings on an attack is without effect These might be considered refractory periods corresponding to an antianaphylactic state and they emphasize the points of similarity between asthma

which is certainly allergic, and migraine. In each, the attacks are periodic nervous influences are important in precipitating an attack, the disturbance frequently disappears temporarily after some prolonged infection, and pregnancy sometimes exerts a favorable influence A certain kind of food has been known to precipitate an attack in both conditions Migraine as well as asthma is often accompanied by eosinophilia These points at most suggest by analogy that migraine is an allergic disease Brown believes that in migraine the condition of the gastro intestinal tract and the character of the diet play at least a secondary or contributory role in producing the explosive phenomena. He divides cases of migraine into four groups (1) those associated with intake of more carbohydrate than can be utilized, (2) those associated with the intake of animal food either in excess or of a type which sets up a specific reaction (3) those few associated with true intestinal toxemia caused by the decomposition products of protein digestion which are possibly related to histamine and (4) those associated with metabolic abnormalities which require complete avoidance of purine containing foods Timme says that two classes of food invariably precipitate attacks in predisposed individuals, *i e* substances rich in iodine such as fish, oysters clams and occasionally spinach and carbohydrates in excess

Foldes believes that migraine is due to increased water retention in meningeal and cerebral tissues but it has been shown that forced fluids and injections of pitressin do not induce headache.

Kennedy gives reasons for believing the migraine attack is due to localized meningeal and cerebral edema on the tentorial shelf causing visual phenomena in the sphenoidal fissure causing compression of issuing nerves and Charcot s ophthalmoplegic syndrome There are studies giving evidence which associates the hypophysis and the ovary with the migrainous attack The joint factual evidence was the demonstration that the presence of prolan in the urine is definitely related to the occurrence of the migrainous seizures Prolan has also been found in the urine of males with migraine

Women are two or three times more susceptible to migraine than men

Morbid Anatomy—The pathology of true migraine is not known at present, and probably cannot be fully discovered until the correlation of the sympathetic nervous system and the endocrine system is better known and the phenomena of allergy are better understood Graham and Wolff have carried out recent experiments which bear upon the mechanism of migraine and the origin of migraine pain They have demonstrated that changes in the intensity of migraine headache are related closely to changes in the amplitude of pulsations of branches of the external carotid arteries Their data lend support to the postulate that the pain is produced by distention of cranial arteries, a view quite at variance with the former conception that vascular spasm might be a factor Obviously the next step is to seek the origin of the arterial distention

Symptoms—Just before an attack of migraine the patient may experience vague feelings of impending malaise for a variable number of hours Severe pains of great intensity then develop sometimes gradually and sometimes with great suddenness They are usually intense across the forehead but may be focused back of or between the eyes or be entirely occipital or temporal and limited to one side In any individual the pain is usually in the same place in every attack. It is severe incapacitating and made worse by such environmental annoyances as jarring movements bright lights and loud sounds During this period there are sometimes flashes of light or dark and light spots before the eyes or scintillating zigzag lights The visual acuity may become dimmed or the visual fields contracted Partial oculomotor paralysis with temporary strabismus sometimes occurs and in rare instances peculiar odors or tastes slight hemiplegia or temporary aphasia has been noted Transitory states of mild confusion with apparent disturbances of perception may develop It has not been shown that these are not due to the mental abstraction which the suffering occasions Vertigo and a distressing tinnitus are frequently seen and nausea often followed by vomiting is a common symptom

Disturbances of the sympathetic system are evidenced by pallor coldness and sweating of the hands and feet unilateral hyper

idrosis pupillary fixation (either dilatation or marked contraction) excessive lacrimal secretion, and abnormal salivary secretion The gastro-intestinal symptoms are probably *referable to the sympathetic system* In most cases they are associated with relatively mild cephalic pain although the usual visual and vertiginous disturbances are present with localization of the severe pain in the abdomen

The attack is never febrile It is not accompanied by leukocytosis but in a large percentage of cases there is temporary eosinophilia (5 to 16 per cent) The pulse may be slow

The attacks usually last one to three days occasionally only a few hours They recur at varying intervals once or twice a month and even weekly and in women are apt to coincide with the menses At the menopause *they are very likely to disappear In rarer* instances the menopause marks the inauguration of migraine not previously present.

In a few cases (about 7.5 per cent) epilepsy and migraine are coexistent. The epilepsy may come in major attacks but manifestations of petit mal are more usual in this association

Treatment —The initial treatment is the establishment of suitable personal hygiene Sufficient and regular sleep regularity of meals avoidance of strain and worry are essential Toxic infections of the tonsils teeth sinuses and intestines must be corrected For the attack itself proper conditions of solitude and quiet may be supplemented by *such simple procedures* as cold and hot compresses the menthol stick and hot foot baths.

Aspirin and other sedatives may be given but morphine and its derivatives should *never* be used in migraine because of the danger of addiction

The administration of calcium lactate by mouth (30 grain doses) with the approach of symptoms may abort an attack Phenobarbital mildly beneficial during the attack may also be *of value in the interval between* attacks in delaying their return The drug most apt to relieve the largest number of patients is ergotamine tartrate (trade name gynergen) an alkaloid of ergot Brock O Sullivan and Young confirm the work of others with this agent. In a majority of patients, subcutaneous injection of 0.5 to 1 cc (0.25 mg.–0.5 mg) causes the headache to disappear in one to three hours Vomiting often accompanies relief The drug may be *given orally in 1 mg doses but subcutaneous* use is more effective However, at times the taking of 1 mg, two or four times a day orally in tablets during the symptom free interval lessens the attacks in frequency and intensity

A therapeutic measure sponsored by Alvarez and which may come to rival gynergen in efficacy is the inhalation of 100 per cent oxygen All one needs is a tank of oxygen an inhalation apparatus a reducing valve and a flow meter The amount of oxygen used is usually between 6 and 8 liters per minute Both cephalic and abdominal migraine have been relieved and attacks terminated within an hour or two

Sluder s cocainization of the sphenopalatine ganglion may relieve atypical cases A procedure based on the allergic conception is the intravenous injection of from 0.5 to 2 cc. of a 5 per cent solution of peptone (Miller and Raulston) Injections starting at 0.5 cc are usually given twice a week but the intervals are gradually lengthened to a month If the medication is discontinued the migraine sooner or later returns the longest period of freedom after discontinuance being nine months.

Finally there is endocrine therapy Pituitary extract (whole gland substance 0 1–1 grain once or thrice daily one hour after meals) may prevent attacks A daily divided *dosage of 5 cc of amniotin (2000 rat units)* orally relieves more than 50 per cent of cases The induction of an artificial menopause by the use of radium has cured some patients

Disturbances of the sympathetic system are evidenced by pallor coldness and sweating of the hands and feet unilateral hyper

or more peripheral branches of the trigeminal nerve They are most common about the nose and mouth These hypersensitive zones are usually referred to as 'trigger zones' since touching them precipitates an attack of pain

The disease usually begins in middle life or later, but occasionally has occurred among children The pain appears periodically lasts for a few weeks is followed by intervals of relief extending from a few weeks to six months. At first the pain may be located along the distribution of one of the branches of the trigeminal nerve but as the disease progresses it extends to involve two branches and occasionally the third The mandibular and superior maxillary branches are affected most commonly but it is not uncommon for the ophthalmic branch to be involved also The particular arrangement of the involvement is not constant however As the disease progresses the symptoms increase in severity and duration The intervals of relief become shorter until the pain is almost continuous. At first the patients are rarely disturbed with pain at night whereas in the advanced stages of the disease the slightest contact with the trigger zone results in the precipitation of a paroxysmal attack

Complications.—Occasionally a boring like pain in the superior maxilla with projection down the neck and shoulder a condition known as *Sluder's neuralgia* is mistaken for the pain of trigeminal neuralgia The pain from neuritis which follows dental operation or caries likewise has been mistaken for trigeminal pain Thus it should be borne in mind that unless the patient has a paroxysmal type of pain with a trigger zone the disease is not trigeminal neuralgia The treatment of these two similar types of pain is not as effective as is the treatment of trigeminal neuralgia Not infrequently patients of advanced years who have cerebral arteriosclerosis complain of a dull aching burning and drawing sensation of the gums and face These symptoms may appear independently of trigeminal neuralgia but are usually associated with it The paroxysmal attacks of pain may be so severe that the patient fails to describe this unpleasant sensation until he has been relieved of the paroxysmal attacks for these continuous dull aching drawing pains are not relieved by injection of alcohol or by section of the sensory root

Diagnosis—Trigeminal neuralgia is accompanied by definite symptoms that are not readily confused with other pains of the face The pain is characteristically periodic, severe of short duration (a few seconds to a minute or two), occurs during waking hours is brought on by external irritation, is almost always unilateral, and differs from the dull aching continuous type associated with *dental caries* or *sinus infection* Furthermore deep alcoholic injection of the trigeminal branches as they leave the skull affords temporary relief and produces anesthesia of the region supplied by those nerves This does not occur with other types of pain of the face

Prognosis and Treatment.—The disease at first is intermittent, but the pain gradually becomes more persistent until it is almost continuous affecting first one branch then a second and often a third and being present in one or all three branches simultaneously It has never been known to disappear permanently without operative interference and while drugs and other kinds of treatment have been thought to afford relief the cessation of the pain during the administration of the particular form of treatment was probably merely a coincidence

The two accepted measures for *palliative treatment* consist of peripheral avulsion and *deep injections of alcohol* in the branches of the trigeminal nerve as they leave the skull. The average duration of relief following *peripheral avulsion* is eight months avulsion cannot be repeated The *deep alcohol injection* which is the best palliative therapeutic procedure affords continuous relief for an average of eighteen months The procedure is not altogether free from complications but proves successful in about 75 per cent of cases and can be repeated a number of times The technic described by Levy and Baudouin and modified by Patrick in 1907 is generally used

The needle consists of a trocar and cannula, 8 cm. in length and 1.5 mm in diameter graduated in centimeters the blunt end is constructed to permit the attachment of a 5-cc syringe The area to be injected is prepared as for surgery The patient is given nitrous oxide until analgesia ensues The needle may

THE NEURALGIAS

Neuralgia' is a term applied to painful sensations that extend along one or more of the cranial or spinal nerves Neuralgia occurs in paroxysms in contrast to neuritic pain which is more or less continuous Neuralgia is probably the result of central lesions whereas neuritis is the result of peripheral involvement

TRIGEMINAL NEURALGIA

(Trifacial Neuralgia Tic Douloureux)

In trigeminal neuralgia it once was thought that only the gasserian ganglion was affected However the disease probably is of a more complicated nature involving not only the gasserian ganglion but also the root of the trigeminal nerve and its connection with other nerve cells affecting one or more branches of the trigeminal nerve It is manifested by sharp shooting excruciating pains The disease usually begins in middle life The pain appears periodically lasting for a few weeks and in the beginning is followed by intervals of relief of from four to six months In increases in severity and duration as the disease progresses and the intervals of relief become shorter until the pain is almost continuous

History—Trigeminal neuralgia was first described by Avicenna, an Arabian physician as *tortura facies* (facial agony) Previous to 1900 various medical remedies (aconite belladonna and opium) were used in the treatment, but with little success In 1891 Horsley and Krause devised their operation for ganglionectomy through the transtemporal route and in 1898 Hutchinson advocated partial resection of the ganglion Spiller in 1898 advocated division of the sensory root of the gasserian ganglion in lieu of radical removal Frazier and Spiller in 1901 proved that division of the sensory root was fully as efficacious as gangliopectomy It was learned later that Horsley also had employed division of the sensory root for trigeminal neuralgia and apparently had performed it prior to Frazier's operation In 1902 Petres and Verger and in 1903 Schlosser described methods of injecting the peripheral branches of the fifth nerve and the gasserian ganglion with alcohol At about the same time, Cushing developed a technic for dividing the sensory root, and also perfected the technic for avulsing the ganglion Since then the palliative treatment has consisted of alcohol injection and peripheral avulsion and the radical treatment of division of the sensory root. There have been minor changes in the operation but most surgeons follow the principles laid down in the physiologic extirpation or division of the sensory root, which gives permanent and instant relief from the neuralgic pains

Etiology—Frazier and Dana were of the opinion that the disease was the result of a lesion situated in the gasserian ganglion Frazier thought the disease was the result of a sclerosing process Dana attributed it to degenerative changes within the gasserian ganglion Horsley was of the opinion that trigeminal neuralgia resulted from an ascending neuritis caused by dental caries Unfortunately these early hypotheses have not been substantiated Even though section of the sensory nerve root or interruption of sensory impulses peripheral to the ganglion by section or injection does give relief from pain the pathologic lesion presumably is situated within the brain central to the trigeminal nerve The exact nature of the lesion is still unknown It has been postulated that the attacks of pain are related to some vascular disturbance. There is no evidence of hereditary tendency although more than one member of a family may be afflicted

Symptoms—The pain is described as shooting stabbing jabbing flash like darting zigzag lightning like and sizzling burning pain As a rule the attack is of short duration and is never continuous or of a dull aching type One severe attack may extend into the next one in such close order that pain may appear to be continuous for an hour or so at a time The attacks of pain are brought on by eating drinking talking exposure to sudden draughts or by washing the face and teeth Most patients complain of hypersensitive regions which involve one

extracranial avulsion of the glossopharyngeal nerve there was a sense of fulness on the side of the pharynx operated on complete anesthesia to pain temperature and tactile sensation over the entire half of the posterior aspect of the soft palate and anesthesia back to 1.5 cm from the posterior border of the upper aspect of the soft palate That portion of the pharynx between the level of the hard palate and the pyriform fossa was likewise anesthetic to pain tactile and temperature stimulation Sensations remained normal over the posterior half of the nasopharynx and over all of the nasopharynx below a line drawn through the hard palate as well as over the epiglottis and the upper aspect of the larynx The sensations of taste (salt, sweet, bitter and sour) were absent over the entire half of the tongue on the side operated on

Prognosis and Treatment—While the pain is primarily intermittent, it tends to recur until it is almost continuous It does not cease spontaneously On account of the position of the glossopharyngeal nerve and its intimate association with the hypoglossal nerve and vagus it is unwise to attempt an *injection of alcohol Intracranial division* proximal to the ganglia is necessary for permanent relief

ALFRED W ADSON

SCIATICA

The term sciatica' is applied to painful conditions of the sciatic nerve The condition has been considered an infectious lesion of the sciatic nerve Therefore the treatment has consisted in eradication of foci of infection and local application of heat However this conception has undergone a radical change during the last few years The fact that unilateral sciatica recurred and failed to respond to treatment employed for neuritis gave rise to investigations that revealed that protrusions of the nucleus pulposus from the intervertebral disks were the most common cause of unilateral sciatica It is true that the sciatic nerves their ganglia and roots are subject to the same lesions to which other nerves are subject and that when they are affected similar treatment is indicated

Before making a diagnosis of sciatica' due to a protruded disk one must differentiate sciatica from such lesions as hypertrophic arthritis, spondylolisthesis, sacralization of the fifth lumbar, anatomic anomalies pelvic tumors and intraspinal tumors which can and do produce local pain with radiation of pain along the sciatic nerve

Symptoms Produced by a Protruded Intervertebral Disk.—Patients who have protruded intervertebral disks in the lumbar and lumbosacral areas complain of localized tenderness muscle spasm scoliosis and a limp with radiations of pain along one or both sciatic nerves The recurrence of attacks with increasing severity and a failure of the patient to secure permanent relief from belts braces and physiotherapeutic measures strongly suggest the existence of a ruptured intervertebral disk with a protrusion or extrusion of the nucleus pulposus The majority of patients give a history of having sustained an injury which has resulted from lifting a heavy object falling and landing on the buttocks or having been more or less jackknifed in between two objects The initial pain is usually a sensation of a sharp sting in addition to the sensation that something has given way Frequently the initial symptoms subside upon bed rest and the application of heat with extension applied to the lower extremities The interval of relief may continue for several months when a slighter injury gives rise to a recurrence of a similar set of symptoms Occasionally patients are unable to recall having sustained any type of injury When this is true the onset is less abrupt but the symptoms may be just as severe as those that develop following a definite injury

As the patient presents himself for examination he complains of a limp and scoliosis with the thorax usually tilted away from the side of the lesion Tenderness is usually elicited in the lower part of the back near the sacro iliac joint and along the course of the sciatic nerve in the buttocks He usually objects to sitting in a chair and prefers to stand or lie with the thigh partially flexed The examination also reveals muscle spasm an inability to flex the thigh with the knee bent (Kernig s sign) and an inability to flex the thigh with the leg extended (Lasegue s sign) Patellar reflexes

then be inserted without pain until it strikes the nerve, when the patient indicates pain by resistance or movement Complete anesthesia is produced before all of the 5 cc of 98 per cent alcohol is injected

The radical treatment consists of injection of alcohol into the gasserian ganglion or of subtotal or complete section of the sensory root by the transtemporal or suboccipital approach The most serious objection to the injection of alcohol is that the procedure is carried out blindly and there is always danger that the alcohol may be injected into the subarachnoid space in the middle fossa and impair the function of the oculomotor nerves Therefore most surgeons choose to visualize the sensory root before sectioning it Since the disease so frequently spreads to other branches of the same nerve I prefer to divide the entire sensory root whenever branches other than the third are involved The present technic of transtemporal division of the root, with preservation of the motor root has been so perfected that the complications of keratitis or facial paralysis are rarely encountered The mortality is less than 0.5 per cent and the result is so gratifying to the patient that the radical operation should be advised and performed in all cases of trigeminal neuralgia At the onset of the disease I believe it is advisable to advocate deep injection of alcohol on one or two occasions as a therapeutic test and as an educational measure in order that the patient may appreciate the effects of numbness that result from injections of alcohol or division of the root and thus may be better prepared to accept the permanent numbness from the radical operation

Alfred W Adson

GLOSSOPHARYNGEAL NEURALGIA

Glossopharyngeal neuralgia is similar to trigeminal neuralgia in that the associated pains are spasmodic excruciating and lancinating but differs in that the pain radiates from the pharynx and tonsillar fossa to the ear The pain may be brought on by swallowing or yawning, lasts from a few seconds to a minute or two and recurs many times during the hour As in trigeminal neuralgia the attacks are intermittent but are of shorter duration and separated by longer intervals of relief

History.—In 1910 Weisenburg described the glossopharyngeal nerve syndromes and in 1920 Sicard and Robineau described 3 cases of "algie velo-pharyngée essentielle the first two of which were seen in the French Army in 1916 and 1917 In both the pain had persisted for several years and was not continuous but recurred frequently day and night in extremely acute paroxysms on the least movement of mastication deglutition or speech The patients developed suicidal tendencies on account of the apparent incurability of the condition They were treated by section of the glossopharyngeal nerve and the pharyngeal branches of the vagus and by ablation of the superior cervical sympathetic ganglion

Etiology—The causes of glossopharyngeal neuralgia are still unknown but are probably similar to those of trigeminal neuralgia Again relief is secured by interrupting the sensory impulse Temporary relief is obtained when the fibers are evulsed peripheral to the ganglion and permanent relief when the root is sectioned proximal to the ganglion through a craniotomy

Symptoms and Diagnosis—Glossopharyngeal neuralgia simulates trigeminal neuralgia in its occurrence, duration repetition and character but differs from it in its distribution and the location of a trigger zone in the tonsillar fossa It is more often brought on by swallowing than by chewing cannot be evoked by rubbing the face and only occasionally by rubbing the ear It also differs from trigeminal neuralgia in that the pain radiates from the pharynx and tonsillar area through the neck to the ear particularly to the tympanum It is possible to evoke paroxysms of pain by stimulating the pharynx but difficult to produce them if the pharynx and tonsillar area have been thoroughly cocainized such anesthesia does not inhibit paroxysms of pain in the maxillary and mandibular branches of the trigeminal nerve in *trigeminal neuralgia* Glossopharyngeal neuralgia also is unlike trigeminal neuralgia since it is impossible to inject the nerve with alcohol because of its close proximity to the vagus hypoglossal and spinal accessory nerves Temporary relief can be obtained however by peripheral avulsion just as in trigeminal neuralgia

Doyle emphasizes the diagnostic symptoms and also the sensory and gustatory changes in glossopharyngeal neuralgia and states that in two patients who had had

extracranial avulsion of the glossopharyngeal nerve there was a sense of fulness on the side of the pharynx operated on, complete *anesthesia to pain, temperature and tactile* sensation over the entire half of the posterior aspect of the soft palate and anesthesia back to 1.5 cm from the posterior border of the upper aspect of the soft palate That portion of the pharynx between the level of the hard palate and the pyriform fossa was likewise *anesthetic to pain tactile and temperature stimulation* Sensations remained normal over the posterior half of the nasopharynx and over all of the nasopharynx below a line drawn through the hard palate as well as over the epiglottis and the upper aspect of the larynx The sensations of taste *(salt sweet bitter and sour)* were absent over the entire half of the tongue on the side operated on

Prognosis and Treatment —While the pain is primarily intermittent it tends to recur until it is almost continuous It does not cease spontaneously On account of the position of the glossopharyngeal nerve and its intimate association with the hypoglossal nerve and vagus it is unwise to attempt an *injection of alcohol Intracranial division* proximal to the ganglia is necessary for permanent relief

ALFRED W ADSON

SCIATICA

The term sciatica is applied to painful conditions of the sciatic nerve The condition has been considered an infectious lesion of the *sciatic nerve Therefore the treatment* has consisted in eradication of foci of infection and local application of heat However this conception has undergone a radical change during the last few years The fact that unilateral sciatica recurred and failed to respond to treatment employed for neuritis gave rise to investigations that revealed that protrusions of the nucleus pulposus from the intervertebral disks were the most common cause of unilateral sciatica It is *true* that the sciatic nerves their ganglia and roots are subject to the same lesions to which other nerves are subject and that when they are affected similar treatment is indicated

Before making a diagnosis of sciatica" due to a protruded disk, one must differentiate sciatica from such lesions as hypertrophic arthritis, *spondylolisthesis*, sacralization of the fifth lumbar, anatomic anomalies, pelvic tumors and intraspinal tumors which can and do produce local pain with radiation of pain along the sciatic nerve

Symptoms Produced by a Protruded Intervertebral Disk —Patients who have protruded *intervertebral disks in the lumbar and lumbosacral areas complain of localized* tenderness muscle spasm, scoliosis and a limp with radiations of pain along one or both sciatic nerves The recurrence of attacks with increasing severity and a failure of the patient to secure permanent relief *from belts braces and physiotherapeutic* measures strongly suggest the existence of a ruptured intervertebral disk with a protrusion or extrusion of the nucleus pulposus The majority of patients give a history of having sustained an injury which has resulted from lifting a heavy object falling *and landing on the buttocks or having* been more or less jackknifed in between two objects The initial pain is usually a sensation of a sharp sting in addition to the sensation that something has given way Frequently the initial symptoms subside upon bed rest and the application of heat with extension *applied to the lower extremities The interval* of relief may continue for several months when a slighter injury gives rise to a recurrence of a similar set of symptoms Occasionally patients are unable to recall having sustained any type of injury When this is true the onset is less abrupt but the symp*toms may be just as severe as those that* develop following a definite injury

As the patient presents himself for examination he complains of a limp and scoliosis with the thorax usually tilted away from the side of the lesion Tenderness is usually elicited in the lower part of the back near the sacro iliac joint and along the course of the sciatic nerve in the buttocks He usually objects to sitting in a chair and prefers to stand or lie with the thigh par*tially flexed* The examination also reveals muscle spasm an inability to flex the thigh with the knee bent (Kernig s sign) and an inability to flex the thigh with the leg extended (Lasegue s sign) Patellar reflexes

are usually normal, but the Achilles' reflex is usually reduced or absent

Aside from the usual symptoms produced by protrusions of ruptured intervertebral disks at one or more levels, unilateral or bi lateral, the occasional patient may complain of localized tenderness and spinal rigidity with none of the radiating symptoms with negative Kernig s and Lasegue s signs and normal reflexes Not infrequently patients with the classical symptoms may have ac companying paresthesias and anesthesias along the lateral distribution of the leg and foot In a few isolated instances the patient s chief complaint was pain and paresthesia along the lateral aspect of the leg and foot with none of the other classical symptoms Several patients have had the usual symp toms but in addition they have complained of peroneal anesthesia and an inability to urinate Therefore roentgenographic inves-tigation has been necessary in order to recog nize a lesion Variation in symptoms is usu ally due to a migration of the extruded nu cleus pulposus The majority of protrusions occur lateral to the posterior longitudinal ligament they occasionally occur in the mid line thus producing pressure on several sac ral nerves rather than on a single nerve root The size of the protruded mass likewise changes the degree of compression of ad-jacent nerve roots, and in exaggerated cases a hypertrophied ligamentum flavum may be responsible for compressing more than one nerve

The variability of symptoms produced by a small protrusion of the intervertebral disk compressing one nerve root against the pedicle of the vertebra and a group of symp toms resulting from an extrusion of the nu cleus pulposus into the spinal canal sub-stantiate the argument that investigation cannot be too thorough The variability of symptoms therefore justifies myelographic studies with one of the following media oxygen oxygen combined with helium air or radiopaque oil (pantopaque or lipiodol) The latter two media may give rise to radic-ulitis and should be removed when possible, either following the study or at the time of the operation Chemical studies of the cerebrospinal fluid which frequently reveal increased protein in the presence of pro-truded disks were once thought to be sig nificant but later they have proved to be of less value in the diagnosis since chronic protruded disks can exist without producing changes in the cerebrospinal fluid

In selecting patients for surgical treat ment all means of investigation should be used in arriving at an accurate diagnosis Surgery should not be advised at the onset of the symptoms until conservative meas ures have been tried since undoubtedly slight lacerations in the annulus fibrosus heal by scar and spontaneous, permanent recov eries result Surgery should be resorted to in the acute case when symptoms fail to subside with palliative measures and is also indicated when recurrent episodes occur which incapacitate the patient Neurologic surgery without myelographic study is justi fied when the patient presents the classical history and neurologic findings However when in the presence of active hypertrophic arthritis of the lumbar portion of the spinal column or the sacro iliac joints the neuro logic and myelographic findings are not diag nostic neurologic surgery should not be ad vised on the basis of the symptoms alone

In view of the fact that an occasional protruded disk may not be visualized during myelographic study though still capable of producing symptoms when protruded (that is when producing a bulge of the annulus fibrosus with the patient in certain posi tions) the orthopedic surgeon advising a fusion for hypertrophic arthritis may re quest an exploration of the suspected disk prior to but during the same operative pro cedure thus avoiding the embarrassment of secondary operation for the removal of the protruded disk when the symptoms fail to disappear following fusion

Diagnosis—The addition of a myelo graphic study of the lumbar spine to a care fully taken history and a thorough examina tion is usually sufficient to determine the presence or absence of a protruded disk Al though protruded disks give rise to sciatica one must also consider all the other possi bilities that can produce sciatic pain

Treatment—The radical treatment irre-spective of the cause of sciatic pain con sists of removing the cause For example in the case in which a protruded disk is the causative factor the object of the operation is to remove the mass of fibromucoid car

tilaginous tissue which bulges through a tear in the intervertebral disk in order to eliminate the trauma to one or more nerve roots which are caught and squeezed between the protruding mass and the osseous and ligamentous structures of the spinal column

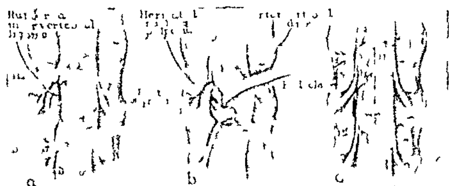

Fig 194—Compression of the nerve root by protrusion of the nucleus pulposus into the spinal canal and the relief of compression when the mass has been removed a protrusion of the nucleus pulposus through a rent in the intervertebral ligament, compression of the lumbar nerve root, b removal of the ribbon fibrocartilaginous nucleus pulposus c relief of compression of the nerve and dura following removal of the fibrocartilaginous mass

The *palliative treatment in the acute* condition usually requires bed rest and sedatives A firm mattress (boards under the mattress) is more comfortable than an innerspring mattress Buck's extension and local heat offer additional relief Preventive treatment

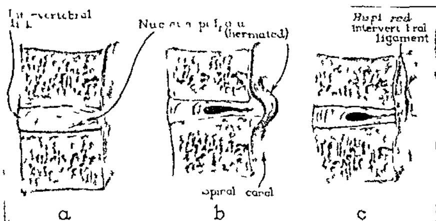

Fig 195—The mechanics involved in the rupture of the intervertebral disk with prolapse of the nucleus pulposus a normal intervertebral disk b prolapse of the nucleus pulposus into the spinal canal c, appearance of the ruptured intervertebral disk following removal of the prolapsed nucleus pulposus

during the interval between attacks consists of caution in avoiding the movements responsible for the attack Lumbosacral belts with Cook s shingle or close fitting canvas lumbar belts offer additional protection

ALFRED W ADSON

CERVICO OCCIPITAL NEURALGIA

Cervico-occipital neuralgia is a painful affection of the four upper cervical nerves chiefly of the great occipital branch of the posterior division of the second cervical nerve

Etiology—Although the cause is similar to that of sciatic and intercostal neuralgia that is, a *focus of infection* or an *acute infection* and occasionally *exposure* the disease is probably due to *specific infection of the dorsal ganglia* of the four upper cervical nerves

Symptoms.—The symptoms are excruciating more or less jabbing *pain* which radiates over the area supplied by the occipital nerve and *muscular spasms* and *stiffness of the neck* The skin over this area is highly sensitive to touch The point of greatest ten

derness is at the exit of the occipital nerve, which is approximately halfway between the mastoid process and the first cervical vertebra Next in order are the areas over the parietal eminence and between the sternomastoid and trapezius muscles

Diagnosis—The diagnosis is often confused with the neuritis due to *cervical arthritis* The differentiating diagnostic features in cervico occipital neuralgia are the primary affection of the occipital nerve and the intensity of the pain The characteristic posture of patients suffering from this disease is slight flexion of the neck with the head held rigid and the hand placed apprehensively at the back of the head to prevent the sensitive area from being touched Cervico occipital neuralgia is generally unilateral but it may be bilateral cervical neuritis with arthritis is usually bilateral

Prognosis and Treatment—The disease persists for several months and may then disappear if the infection has been removed It may recur much as does sciatic neuralgia

The *treatment* consists of removal of all *foci of infection* and local application of *counterirritants* *Injection* of alcohol into the cervical roots, as they leave the spine is frequently resorted to but is rarely successful *Anodynes* and *hypnotics* are necessary to alleviate the pain, if these fail *intraspinal division of the sensory roots* becomes necessary

Alfred W Adson

OTHER NEURALGIAS

Intercostal Neuralgia—Intercostal neuralgia is a painful affection of the intercostal nerves which may occur without an eruption of the skin as seen in herpes zoster Attacks of pain are paroxysmal and may return at intervals for many years Occasionally the primary attack never subsides *Palliative treatment* in the form of physiotherapy offers some relief but cannot be applied in the presence of eruption of the skin Frequently the *subarachnoid injection* of small quantities of *absolute alcohol* is effective in controlling the pain No more than 12 minims should ever be injected at any one time The injection should never be done unless the patient is placed on an operating table and the pillow so adjusted that the painful roots are on the upper side at the apex of the spinal curve In this position the droplets of alcohol may ascend through the spinal fluid to reach the sensory fibers of the involved nerve roots In most instances the subarachnoid injection of alcohol for *postherpetic pain* is a most satisfactory procedure but it may fail to produce relief in the intermittent type of intercostal neuralgia when herpes has not been present *Rhizotomy* and even *chordotomy* have failed to produce relief in this same group of cases

Atypical Neuralgia—Atypical neuralgia includes the various types usually classified in textbooks of medicine as *definite neuralgias* The term atypical neuralgia is used because in many instances the pain is due to neuritis or is referred along certain nerves as the result of various organic diseases and anatomic anomalies

Brachial Neuralgia— Brachial neuralgia is a term applied to the condition in which there is pain over the area supplied by the four lower cervical and the first thoracic nerves tenderness in the axilla over the deltoid behind the elbow, and in front of the wrist The pain is dull and aching and may persist for a few weeks to a few months, or longer

Lumbo Abdominal Neuralgia—Lumbo abdominal neuralgia affects the posterior fibers of the lumbar plexus particularly in the ilioscrotal region The pain is usually unilateral in the region of the iliac crest or along the inguinal canal in the spermatic cord in the scrotum or around the anus It is sometimes associated with a sacral neuralgia and causes the patient to complain of pain around the anus and the perineum

Coccygodynia—Coccygodynia is regarded as neuralgia of the coccygeal plexus It is generally considered a functional disorder although it is occasionally attributed to injury of the coccyx It is more common in women than in men and is aggravated by a sitting posture The disease is extremely difficult to cure

Phrenic Neuralgia—Phrenic neuralgia usually occurs in the lower part of the thorax but may be referred to the supraclavicular region of the neck The pain is aggravated by breathing movements coughing and deglutition and is usually associated with

diaphragmatic pleurisy or pericarditis In all probability it is due to a form of neuritis

Visceral Neuralgia.—Visceral neuralgia is more common in women than in men and is often associated with neurasthenia and hysteria The pain is usually in the pelvic region particularly around the ovaries but the gastro intestinal tract and kidneys may be affected The cause of the pain is questionable, since it is difficult to demonstrate a lesion in the organs affected or in the nerves supplying them

Neuralgias of the Nerves of the Feet.—Cases of neuralgia of the nerves of the feet are divided into three groups *Group 1 painful heel* painful heel is equally common in men and women and is so severe as to interfere with walking It is thought to be due to bony spurs or to gonococcal infection evidence of arthritis is not always present *Group 2 plantar neuralgia* the pain in plantar neuralgia is associated with numbness tingling and hyperesthesia in the tips of the toe and in the ball of the great toe Occasionally there is sweating on the plantar surface of the foot This phenomenon thought by Drs Henderson and Adson to be of vasospastic origin is relieved by sympathetic ganglionectomy *Group 3 metatarsalgia* metatarsalgia is described by Morton as a painful affection of the fourth metatarsophalangeal articulation he ascribes it to pinching of the metatarsal nerve Relief is usually afforded by operative intervention.

Sluder's Neuralgia.—Sluder's neuralgia is a painful affection of the sphenopalatine ganglion which causes what Sluder calls a lower half headache' with boring and burning pain in the superior maxillary region and a radiation of the pain into the neck and the shoulder It is frequently associated with ophthalmic migraine Sluder has been able to relieve certain of these conditions by the injection of alcohol and phenol into the sphenopalatine ganglion

Otalgia and Mastoidalgia.—Lillie describes otalgia and mastoidalgia as pain in the region of the ear and of the mastoid without any obvious evidence of inflammation. Wilson believes that they are brought about by a referred pain along the auriculo temporal nerve

PROFESSIONAL CRAMP

A professional cramp is a special form of occupation neurosis Cerebral in origin it is best described as a focal fatigue ataxia. In mechanism it is allied to tic and especially to stuttering The commonest variety is the so called writer's cramp' though we also meet with similar conditions in the cramp of typists, cutters telegraphers cigar makers and so on Every type of musician has been the subject of this condition It shows itself in an inability to use a part, usually a hand or arm to do a particular movement The extremity is normal for all motor actions except the particular one When a person is learning an occupation he risks no cramp of the kind under discussion When he is expert and is having to repeat a movement over and over for long hours at a time he may develop it The patient with writer s cramp may no longer be able to write with a pen though able to use his hands and fingers skilfully in playing a piano This is because there is a cerebral fatigue not a muscular fatigue to blame At first the patient may have only a weakness or slight cramping which makes the full completion of the movement difficult Later the difficulty may be an effective paralysis of the hand when the particular movement is attempted In some instances tremor may be added to the situation when the patient is endeavoring particularly to overcome it

True professional cramp is free from the sensory or vasomotor signs of neuritic disease and leaves the muscles normal in contour and substance Occasionally slight grades of neuritis may develop as a coexisting difficulty

The chronic character of a majority of cases of professional cramp needs emphasis In treatment a temporary or permanent change in occupation is required with well apportioned diversion At this point motor activity of the affected parts for all movements in general should be insisted upon Physiotherapy and general tonic hygienic treatment are indicated, the former best directed not alone to the parts disabled Mental conflicts, important etiologic factors in some instances must be solved by mental analysis, freudian or otherwise In writer s cramp the introduction of different motor maneuvers, such as writing with more shoulder movement and less wrist, is helpful and often it is wise to have the patient train himself to use the other hand These shifts in the form of the motor endeavor need to be encouraged In all cure is sought along lines of reeducation combined with physiotherapy *and skillfully controlled rest Drugs are not* indicated except as placebos Some cases fortunately come to a spontaneous quiescence

Thomas K Davis

THE NEUROSES OR THE PSYCHO NEUROSES

Introduction —It *is* difficult in the present state of knowledge to define precisely what is meant by the term neurosis Essentially this is due to lack of knowledge of the ultimate cause or causes, but the difficulty also derives from confusion of terminology and conflict of points of view While it is obviously impossible to discuss in a few pages the many theoretic questions involved a few general considerations are necessary for the understanding of the *problem* For practical purposes it is perhaps better to look upon the neuroses as one large group as a *congeries of symptoms* or syndromes or disease entities which have varied manifestations, but which have a number of underlying factors more or less common to all of them

At the present moment two schools of thought dominate the field One which defends the psychologic or psycho*pathologic* point of view, the other which adheres to the organic somatic or pathophysiologic theory of the *neuroses A third approach* is the one which attempts to correlate the two seeing that it is impossible to define the *problem* either in purely psychologic or purely somatic terms However great the temptation and the justification for such correlation it must be admitted that we are as yet unable

to speak of physiologic processes in psychologic terms or of psychologic processes in physiologic terms It is to be feared that much of the prevailing confusion is the result of such attempts None the less numerous studies in what is known as psychosomatic medicine have sought to explore the field between psychiatry and internal medicine

Obviously the practising physician is primarily interested in the medical aspects of the neuroses namely, their etiology symptomatology and treatment and is prone to lay emphasis on the organic or pathologic point of view So too is the neurologist whose primary emphasis is on structure and function But there are a number of psychologic, more particularly psychoanalytic concepts without which it is impossible to give any modern formulation of the psychoneuroses Before proceeding therefore and to avoid undue repetition it may be well to define a few general concepts particularly those relating to mental mechanisms or psychodynamics

Psychopathology postulates the existence of unconscious mental processes which motivate normal as well as abnormal behavior and are regarded as the source of neurotic symptoms That is there is a *dynamic unconscious* the repository of experiences dating back to infancy which may come into *conflict* with objective reality and within which conflict may on occasion arise. This unconscious with its ideas cravings and groups of ideas or complexes is conceived of as being charged with energy derived from primitive impulses The energy directly traceable to sex impulses psychoanalysis terms the *libido* It is the restlessness of this primitive emotion which makes the unconscious dynamic The theory of the libido is not quite so strictly adhered to now and has also been considerably expanded In addition to the unconscious there is assumed the existence of a *preconscious* or subliminal state which unconsciously motivated ideas must pass before they can reach *consciousness* Here we have a theoretic scheme of *mental topography*

By a *complex* is understood an unconscious group of ideas charged with various emotions The psychologic importance of complexes lies in the assumption that they influence conduct indirectly and therefore in inexplicable ways The two psychoanalytically best known and most disputed are the *castration complex* and the *Oedipus complex* The former is understood to represent an infantile phantasy about the loss of the phallus or the threat against it the latter embodies identification with the parent of the same sex and a hostile intent against that parent with the desire of displacing him or her in the affection of the parent of the opposite sex To prevent the emergence of incompatible unconscious ideas which are apt to engender conflict a higher force is assumed to exist, that is there is *resistance* The process of submerging unconscious ideas is known as *repression*

The primitive emotional energy is regarded as capable of investing various parts of the body and of being arrested as it were at various stages of infantile development The former is spoken of as *cathexis* and the latter as *fixation* The stages or loci at which the libido is arrested are known as *points of fixation* among which may be mentioned the oral anal and genital That which attaches to the ego is known as auto erotic or *narcissistic libido* But this energy can be shifted from the ego to objects and persons outside it the process of shifting from person to person is spoken of as *transference* The return of the libido to earlier points of fixation, the withdrawal in the unconscious to infantile modes of behavior to lower levels of adaptation is known as *regression* But emotions may be detached from objectionable ideas and attached to such as can pass conscious censorship , and we then get *displacement* of affect Occasionally repressed ideas are regarded as belonging to other persons that is they are *projected* This mechanism of shifting onto others fears and wishes belonging to oneself is more commonly observed in the psychoses Sometimes emotionally toned ideas or complexes are withdrawn into logic tight compartments within the unconscious and there results *dissociation* of incompatible or contradictory ideas Another mental process utilized by the unconscious for the purpose of giving plausibility to incongruous ideas is *rationalization* This has been defined by Hart as a process of self deception by means of adventitious reasons '

Dissociation of affect or of the energy of the libido its shifting to low somatic levels and its attachment to bodily organs so that it may give rise to signs and symptoms is known as *conversion* *Ambivalence* is the existence side by side within the unconscious of ideas surcharged with opposite emotional tones, for example, love and hate or regard and contempt Occasionally one observes what is termed as *compromise formation'* in which there is partial gratification of conflicting emotional impulses In many normal people and most labile neurotics there is the tendency of the mind toward *identification* with persons representing ideals such as parents and teachers Another mental mechanism is that of *reaction formation*, with which is generally associated that of *compensation* Herein is involved a process of *substitution* of one set of acceptable ideas or actions for the very opposite which actually characterize an individual Finally there is the process of *sublimation* which consists of the vicarious gratification of sex impulses by their substitution with or direction into asexual socially useful aims

Psychopathology puts considerable emphasis on the significance of *dreams* and phantasies or primitive wishes in the mental economy Psychoanalysis regards the dream as representing the fulfilment of an unconscious wish The surface story is spoken of as the *manifest content* the underlying psychic process is the *latent content* The latter requires interpretation which is always carried out by means of *free association* and sometimes by the use of symbols Characteristic of the dream is its tendency to the transformation of stimuli into visual images to the condensation or distortion of ideas and images to the displacement of emphasis and to dramatization Most important is the lack of logic temporal or moral consistency *Autistic thinking* is a neurotic sort of daydreaming

To round out the psychoanalytic structure there remains the mention of what are known as metapsychologic concepts Among these are the *pain pleasure principle* and the *reality principle* each respectively characterizing unconscious infantile thinking and adult conscious behavior Then there is the conception of the unconscious *id* the *ego* or real ego and the *superego* or ego ideal Finally, there is the division of *ego* or *self preservation instincts* from *sex* or *procreative instincts* and the postulation of a *death instinct*

Without attempting adequate explanations, the various concepts enumerated have been introduced in order to illustrate the language of psychopathology Among the fundamental psychoanalytic concepts must be included the theories of a dynamic unconscious of unconscious conflict, of repression transference and infantile sexuality Whether one accepts or rejects the various theoretic concepts a knowledge of them is imperative for the discussion of the neuroses from a psychopathologic point of view

Etiology—Underlying every theory of the neuroses is the assumption that there is an indefinable hereditary or constitutional factor which plays the ultimate role in their causation Naturally those who hold to the organic point of view put greater emphasis on the constitutional factor while those who adhere more strictly to psychopathology lay the major stress on development and environment conditions At the present time it is not known what is the precise relationship of heredity to the neuroses what is the ratio between inherent predisposition and environment, nor what is the exact mode of their interaction The most, therefore that can be said is that heredity is one important cause, but whether it be a neuropathic or psychopathic" constitution a degenerative' tendency psychosexual predisposition defective *anlage* or what not we are unable to state

The *pathologic theory of the neuroses* postulates the existence of molecular biochemical or physical alterations in the nervous system with consequent disturbance of function to account for the physical signs and mental symptoms These changes are assumed to be the result of exhaustion or fatigue of the nervous system Among the causes invoked may be mentioned intense fear or fright other emotional shock prolonged starvation, excessive masturbation trauma to the head alcoholism infectious diseases and various acute and chronic intoxications whether endogenous or exogenous While this theory may account for some few neuroses and the causative factors assumed may serve to initiate or precipitate

a few others they certainly cannot be held responsible for all

The *physiologic theory* seeks to account for the neuroses by the assumption that there is interference with the normal functions of the brain, that is they are the result of excessive stimulation or inhibition which interferes with the passage of impulses over synaptic junctions and gives rise to dissociation either at high psychic or low physiologic levels While there is no doubt some truth in this view and it leaves out of consideration some vital etiologic factors it involves a number of theoretic postulates among them inhibition which is not even definable The *behavioristic theory* is one phase of the psychologic concept of the neuroses and is merely a verbal formulation of the physiology of conditioned reflexes Behaviorism assumes the establishment of motor behavior patterns and their gradual integration from infancy onward and conceives of the neuroses or anomalies of behavior either as failures of integration or as results of disintegration Here again one may accept all the facts of conditioned reflexes yet be unable to build a comprehensive theory of the neuroses on a few profound observations

The *endocrine theory* seeks to correlate disturbances in the function of the glands of internal secretion with the mental and physical symptoms of the neuroses For this there is a great deal of anatomic physiologic pharmacologic and clinical evidence Some of signs and symptoms of mild hyper- and hypothyroidism adrenemia dyspituitarism and dysfunction of the gonads bear close resemblance to those of the neuroses Certainly the occurrence of neuroses in relation to puberty menstruation pregnancy and the menopause is significant of the influence of the endocrines on psychic life. Conversely many of the signs and symptoms commonly seen in pure psychoneuroses are also found as early manifestations of definite disease of the glands of internal secretion There is therefore undoubted etiologic relationship of some kind but it is impossible in the present state of knowledge to define that relationship The same may be said of the relationship of the *vegetative nervous system* Here too the anatomic and functional relation of the hypothalamic vegetative centers of the brain and the nervous manifestations of impairment of the parasympathetic and sympathetic systems argue strongly for the vegetative theory of the neuroses Furthermore the so-called "vaso vagal crises bear close resemblance to the paroxysms of anxiety hysteria For the present, however, one can do little more than speculate Psychosomatic investigations concern themselves particularly with this field

One of the most widely held views is that the neuroses are caused by *suggestion* By suggestion is understood the inculcation and ready acceptance, without proof of propositions which have no logical basis and are contrary to reason Whether this state of rapport be one of dissociation a prestige relationship a propensity to sympathetic identification or a libidinal process as psychoanalysis would have it, the fact is that most people are suggestible to varying degrees and that neurotic symptoms can be brought about as well as dispelled by means of suggestion Unfortunately we cannot precisely state what suggestion is and how it works and when we state that a person is hysteric because he is suggestible and suggestible because he is hysteric we are merely begging the whole question

The *social biologic theory* seeks to explain the neuroses in terms of the conflict which frequently results from the inability of certain individuals to adjust to the environment and the social group within which they live The struggle between the primitive impulses or instinctive drives of the individual and the equally insistent restraints of a complex social order may lead to flight from reality and an evasion of the demands of life This is particularly true when it comes to the powerful sex instinct which chafes under the restraint that ethics morality and legal and social codes have set up Times of social stress such as wars famines economic and other upheavals frequently result in crops of neuroses among individuals who cannot meet the severe tasks to which they are subjected So too inability to submit to authority or discipline to break parental attachments to adjust properly to love life, to submit to the rules of the marital state or to conform to religious rituals all may lead to conflict and to neurosis as an escape from the struggle

Psychoanalysis postulates the existence

of an innate psychosexual predisposition which, if it comes into conflict with the environment *during the developmental age* and later in life gives rise to neurotic reactions Accordingly three steps are regarded as essential predisposition, situation and conflict Furthermore, persistence of infantile trends and abnormal psychosexual development are the characteristics of the neurotic And it is true that in general the neurotic is sensitive, self centered given to phantasy attached to mother suggestible, emotionally unstable inadequate immature, and incapable of adjustment to sex and love life on an adult basis Frequently he is narcissistic and auto erotic his sex impulses are infantile fixed at levels to which he regresses when adjustment to life in the face of difficulties becomes impossible

The unconscious dynamics then of a neurosis are as follows *external conflict* because of difficulties in adjustment to adult love life, withdrawal into phantasy and *regression repression* as the answer to frustration *inner conflict* and symptom formation The neurosis is regarded as the result of failure of repression and inability to resolve inner conflicts Metapsychologically speaking *the neurotic is sick because the super* ego frustrates the wishes of the unconscious (the id) The symptoms are explained in terms of regression of the libido Then too there is dissociation of the affective mental currents within the unconscious Where there is regression to infantile sexual patterns but no repression or inner conflict, the result is not a neurosis but a *perversion*

To sum up we have the pathologic theory of the neuroses the physiologic the endocrinologic vegetative physiologic behavioristic dissociation or suggestion social-biologic and psychoanalytic In the first, emphasis is put on organic changes in the next four on disturbance of organic functions in the last three on pure psychologic *mechanisms* An hereditary constitutional predisposition is assumed in all theories except possibly the behavioristic with this distinction, that psychoanalysis refers to an innate psychosexual predisposition The latter *alone assumes* the existence of a dynamic unconscious as the seat of conflict of infantile impulses

Classification of the neuroses obviously is important not only from the point of view of diagnosis but from that of prognosis and *treatment* However, owing to the multiplicity and complexity of clinical and theoretic views it is difficult to make one general classification Actually it matters comparatively little what classification one adopts, although here I shall follow the freudian, provided one maintains a fairly consistent point of view But even so, it is well to bear in mind that clinically one does not often meet with sharply circumscribed entities that more often one encounters syndromes which partake of various nosologic groupings that anxiety as a symptom colors most of the neuroses and that borderline and transition cases not only between the neuroses but between them and the psychoses, are quite common

The Neuroses

(*A*) Actual or organ neuroses
- I Anxiety neurosis
- II Neurasthenia
- III Hypochondria
- IV Traumatic neurosis (?)

(*B*) Psychoneuroses regression or fixation neuroses
- I Transference neuroses
  - (*a*) Hysteria
    - 1 Conversion hysteria
    - 2 Anxiety hysteria (phobias)
  - (*b*) *Compulsion neurosis* (obsession)
- II Other regression neuroses
  - (*a*) Perversion
  - (*b*) Character types erotic obsessional narcissistic
  - (*c*) Neurotic types (nonpsychoanalytical concepts)
    - 1 Introvert, schizoid
    - 2 Extrovert, cycloid

(*C*) Mixed neuroses
(*D*) *Borderline cases*

It is assumed that there is no regression in the organ neuroses but that there is a specific trauma" an actual disturbance of physiologic function and a psychologic reaction to it *Anxiety neurosis* is conceived of as the direct result of sexual frustration Wherefore it is observed in adolescent virgins in young adults who indulge in erotic stimulation without coitus in frustration by fear of pregnancy, coitus interruptus or ejaculatio praecox or abrupt cessation of masturbation and in cases of unendurable continence The attack of unmotivated anxiety is characterized by fears of death insanity heart disease or some impending calamity and is accompanied by palpitation tremor faintness dyspnea, dizziness etc

Neurasthenia is restricted by many psychiatrists to a syndrome which is characterized by lack of mental and physical vigor Lack of potency or ejaculatio praecox chronicity hypochondriacal symptoms and general fatigability constitute practically the whole picture Generally the patient is narcissistic but anxiety is usually lacking Altogether it simulates incipient organic diseases The syndrome rarely occurs in women *Hypochondria* is characterized by fixed almost delusional preoccupation with symptoms referring to bodily organs Anxiety frequently accompanies the syndrome which most commonly occurs in women often at the menopause age *Traumatic neurosis* is an ego rather than a psychosexual neurosis following injury generally to the head and is characterized essentially by subjective complaints such as headache dizziness loss of memory lack of power of concentration frightening dreams and a host of others

In addition to conflict and regression the psychoneuroses manifest efforts at restitution somatic conversion signs and symptoms psychologically elaborated anxiety and *phobias* consisting of unconsciously detached anxiety projected upon persons or things *Compulsion neurosis* (also known as *psychasthenia*) represents a further stage of regression to unconscious homosexual levels and an intellectual elaboration of defenses against the fulfilment of tabooed impulses Anxiety generally is lacking unless the compulsion is not allowed expression or the obsession paralyzes activity It is narcissistic neurosis *Neurotic character* represents a problem in social adjustment The *constitutional psychopath* belongs to this group and illustrates the influence of heredity The *introvert* is the subjective individual who is preoccupied with his own phantasies the *schizoid* is an exaggerated unsociable introvert The *autistic* type is Bleuler's concept of the introvert The *extrovert* is the sociable group man who deals in externals The *syntonic* is the integrated individual and the *cycloid* the one who oscillates between elation and depression The *borderline cases* between the neuroses and psychoses represent those wherein the symptoms partake of the nature of both entities Thus a deep hypochondria may simulate a psychotic delusion a compulsion a schizophrenic state and a neurotic depression a manic-depressive psychosis The title *mixed neuroses* sufficiently describes the group

Perversions which show regression but no repression conflict or symptom formation, are not true psychoneuroses There are partial and complete innate and acquired tendencies to perversion *Masturbation* while not a perversion in itself may become so if practiced inveterately and as an end in itself Mild degrees of 'perversion' characterize normal sex life *Masochism* expresses itself in sexual enjoyment of suffering *sadism* in the sexual gratification by infliction of pain *Exhibitionism* consists of sexual gratification from exposure of the genitals *Fetishism* is the enjoyment of objects endowed with sexual meaning *Homosexuality* is the practice of the sexual act with persons of one s own sex Among other perverted relations may be mentioned intercrural oral and anal (*pederasty*) practised mainly by the male *cunnilinguism* and *fellatio* the former more common among males the latter among females *Bestiality* denotes the practice with animals *necrophilia* with dead bodies *Incest* is the relationship with blood relations There is something of the compulsion in the perversions They seem to increase among intellectuals and in cultured societies They are seen among mental defectives and the insane and are apt to crop out under the influence of alcohol

In summary it may be reemphasized that psychopathology permits of no rigid classification that mixed neuroses are fairly common that there is a constitutional factor a character make-up in all neuroses and that in every neurosis one may observe considerable evidence of normal character and attempts at adjustment in addition to various psychopathologic phenomena Finally, to avoid giving an erroneous impression it may be stated that the possession of a mild neurosis or neurotic character or even an outspoken neurosis is not necessarily incompatible with social adjustment or even great usefulness Numerous artists and scientists and a host of others who have contributed to progress have suffered from inner conflict and been highly neurotic Nonetheless the psychoneuroses present a very difficult problem perhaps more important socially than that presented by the psychoses

Symptomatology—*Anxiety* is the most common symptom of the neuroses It constitutes the whole syndrome of anxiety neurosis, completely colors anxiety hysteria is the outstanding feature in phobias is frequent in hypochondria sometimes intense in melancholia and other depressive psychoses and may be seen in compulsions or obsessions Despite the apparent absence of motivation and the ridiculousness of the fear, the patient is helpless before his vague anxiety or the fear of death disaster, heart failure, insanity cancer, apoplexy, and so forth The anxiety may arise spontaneously by day or wake the patient out of sleep The *heart generally beats violently* there is a choking sensation in the throat breathing is rapid there is trembling faintness and a *feeling of impending dissolution or insanity* The patient appears anxious perspires, feels his body and limbs numb and he may be nauseated and have the desire to urinate or defecate After a shorter or longer period, with or without medical assistance the attack gradually tapers off *Hysteric anxiety* is apt to be more intense and accompanied by conversion phenomena (*q v*), also there is *more psychic* elaboration Insomnia and false vertigo frequently coexist *Pavor nocturnus* represents an hysteric anxiety attack and so does the *nightmare*

Phobias are specific hysteric fears with definite ideational contents The phobia is supposed to represent an unconscious wish an emotion dissociated from a tabooed impulse and attached to a harmless idea It differs from a compulsion in that the latter is supposed to be a ceremonial designed as a defense against sex transgression However it is sometimes difficult to differentiate clinically between an obsession and a phobia Fear of snakes, mice, thunder lightning darkness and so on, represents specific phobias *Agoraphobia* signifies fear of open places, crossing streets and squares *Claustrophobia* is fear of closed places such as churches theaters subways or elevators *Mysophobia* is fear of dirt or contamination *Anthropophobia* is fear of men *erythrophobia* of blushing *zoophobia* of animals *pyrophobia* of fire, *phobophobia* of being afraid, *syphilophobia* of venereal disease

The *symptoms of neurasthenia* consist essentially of abnormal fatigability and exaggerated irritability The neurasthenic gets up tired in the morning, complains of muscular weakness, is irritated by noises cannot concentrate, complains of memory defect, and is preoccupied with physical ailments He has pressure on top of the head pain in the spine, dizziness, weakness of the eyes (*asthenopia*) and tiredness on effort *Orthostatic tachycardia* so-called *'neurocirculatory asthenia'* and *neurasthenia cordis* may be part of neurasthenia or hysteria Gastric atony and enteroptosis are not uncommon Most important, however, are the sexual disturbances Aside from chronic masturbation there are nocturnal emissions, spermatorrhea, futile erections ejaculatio praecox or complete impotence and, withal increased sexual desire *Wherefore the neurasthenic is gullible* as to treatment and frequently a victim of quacks

Hypochondria is a symptom which occurs *in mild form in the neuroses and in exaggerated form* in the psychoses It is a more or less delusional preoccupation with symptoms *referring to bodily organs particularly* the nose, mouth and tongue anus and genitals There is as a rule little insight into the symptom and it *yields practically not* at all to medication or other therapy Hypochondria is most common in middle age and in women at the menopause It may persist unchanged for years or be the forerunner of schizophrenia Anxiety occasionally accompanies it

Compulsion neurosis of which the compulsion is the active urge to do things and the obsession the ideational counterpart consists of impulses which seem like intellectual foreign bodies They appear meaningless and purposeless and occur in certain types of individuals The compulsion may set in early in life or occur at any age, following apparently trivial incidents Both the compulsion and the obsession which neither logic nor reason can cope with persist despite every effort to dislodge them The obsession may consist of the thought or wish to hurt oneself or others to jump off heights to blaspheme to doubt—*folie de doute*—to repeat numbers or count windows, to think that the nose ears or hands are growing large to fear contamination and to repeat words or phrases

The compulsion to act frequently takes

on the form of simple or complex ceremonious rituals In order not to soil himself the compulsive neurotic may repeatedly wash his hands to overcome doubts he will shut doors windows or gas jets to see if his nose is large look at every mirror, to prevent a calamity write down names walk along the curb touch things or count on his fingers It seems as if he does all these things to defend himself, to build a citadel around himself to prevent the expression of tabooed cravings, and to escape anxiety This *repetition compulsion* this making of rituals may manifest itself in extreme orderliness in arranging clothes, pillows chairs and other objects by day or on going to bed in attending to business eating drinking walking receiving guests, answering letters or telephone calls or making love The compulsive act takes on the form and force of a religious ritual or ceremonial The compulsion to steal is known as *kleptomania* to take drugs *toxicomania* to drink periodically *dipsomania* to start incendiary fires *pyromania* to pull out hairs *trichotillomania* The compulsion or obsession may be so severe as to paralyze all thinking and action yet it may disappear and reappear as inexplicably as it originally set in Generally it persists most stubbornly

The *signs* and *symptoms of hysteria* are numerous protean and kaleidoscopic They can simulate practically every organic affection While *monosymptomatic hysteria* is not rare, there are as a rule a number of varied manifestations important among which are mood character and personality changes anxiety states subjective sensations and objective somatic signs Hysteria may appear at any age but generally sets in early in life not infrequently in childhood It is rather more common in women The *hysteric personality* is infantile The individual *is* hypersensitive self-centered narcissistic moody impulsive somewhat histrionic and generally deficient in emotional control He is anxious fearful affectionate and resentful by turns exaggerates complaints loves to indulge in phantasy and is highly suggestible The male may be ardent though impotent the female passionate yet suffer from *vaginismus* or even be frigid and have disgust for the sexual act *Pseudologia phantastica* a certain childish make believe or even outright lying are not at all uncommon Psychologically speaking the hysteric reaction represents flight from reality and every hysteric is a sick person who suffers a great deal

Among the sensory symptoms *hysteric pains* of every variety and severity are very common So are hysteric *headaches* of which *clavus* the boring type is somewhat characteristic Special mention should be made of spinal pains and rigidity, particularly *coccygodynia* of breast pains or *mastodynia* and of abdominal and other pains simulating visceral diseases There are subjective surface pains or *dysesthesias* objective *paresthesias* and localized hyperesthesias which formerly used to be known as *hysterogenic zones* A very stubborn dysesthesia of the tongue—*glossodynia*—is frequently accompanied by fear of cancer itching about the vulva is not uncommon as a paresthesia *Acroparesthesia* consists of numbness and tingling of the distal portion of the limbs and is especially common in middle-aged women *Hysteric anesthesias* are generally the result of suggestion They follow no anatomic neural distribution but affect a functional part—half of the body and face including the mucous membranes limbs and parts of limbs—and include every form of sensation even the special senses

Hysteric anosmia includes the loss of sense of smell and the perception of irritative substances Among the visual disturbances are unilateral and more rarely bilateral *amaurosis* suddenly following emotional shock and lasting for hours days or months *Dyschromatopsia* or perversion of color sense is rare Hysteric amaurosis is fairly easily detected *Photophobia* and *blepharospasm* are not rare while hysteric *myopia* is less common *Micropsia* and *macropsia* may be hysteric symptoms and *monocular diplopia* is practically invariably hysteric in nature

Hysteric paralyses while not as common as formerly are still rather frequent The paralysis *involves functional parts and not* groups of muscles innervated by special nerves Reflexes are present and atrophy is generally absent, though contractions and vasomotor changes may appear later The hysteric hemiplegia is apt to be flaccid the

leg being dragged rather than circumducted The *important feature of hysteric paralyses* is the apparent indifference of the patient and the lack of effort to *move the part* *Glossolabial spasms* and hysteric *pseudoptosis* may coexist Hysteric *astasia-abasia* is *the inability to stand* or walk despite normal power of the legs on lying down The fear to walk may amount to a phobia Urinary *retention* may go along with hysteric leg palsies, also pseudoclonus *Pollakiuria* is a rather common hysteric symptom Hysteric *aphonia* is the most common psychogenic *palsy* The vocal cord is found paralyzed and the voice is very hoarse Hysteric *mutism* is much rarer and should be distinguished from negativism *Stammering* is rather common *Hysteric contractions* set in very late and may manifest themselves as flexion of the fingers or fixation at larger joints, as torticollis, scoliosis and so on They generally disappear under anesthesia

While *hyperkinesias* are coming to be regarded more and more as organic in origin there are *hysteric tremors spasms* and *tics* There is no such entity as hysteric chorea it is either the one or the other *Torticollis* is not rare but in every case dystonia should be ruled out Some of these movements are compulsive rather than hysteric in nature *Hiccup belching aerophagy* are fairly common hysteric symptoms *Globus hystericus* lump in the throat, is typical and *esophagospasm* not rare *Hysteric anorexia* is very common, *vomiting* fairly so and *bulimia* or gorging least so Hysteric borborygmi are sometimes encountered but *meteorism* is rare extremely rarely the latter takes the form of *pseudocyesis* Psychogenic *constipation* is extremely common *diarrhea* and *mucous colitis* occur spasmodically following emotional trauma The colitis can become a very stubborn affair *Oliguria* and *anuria* are never hysteric hence the need for detecting deception The same may be said of *hysteric fever* though it has been reported

Hysterics may mutilate themselves though not so commonly as malingerers and psychotics Fanatics sometimes do in religious frenzies *Dermographia* and *ecchymosis* are more common among hysterics Vasomotor disturbances such as blushing and redness are occasionally encountered while cyanosis and edema may be seen late in hysterically paralyzed limbs Mention may be made of *urticaria factitia* Vaginal *pruritus* may occur in response to masturbatory phantasies Rectal pruritus is not rare When the former occurs in middle aged women it is well to rule out diabetes or some local condition

Hysteric convulsions are quite rare, but rather typical when they occur Generally after a prodromal period of *excitability* anxiety and globus hystericus the patient suddenly goes off into a convulsion or falls without hurting himself There may be no warning at all The body is rigid frequently arched backward the hands are closed the jaws tightened, the legs extended While the convulsion is tonic the patient holds his breath and gets blue in the face The tongue is not bitten but the lips may be Nor is there incontinence though there may be purposeful urination There may be grimacing laughing, crying, howling barking, thrashing about or snapping and biting What is known as the *attitude passionnelle* represents an ecstatic coitus exhibition The attack may last a few minutes or pass over into status hystericus All the while the pupils react to light, though the patient may resist opening the eyelids and there is no true coma Never as in genuine convulsions is there a fixed or non reacting pupil a Babinski sign or posttraumatic headache and somnolence A sharp stimulus can put a stop to the convulsion Hysteric epilepsy is a definite misnomer

Occasionally one observes profound alteration of character amounting to complete splitting or *dissociation of personality* These states can be brought about in hypnosis but may occur spontaneously The simplest are the *automatisms* during which the patient carries out coordinated acts of which he is totally unaware in his normal state They may be seen after hysteric fits *Automatic writing* belongs in this group The hand seems to move spontaneously and to record lost memories or imaginary conversations Hysteric and other mediums indulge in this during seances Then there are the *amnesias* wherein the events of brief or long periods are totally forgotten The simplest is the *lacunar* or *circumscribed* form *Anterograde amnesia* denotes loss of memory after

the onset of the illness and *retrograde amnesia* the loss up to it These are not to be confused with true *amnesic aphasia* which is an organic brain condition *Tropic amnesia* or *coast memory* occurring among the whites on the West Coast of Africa, may possibly be hysteric in origin

Hysteric catalepsy manifests itself as a psychogenic fit The patient is speechless motionless rigid and the limbs are in the condition known as flexibilitas cerea Sensation is lost except for the corneal This state must be distinguished from catatonic rigidity Hysteric *lethargy* or *trance* is also known as *narcolepsy* It is like a profound hypnotic state The muscles are however relaxed and the patient may swallow food Indian fakirs and *mediums* can spontaneously go into these lethargic states The condition may simulate death though there is hardly danger of burial alive True narcolepsy is an organic condition occurring either idiopathically following encephalitis or in the course of tumors of the brain especially in the region of the third ventricle

Somnambulism is a brief hysteric dissociated state generally occurring at night during which the patient carries out automatic acts without being aware either at the time or on awakening The individual may unwittingly hurt himself during these nocturnal episodes The same state can be induced hypnotically *Hysteric fugues* are ambulatory automatisms lasting days or weeks and represent daydreaming adventures The patient may take long trips or carry out apparently responsible activities of which he is utterly unaware at the cessation of the fugue *Dual* or *alternating personality* is a hysteric splitting of character of long duration There is a complete change of personality with different states of consciousness The individual may assume a new name carry on an occupation wholly different from the one he left behind and after a long period suddenly awake to wonder what he is doing in his new environment Or the individual may find himself in a blank state not knowing his name or who he is We have thus a primary and secondary personality each unaware of the other that is there is *reciprocal amnesia* *Hypnagogic hallucinations* consist of momentary flashes of scenes or events occurring in the twilight states before falling asleep These may occur in normal as well as in hysteric individuals While it is doubtful whether there are hysteric psychoses there is hysteric depression The *Ganser syndrome* is regarded as a hysteric twilight state, occurring in prisoners and is characterized by dulness confusion and indifference to surroundings

Psychic impotence refers to the male *frigidity* to the female There are varying degrees of impotence, depending normally on time place and person Whereas impotence precludes coitus, frigidity does not Frigidity is not synonymous with psychic impotence, as the former implies either absolute lack of desire or actual aversion Both impotence and frigidity may occur in hysteria Neurasthenics and other chronic masturbators may suffer from ejaculatio praecox or complete impotence Frigidity is seen in conscious and unconscious female homosexuals Psychic impotence occurs in depressions Schizophrenics frequently are impotent or frigid Perversions may be caused by or result in impotence Psychic impotence with normal facultas coeundi but no orgasm is common in the female but extremely rare in the male

Occupation neuroses manifest themselves in inability to perform skilled acts learned by use despite absence of signs of involvement of the nerves or muscles supplying the parts They simulate apraxias without brain disease Thus a person may be unable to write though he can use his fingers to play the flute though he can pucker his lips whistle and so on to play the piano or typewrite though his fingers are otherwise skilful These conditions are generally regarded as hysteric in nature and indeed one frequently observes other phenomena which confirm the diagnosis But it is well to rule out apraxia incipient dystonia and other organic diseases of the nervous system Occupation neuroses are seen in typists telegraphers bookkeepers seamstresses watchmakers tailors blacksmiths and in piano violin and flute players always affecting the muscles most used in the particular occupation *Writer s cramp* is the most common occupation neurosis but before making the diagnosis one should always rule out an organic condition At first there is easy fatigability then difficulty in writing finally

total inability, requiring the training of the left hand or the substitution of typewriting It is a particularly stubborn condition sometimes necessitating change of occupation

War neurosis is the designation applied to a multitude of neurotic conditions observed in soldiers during the World War Other terms were *shell shock fright neurosis concussion neurosis neurocirculatory asthenia* None of these terms does more than superficially describe conditions which actually cannot be dignified as special nosologic entities Some of them like shell shock are misnomers At best they describe symptoms Many of the manifestations appeared in soldiers who were in camps behind the front, or received no injury at all even while engaged in combat On the other hand some followed temporary burial alive or occurred in close proximity to violent explosions The majority however were true hysteric manifestations Among the physical conversion signs may be mentioned paralyses astasia abasias and other gait anomalies stammering aphonias blindness deafness tremors palpitation sweating and anesthesias Among the mental symptoms were intense anxieties *fears phobias and terrifying dreams or nightmares* Essentially these signs and symptoms did not differ from those seen in civil practice Most of them were the result of auto or heterosuggestion in response to a desire to escape from a frightful experience They were unconscious defense reactions to immediate threats to life They were not conscious purposive flights from combat where they were the condition was that of malingering Evidently the threat was not to the sex but to the *ego instincts* Hence war neurosis may better be described as an ego neurosis But the mental mechanisms were the same inability to adjust to a situation *external conflict regression* repression inner conflict defense symptom formation flight from reality and escape from danger

Traumatic hysteria and *traumatic neurosis* are applied interchangeably to a group of symptoms following trauma Actually I believe they represent two psychologically and clinically distinct syndromes though their manifestations are almost identical Following some trifling or more serious trauma, often to the head in which there may or may not be a brief period of unconsciousness the patient develops a series of minor or major incapacitating signs and symptoms Sometimes these follow immediately after the accident at others there is an 'incubation period' of variable duration in which the individual is well and possibly able to return to work The actual symptoms, most of which are subjective and difficult to evaluate, are many and varied The most important and most persistent are *headache* and *dizziness* In addition there may be anxiety, depression irritability, general lack of vigor inability to concentrate impairment of memory noises in the ears and head faintness or fear of fainting feeling of numbness and various pains and aches Also there may be tremors, sweating palpitation, dyspnea flushing and possibly attacks of syncope In the case of traumatic hysteria there may be gross signs, such as staggering other bizarre gaits stammering and various palsies or anesthesias The pulse may be rapid the reflexes hyperactive the blood pressure low Sometimes nightmares occur during which the traumatic experience is relived

The following criteria may serve to distinguish between traumatic hysteria and traumatic neurosis Both are unconsciously motivated where they are not and the person consciously and purposely utilizes the injury for personal gain he is a malingerer But traumatic hysteria develops in a person who has been previously neurotic and of hysteric make up The trauma precipitates a series of symptoms in a person who is predisposed What happens is that the individual unconsciously utilizes the injury as a refuge from personal conflicts The symptoms may occur after trifling injury and in the absence of litigation Where the question of compensation enters it need not be regarded as the major role though it may play an important part both in the traumatic hysteria and in the neurosis Where litigation and compensation are the sole motives we are once more dealing with malingering In traumatic neurosis the hysteric mechanisms are lacking It probably is a true neurosis more of the nature of an ego neurosis It is possible that there is actual brain injury though where this is of a more or less definite

nature the term "traumatic encephalopathy" or "concussion of the brain" is the more suitable term In traumatic neurosis which most often follows injury to the head the *individuals suffer from intense anxiety and* nightmares reproducing the accident and they are unable to return to their usual occupation The condition is much the more stubborn, resisting all forms of therapy

All cases of trauma are complicated by the suggestibility of most individuals by desire to escape drudgery and by incentives to litigation But if one excludes the malingerers there remains the small traumatic encephalopathy group which is obviously organic in nature the hysteria and the traumatic neurosis All are precipitated by the trauma The first is also caused and maintained by it The traumatic hysteria is not truly caused by the injury and is unconsciously maintained by personal *difficulties for which the* accident serves as a spark without which there might not have been a lighting up of the process In traumatic neurosis the injury may be held strictly accountable Litigation may play a role but it is not the decisive one in either case In both instances we are dealing with sick people So-called compensation neurosis which comes dangerously close to malingering is in the words of Foster Kennedy an anxiety state born of fear nursed by litigation kept alive by greed and terminated by a verdict

Diagnosis —The diagnosis of the neuroses requires thorough neurologic and general medical knowledge no less than sound *psychiatric insight* The absence of organic signs and symptoms does not always imply the existence of a neurosis and their presence does not necessarily exclude its possibility Certainly the present state of knowledge does not justify the diagnosis of any neurosis by exclusion alone As a general rule it may be stated that no diagnosis of hysteria anxiety states or compulsions and obsessions should be made without effort to discover some underlying psychogenic factors because *it not infrequently* happens that a tumor of the brain a latent carcinoma an obscure anemia mild hyperthyroidism or incipient tuberculosis fail to show definite organic signs and sometimes mask themselves under a group of symptoms which are commonly regarded as neurotic So too it is well to bear in mind that a neurotic can develop organic disease which may be overlooked It is important therefore not only to begin with a thorough physical *examination but to reexamine* the patient from time to time This does not, however justify indiscriminate "work up" of cases with all sorts of irrelevant tests Sound clinical judgment is very often superior to so called "laboratory facts" While there are no absolute diagnostic criteria, intense individual study of each case a good detailed history not too much emphasis on isolated signs and symptoms proper evaluation of the whole clinical picture and understanding of the mental reactions and the social setting will serve as the best general guides Finally as most neuroses trace back to adolescence one should make with caution such a diagnosis in a person past forty who *has been well previously*

The diagnosis of the neuroses involves the differentiation of psychogenic from organic diseases of one neurosis from another of neuroses from borderline psychoses and of neuroses from malingering

Angina pectoris and other cardiovascular disease may be mistaken for anxiety neurosis or anxiety hysteria But while cardiac conditions are frequently accompanied by anxiety there is pain on exertion the distress is generally precordial the dyspnea genuine and the gastric distress peculiar and there are blood pressure variations electrocardiographic evidence and other definitely organic signs In the anxiety states on the other hand there are no heart signs other than the palpitation one may elicit a history of coitus interruptus fear of pregnancy other sexual frustration or conflict over masturbation the patient generally is young there may be a precipitating psychic factor and a history of previous attacks with remissions is not uncommon When a syndrome of so called "neurasthenia" appears in an adult or middle aged person who gives no antecedent history the following organic conditions should be ruled out

Cerebral arteriosclerosis is characterized in addition to mental symptoms by focal signs of brain damage retinal arteriosclerosis some hypertension cardiac enlargement and renal damage and definite memory impairment with character alteration In *Ad*

dison's disease there is marked hypotension severe asthenia loss of weight diarrhea, and bronzing of the skin and mucous membranes *General paresis* is a psychosis with special physical signs the Argyll Robertson pupil or other pupillary anomalies the speech disturbances, tremor of the lips the true psychotic manifestations and the positive blood and spinal fluid reactions are absolutely pathognomonic *Tumors of the brain* will ultimately be signalized by the typical headache, vertigo and vomiting by focal signs and symptoms, and by choked disk *Pernicious anemia* and *pulmonary tuberculosis need only to be mentioned* the blood picture and the x ray are sufficiently conclusive *Tuberculous spondylitis* and *cancer of the spine* however may lead to an erroneous diagnosis In the former the x ray is diagnostic in the latter time alone and clinical judgment decide *Multiple sclerosis* also occurs in the young and is characterized by remissions but the nystagmus Babinski sign absent abdominal reflexes tremors ataxia speech disturbances and other signs of *dissemination serve as diagnostic aids* With regard to the endocrinopathies it is well to bear in mind dyspituitarism adrenal, gonadal and thyroid insufficiency and hyperthyroidism Rapid pulse loss of weight ocular signs sweating and especially increase of basal metabolic rate should rule out incipient *Graves disease Acroparesthesia* occurs in women at the menopause age

There are so many conditions which give rise to *headache* that it is quite impossible to enumerate *them here Suffice it to say* that all efforts should be made to rule out organic disease, that *migraine* deserves special mention and that the psychogenic headache is more of a pain in the head or scalp It has already been stated that hystero epilepsy is not a true entity In any case, the true *convulsive state* whether petit or grand mal is characterized by absolute unconsciousness and the convulsion by falling with injury, tongue biting incontinence, *fixed* pupils and by subsequent headache and somnolence *Postepileptic confusional states* differ from hysteric *fugues* in their briefness suddenness violence sometimes *furor* absolute *amnesia and a history* of convulsions *Hysteric syncope* occurs in neurotic individuals after psychic trauma the unconsciousness is not very deep and the attack is brief

While there is no doubt of the existence of hysteric *dyskinesias especially tremors* spasms and tics, although the latter is more apt to be compulsive in nature, the burden of proof is on him who makes the diagnosis Organic dyskinesias may occur in the absence of all other signs It is doubtful whether myoclonus ever is hysteric in nature, certainly chorea, athetosis and dystonia never are Torticollis may be either In all *occupation neuroses* it is important to rule out neuritis, apraxia, tabes, syringomyelia *and dystonia Obviously, local* atrophies, sensory loss fibrillations and loss or increase of deep reflexes point to organic brain or cord disease *Hysteric vomiting* and *anorexia nervosa* may lead to diagnostic errors The history the comparative absence of loss of weight, the negative x ray and other findings and the general picture speak for the psychogenic disturbance Pituitary cachexia *Simmonds disease,* should be borne in mind

The *diagnosis of one neurosis from an other* is of importance as a guide *to treat*ment but, aside from the difficulties arising from lack of consistency as to classification the infrequency of pure' syndromes makes absolute differentiation rather difficult If the freudian view of *anxiety neurosis* is correct it should be limited to cases which are the result of psychosexual trauma such as coitus interruptus ejaculatio praecox forced abstinence dread of pregnancy conflict over masturbation and other sex frustrations In *anxiety hysteria there is greater* psychic elaboration the conflict is deeper unconscious conversion hysteric symptoms co exist and surface explanations do not help as in the neurosis Accepting *the freudian* concept the diagnosis of *neurasthenia* should be restricted to patients who suffer from loss of energy physical and mental fatigability pain in the back or *the head* and ejaculatio praecox or impotence all this whether there is a history of chronic masturbation (which there usually is) or not

The difference between a *phobia* and an *obsession* lies in this that the former is always characterized by the intense anxiety the latter by none or very little that the first is specifically emotional the second compulsively intellectual that the one is a

hysteric reaction masking an unconscious wish the other a ritual of defense, that the hysteric is a disorganized personality the compulsive often a superior intellectual with fixed traits that the phobia is more amenable to suggestion and other treatment than the obsession or compulsion However it may on occasion be very difficult to differentiate between them and the two may coexist The criteria for diagnosis of war neuroses and traumatic hysteria and neurosis have already been given under symptomatology The first and last are really ego neuroses and not psychoneuroses

The following clinical and psychologic criteria will serve to differentiate a severe *neurosis* from a mild *psychosis* The neurotic however sick he may be realizes the fact suffers from his symptoms makes effort to get well and keeps in touch with his environment Generally he is not antisocial The psychotic does not realize that he is sick hence sees no reason for seeking medical aid he has no insight into his condition has broken with his environment and become antisocial The delusions and hallucinations are very real to him and he projects onto others conflicts which rage within Thus for instance *competitive jealousy* is a properly motivated reaction to the threatened loss of a love object *projected jealousy* such as the false accusation of infidelity is a phantasy reaction to a possible situation *paranoid jealousy* directed to members of the same sex probably is a defense against unconscious homosexuality *Transient depressions* may occur in the neuroses, profound depression or melancholia with suicidal ideas only in the psychoses *Motivated depression* is an in between reaction

Schizophrenia or *dementia praecox* is progressively characterized by a shut in unsocial personality by overattachment and latent hostility to parents by ideas of reference and suspicions by delusions that the patient is watched plotted against persecuted or being poisoned by auditory hallucinations by negativism mannerisms catatonias or even stupor and by emotional poverty which indicates a splitting (whence the name schizophrenia) between the intellectual content and its appropriate emotional overtone The schizoid individual is really a *forme fruste* of the preceding but not necessarily psychotic The *hypochondriac symptom* is always delusional, but depending on its intensity and complexity and the degree of dominance over the individual it may occur either in the neuroses or the psychoses The *obsession* or *compulsion* may be so paralyzing as to appear delusional but in essence it is not, seeing that the patient has comparatively good insight into his general condition and realizes that he is sick

Malingering or *feigning* is more common with regard to psychoses The malingerer to evade responsibility, escape punishment or acquire gain simulates or exaggerates symptoms or diseases There is conscious purposive effort to deceive by means of imposture The malingerer alleges loss of memory deafness blindness or mutism and complains of subjective symptoms which cannot be evaluated He may simulate paralyses tremors or fits Generally he overdoes his stunts especially when he knows he is being observed The diagnosis of malingering is not always easy hence special tests or even tricks are utilized for purposes of detection Obviously the malingerer cannot feign true organic signs nor is he as a rule so well informed as to simulate consistently neurologic and psychiatric conditions

Course and Prognosis —These vary with the type of the neurosis and its duration with the environmental circumstances and the skill of the therapist The course is episodic and frequently characterized by remissions The prognosis is better in young persons than in old and confirmed neurotics in the flexible emotional type than in the rigid shut in personality *Anxiety neurosis* has a comparatively good prognosis provided the cause can be favorably influenced *Neurasthenia* is a stubborn condition difficult to cure in the young and almost impossible of resolution in confirmed masturbators who are impotent *Hypochondriac symptoms* are most refractory and persistent they occasionally subside spontaneously and more rarely pass over into true delusions

The prognosis in *hysteria* is most variable Anxiety symptoms and conversion signs are frequently cured Phobias are very stubborn Much depends on the skill of management Hysterias in children offer the best prognosis Generally speaking once a hysteric

always a hysteric, but remissions are very common and adjustment usually possible Compulsions and obsessions are extremely refractory to treatment Remissions are not uncommon The narcissistic neurosis generally begins early in childhood though it may be overlooked and often persists throughout a whole lifetime Sometimes the condition merges into a psychosis Complete cures are extremely rare but amelioration of symptoms is quite common Occupation neuroses have a more or less favorable prognosis The outlook in writer s cramp is not so good Very frequently the patient is compelled to give up his occupation Tics and spasms are not easily or favorably influenced even if they are psychogenic in nature Torticollis is a particularly stubborn affection

Treatment —The treatment of the neuroses requires in addition to knowledge and experience much tact and understanding and considerable self assurance Although psychoanalytic insight is invaluable and the method useful in selected cases there are a great many therapeutic measures which can be successfully employed The fact is that most neuroses are amenable to treatment certainly all of them can be managed intelligently even if a good many cannot be cured The most difficult to manage are old and confirmed neurotics unimpressionable and intensely narcissistic individuals and patients whose neuroses are rooted in insuperable social economic or familial situations Even so provided one can win the confidence of the patient much may be done to help him to understand the problem and to get him to adjust himself in some measure

Most neurotics are highly sensitive, wherefore it is necessary to make good contact on the first examination The most important thing to do is to get a detailed medical social and psychosexual history and follow it up with a thorough physical examination The first is for the purpose of gaining insight into the patient s condition and the second to eliminate the possibility of organic disease as well as to convince him that his complaints are taken seriously Both will beget confidence One must avoid the error of telling a patient that he imagines' he is sick or that the whole thing is mental and there is nothing the matter with him Neurotics resent the first and misinterpret the second In any case, a neurosis is just as much a sickness as any other disease and causes a good deal more suffering besides

If no evidence of organic disease is found the patient may be reassured on that point, but he must be promptly told that nervousness' is a medical condition which requires treatment like any other One may explain however, that psychic shock, such as fright worry and anxiety, or social conflict and sexual difficulties, can cause all sorts of subjective symptoms and objective signs Should some organic disease be discovered it is obviously necessary to treat it but one should be careful not to overemphasize the organic condition in a neurotic lest he cling to that and refuse to face the more important problem of the neurosis

Medicinal treatment has some value but no specific virtues As a matter of fact most neurotics show their lack of faith in medication by asking not to be given drugs or "dope" In many cases the value of the prescription is in direct proportion to the amount of suggestion it embodies Even though neurotic insomnia does not readily respond in hypnotics it is frequently necessary to prescribe phenobarbital allonal, amytal or some other preparation For sedative purposes chloral and bromide are useful Narcotics should be avoided because of the danger of addiction A warm bath often acts as a sedative A mild laxative may be given to overcome constipation or simple dietary rules laid down but enemas should be advised against because neurotics tend to become enslaved to them and make a ritual of colonic irrigations

Extracts of the *glands of internal secretion* may be prescribed where evidence of endocrine dysfunction is present Not that present knowledge justifies the indiscriminate prescription of the extracts for the neuroses certainly no phobia or compulsion has thus far been cured by any of them but there are instances where thyroid or pituitary extract is of value or even the extract of suprarenals and the more recent one of the ovaries The last especially theelin may be useful in the so called menopause neuroses Experience justifies the statement that re

moval of foci of infection has no effect in the vast majority of the neuroses Obvious infections should be treated of course but, aside from the fact that the whole theory has been tremendously overemphasized indiscriminate extraction of teeth excision of tonsils and other heroic operations only do violence to patients and confirm their neuroses

Except in cases of so-called colitis or where the problems of specific anaphylaxis and possibly of avitaminosis come into question *diets* seem to play no etiologic or other role in the neuroses That neurotics will slavishly follow dietary rules evolve weird ones of their own and make rituals of meals is no reason for prescribing special diets unless one wishes to embody suggestion thereby Even so one many only succeed in perpetuating symptoms Unless therefore there are special contraindications it is best to avoid undue emphasis on any diet and advise simple nourishing easily digestible foodstuff possibly rich in vitamins

Rest is of some value in anemic emaciated patients but *rest cures* have little to recommend them Sojourn in a hospital at a health farm sanatorium or spa may have temporary worth essentially this lies in sound routine and the power of suggestion The last is the main ingredient in places of religious pilgrimage Nonetheless temporary removal from home is frequently advisable even though the patient takes his inner difficulties with him and must return to his environmental ones *Massage* and *hydrotherapy* are sometimes indicated for their physical as well as for their psychotherapeutic effects *Occupation therapy* is also of some value particularly if intelligently directed so as to serve a useful purpose

It has already become clear that *suggestive therapeutics* is what one consciously or unconsciously employs with greatest effect in most cases no matter what form the treatment actually takes Whether suggestion be regarded as a prestige phenomenon a so called libido transference reaction or a simple emotional identification rapport the fact remains that it will favorably affect many of the neuroses and definitely succeed in removing individual symptoms Suggestion is most effective in the hysterias especially the anxiety and conversion types and in anxiety neurosis It is less effective in phobias Compulsive neurotics respond least It may have some value in neurasthenia, but practically none at all in hypochondria Suggestion may be embodied in a word, a prescription a hypodermic injection electricity, or a pious ritual *Hypnosis* is merely a deeper form of the waking rapport of suggestion It is also a substitution neurosis almost an induced hysteria Not everybody is hypnotizable and few patients require hypnosis Given absolute self assurance hypnosis may be induced by restricting the field of conscious attention by means of a mirror a dim light a key or other small object stroking or monotonous verbal soothing Generally it is not necessary to proceed to very deep unconsciousness somnambulism or catatonia Like suggestion hypnotism removes symptoms but does not resolve conflicts It is especially valuable in monosymptomatic hysteria *Persuasion* consists of a conscious appeal to reason and to powerful sentiments In view of the fact that most neuroses are so emotionally toned so unreasonable it is difficult to see how an appeal to reason can be effective nonetheless an impressive therapeutist may try it and be successful in proportion to the amount of suggestion he will unwittingly convey *Reeducation* or *reconditioning* embodying behaviorist principles built around conditioned reflexes are also worth employing

Besides utilizing some of the above therapeutic principles anxiety neurosis can often be relieved by removing specific underlying factors Coitus interruptus should be interdicted undue sexual excitement avoided and dread of pregnancy met by contraceptive teaching Neurasthenics though difficult to manage may be treated with prostatic massage tonics and sedatives and kept out of the hands of quacks More difficult is it to get them to give up masturbation or to restore their potency Hypochondriac symptoms are extremely refractory and the best one can do is to give medication try suggestion and attempt some degree of adjustment to complaints Traumatic hysteria and traumatic neurosis are treated like other neuroses Psychic impotence is best influenced by suggestion and analysis Frigidity in women is a very stubborn condition hysteric anesthesia though refractory is much

less difficult to overcome Both impotence and frigidity are always the cause of marital unhappiness frequently of infidelity and sometimes of divorce Dissolution of marriage is justified where the husband knew of his impotence beforehand Interruption of pregnancy is sometimes indicated when an unwelcome conception precipitates or aggravates a severe neurosis or threatens the onset of a psychosis The same is true of hysteric pernicious vomiting of pregnancy

Psychoanalysis is most useful in the transference neuroses, namely, anxiety hysteria and conversion hysteria phobias and compulsion or obsession neuroses The first two respond best the third fairly well the last not so favorably This is not the place to discuss the theory of psychoanalysis or describe the therapeutic procedure Suffice it to say that in order to practise psychoanalysis one should be well trained in psychiatry and have acquired experience with the method itself A certain amount of judgment and flexibility will obviate the danger of becoming a slave to the method or to rigid technic To be properly analyzed the patient must be fairly intelligent and appreciate the expenditure of time and effort and money necessary for a complete analysis Psychoanalysis differs from all other psychotherapeutic methods in that the patient must learn to accept a new point of view of unconscious psychosexual dynamics It is a question of transference and resistance of dream analysis of neurotic identification with an attachment to the analyst of resolving this transference or substitution neurosis and of sublimation of symptoms and final adjustment of the individual

Obviously only few patients lend themselves to such time consuming treatment—it takes over a year to get results—and not all neuroses are subject to psychoanalytic therapy Nor is it always successful Both the patients and the types of the neuroses therefore require careful selection And while analysis in the hands of an ethical properly trained and intelligent analyst is never harmful it may be wasteful of time and money in unsuitable cases Only very rarely is there danger of precipitating a psychosis but here too a properly qualified analyst knows when to stop or when to begin As the method itself is by no means perfect and the theoretic implications are far from offering an ultimate understanding not to say a solution of the problems of the neuroses it follows that *not even all suitable* cases are cured by analysis In my opinion therefore, there is no good reason for keeping up an analysis for years If one sees no promising results within six months or hopes of a cure within a year, the analysis had better be terminated Not infrequently the method can be modified to suit individual cases Whatever the ultimate judgment on psychoanalysis may be, and particularly as to the efficacy of the method to bring about cures, there can be no doubt of the profound insight into the neuroses it has thus far vouchsafed Nor is there any doubt that many conditions which do not yield to other forms of therapy are resolved by psychoanalysis

VASOMOTOR AND TROPHIC DISORDERS

HEREDITARY TROPHEDEMA

This disease is manifested by chronic edema of one or both legs one or both arms or of the face It may affect but a part of an extremity The condition is hereditary often congenital and extremely

rare In ten years not one was admitted to Bellevue Hospital It affects women more frequently than men and appears in the decade after puberty

The cause is not known The characteristic symptom is a great swelling of the affected parts which either pit but slightly or not at all The skin is much thickened There is no pain or tenderness The discomfort results entirely from the deformity (swelling) This disease is often associated with spina bifida There are transitional forms of the disease which have the characteristics of both angioneurotic edema and trophedema The former condition may precede the latter which becomes its chronic persistent form.

Diagnosis is not difficult Complete or nearly complete absence of pitting upon pressure serves to differentiate the condition from cardiac or renal edema Progressive lipodystrophy is ruled out by absence of the characteristic distribution of fat and by the absence of lipomatous atrophy above the waist line

The prognosis is not favorable No treatment is of advantage The disease is incurable but does not cause death

W M Kraus

CAUSALGIA

Causalgia is a painful condition of the hands or feet which is due to irritation of a nerve by injury Associated with the pain which is characteristically burning in type are glossiness of the skin swelling redness trophic changes of the nails and sweating The slightest stimulus physical or mental, brings a paroxysm of pain The condition was fairly common during the World War I but is rarely seen in civil life

The underlying cause is a disorder of the sympathetic fibers of the injured nerve The disease affects the nerves of the arm in the following order of frequency median ulnar and radial those of the leg as follows internal popliteal external popliteal

Scars and foreign bodies about the nerves should be removed Operations with the object of dividing the sympathetic pain fibers to the affected part are of value in many cases

W M Kraus

ACROPARESTHESIA

Acroparesthesia is a subjective sensory disorder of the fingers which has been known for many years The patients feel tingling and have a sensation of pins and needles or formication in the fingertips The condition is seen not infrequently It occurs almost always in females at puberty or when a true or an artificial menopause occurs Various diseases of the spinal cord have also been found in acroparesthetic patients *e g* tabes dorsalis tumor syphilis multiple sclerosis and syringomyelia Acroparesthesia may be the first symptom of Raynaud s disease It is a disease of the involuntary nervous system which may be due to disease of its centers in the spinal cord or to more general conditions of endocrine origin The disorder is believed to be due to a vasoconstriction of the blood vessels of the distal nerves of the affected extremities Wartenberg attributes the paresthesia to postural compression of the brachial plexus

Symptoms —The condition which is almost always bilateral may begin slowly or suddenly Plunging the hands in icy water may be the immediate cause It is worse during the night and in the morning as a rule In some cases the skin looks blanched. Very slight hypesthesia may be found over the fingertips Pain is rare

The disease is *chronic* but disappears as a rule in later life It does not lead to death It is easily diagnosed either as a symptom or as a disease

The treatment in cases definitely associated with a disorder of the gonads in females should be treated by administering theelin Antuitrin S may also be tried General tonics such as arsenic and iron and faradization of the affected parts are of value in many cases

W M Kraus

MULTIPLE SUBCUTANEOUS GANGRENE

This is a condition closely allied to Raynaud s disease in which multiple areas of gangrene occur It develops in hysterical or neurotic individuals In some cases it is self-inflicted but in others it is definitely of organic origin If the skin is intact over the

subcutaneous gangrene self infliction of the condition can be ruled out

The disease usually occurs in women under forty Frequently a local trauma such as a burn or pricking by a needle has preceded it by months or years Pain and paresthesia often develop before the gangrene The affected areas are of various size and may be anywhere on the skin or mucous membranes They may coalesce The disease may recur frequently or become progressive, spreading widely It sometimes lasts for years but is not fatal The treatment of the organic type is unsatisfactory Psychotherapy should be tried in both the organic and self inflicted types of cases

W M Kraus

PROGRESSIVE FACIAL ATROPHY

This disorder is characterized by wasting of the fat of the face, usually unilateral This is associated with thinning of the skin and depigmentation or abnormal pigmentation The muscles and bones may also be affected The disease is extremely rare

Etiology —The cause is still obscure but is in all probability a disorder of the involuntary nervous fibers in the head region or of the central nervous system The distribution of the disease is certainly that of the sympathetic supply to the head region and not that of any cranial nerve

Symptoms —The disease usually begins before thirty It is found equally in both sexes It may begin about the orbit the cheek or the lower jaw The masticator and tongue muscles may be affected as well as those of the face This involvement does not interfere with muscle function, and there is no reaction of degeneration on electrical testing The eyelashes may fall out or become gray The pigment of the skin becomes either brown yellow or bluish or disappears Pain is often present The atrophy may remain limited to one half of the face but not always Further hemi atrophy of the same type affecting the entire body may occur It is often associated with disorders of the sympathetic system and is closely allied to scleroderma—indeed Cassirer regards it as a form of this disease

This disease may only involve the sub cutaneous fat, and thus resemble progressive lipodystrophy

Diagnosis —The diagnosis is not difficult in clearly defined cases When only pigmentary changes and cutaneous atrophy are present the condition is hard to differentiate from *scleroderma* Cases with loss of subcutaneous fat only are easily differentiated from *progressive lipodystrophy*

Prognosis —The disease as a rule is progressive for a considerable period after it is first observed It then reaches a standstill It does not cause death

Treatment —*There is no beneficial treatment* Removal of the superior cervical ganglion has been attempted

W M Kraus

FACIAL HEMIHYPERTROPHY

This is an extremely rare disorder in which there is unilateral hypertrophy of the skin muscles, and bones of the face This condition may form a part of a generalized hemihypertrophy Some of the cases are congenital others postnatal It is slowly progressive but finally comes to a standstill There is no treatment The diagnosis is best made by x ray of the skull

W M Kraus

PROGRESSIVE LIPODYSTROPHY

This is a disorder of the subcutaneous fat in which there is atrophy above the waist line and hypertrophy below it Relatively few cases have been reported Both men and women are affected The *cause* is unknown

Symptoms —There are no symptoms or signs except the disorder of fat distribution The face is involved as a rule Below the waist line there is accumulation of fat in large masses over the buttocks inguinal regions inner aspects of the knee and the lower legs Pitting is either slight or absent The disease begins usually in the second or third decade and progresses very slowly for a period of years It usually becomes arrested in adult life The condition is not fatal and appears to have no ill-effects

whatsoever One patient seen by the writer passed through a pregnancy quite normally

Diagnosis is not difficult The disease may be confused with the *trophedema of Meige* but the atrophy in the upper parts of the body and the fact that the changes are bilateral are diagnostic

Treatment —No treatment has served to alter the condition

W M KRAUS

MENTAL DISORDERS

(*The Psychoses*)

GENERAL CONSIDERATIONS

THE task of recognizing and characterizing appropriately the different types of psychotic reactions is inevitably complex Some of this complexity is due to uncertainty of knowledge and confusion of thought Since in general more definite knowledge leads to clarification and favors simplification many physicians who have a considerable ignorance about psychiatry may be complacently postponing the necessary study to the time when the complexities may thus be eliminated It seems improbable however, that any highly simplified scheme can be valid or useful because of the inherent complexities of personality functions

Some decades ago when the Kraepelinian nosology ruled it seems to have been generally presumed that the field of clinical psychiatry had been adequately surveyed and plotted into disease entities and that the remaining tasks were the discovery of the corresponding specific pathology and etiology and the development of therapy based thereon A certain measure of success of this type has been brilliantly achieved in two small sectors—in the fever treatment of general paresis and quite recently in the recognition and therapy of certain specific nutritional deficiencies associated with alcoholism Yet, as regards numerically larger groups of psychotic patients those presumptive specific etiologies have not been brought to light by histological biochemical physiological or psychological research It has remained the usual custom in textbooks however to repeat the same old nosologic scheme sometimes varied by substituting other terms—a custom which tends to obscure certain significant changes in psychiatric understanding and practice

The principal modern advances in psychiatric knowledge have been in the direction of a better appreciation of the nature of *integrated personal functioning* and the self induced difficulties involved therein There has been a comparable functional trend in internal medicine aimed at the elucidation of the functional interrelationships of organs and organ systems of tissues and body fluids as they are involved physiologically (*i.e* functionally) in the body s reactions and adjustments to noxious agencies injuries and deficiencies The signs and symptoms brought to light in complaint and by examination are not now viewed by the internist merely as clues to the selection of a diagnostic label they are also utilized as indicators of how the resources of the organism are being employed These findings serve therefore as guides in treatment There is a superficial resemblance to the empirical 'symptomatic treatment of a less enlightened period but the main difference lies in the physiologic strategy by which the clues obtained through clinical reconnaissance and special tests are utilized in care and treatment This functional understanding of disease symptom and treatment in internal medicine has been greatly advanced by the use of new biochemical and physiological technics

In a somewhat comparable way in psychiatry but by different technics there has been a gain in understanding the functioning of the person as a person and a gain in the utilization of such understanding in the strategy of treatment The principal advances have been won by intensive individual biographical case studies and especially by the close scrutiny of patients interpersonal attitudes as these become manifest and modified during study and treatment It is not merely in regard to psychotic patients that the study of interpersonal attitudes has been developed to yield significant facts and insights such attitude-investigation has also great importance for psychoneurotic or psychosomatic conditions and indeed in all phases of medical or surgical practice where the patient as a person has to be specially considered It is

typically through persistent or repetitive patterns of maladjustment in interpersonal relationships that one develops those 'intolerable situations" from which one then recoils into neurotic and psychotic reactions Inadequate or faulty modes of handling the problems of interpersonal relationship produce a large share of the tensions and anxieties which beset every patient in some degree, and in extreme cases seriously upset his physiology and complicate his treatment *Through the study and utilization of patients* interpersonal attitudes one is also able to find or to engender helpful incentives and inner psychotherapeutic resources

A knowledge of the usual course of personality development has special pertinence in the recognition and management of psychiatric conditions because many adult patients revert to, or may never have grown beyond the emotional development of infants, children or adolescents in regard to the manner in which they relate themselves to others and carry on their personal life Special terminologies for the formulation of such emotional fixations or regressions of attitude have been evolved, for example such psychoanalytic terms as narcissistic oral anal urethral phallic genital polymorphous perverse and so on for characterizing zones and stages of erotic interest Less technical sounding terms are probably more generally useful Almost any observer can readily learn to recognize an infantile attitude of expecting infinite service and infinite tolerance from others an attitude of childish irresponsibility and dependence, or an adolescent attitude expressed in gang spirit *hero worship* and 'crushes' a line' of wise cracks and other excesses in adventurous and exhibitionistic activities

In the detailed scrutiny and analysis of disordered personality functioning psychiatrists frequently speak of defense mechanisms or escape mechanisms referring thereby to a variety of unconscious or dimly conscious modes of self deception by which one gains a modicum of self esteem or favorable attention from others By exaggerated distress or by extreme penitence or by ostentatious scrupulosity one may gain in a dependent way from other persons a sort of commiserative favoritism or a mitigation of blame There may be little if any overt behavior in a given situation which an observer would consider blameworthy or in need of mitigation, but even then it is still possible for a person to feel within himself some guilt over suppressed grudges or reactivated resentments, and as a mode of dealing with such a sense of guilt one may resort to propitiatory penitence or distress which seems singularly inappropriate to the overt situation Inwardly censoring and inwardly exculpating reactions may confuse an observer's efforts at understanding Enlightenment may not be readily obtainable from the patient himself, for anyone in emotional situations tends automatically to forget or distort the memory of events having unpleasant implications—as exemplified in almost every traffic altercation In an objective appraisal many of these ego defense reactions seem purely incapacitating or even catastrophic as in suicide or in organ sacrifice via surgery From an adult point of view some of these ego defense mechanisms seem anything but biologically self-defensive They seem biologically futile and senseless Yet every person has lived for a time in a state of infantile and childish dependence when attention seeking and favor inducing behavior constituted his main technic for survival A persistence in or a reversion to such modes of behavior is biologically understandable particularly when one takes into account the social milieu and the possibilities of eliciting favoritism from the social milieu by such 'symptomatology'

Much has been said and written about the emotional determinants of personality disorder or mental illness in a way which may foster the misunderstanding that emotion is pathologic and pathogenic. Emotional experiences are part of normal personality functioning Anxiety and emotion even of a crude and disorganizing sort may serve a biologic function in stirring up reserve resources and forcing needed changes in attitude, and some degree of emotionality is apparently essential in the development and operation of all useful sentiments Unhealthy deviations in personality development arise through the *miscarriage* of emotional functioning *rather than* through emotion Indeed, one may say of all the items of behavior which are observed in

psychotic patients that they are not in themselves specially abnormal for they may also be observed in normal persons the particular psychotic abnormality lies characteristically in the inappropriateness of reaction to the actual situation and in the extraordinary persistence of the patient in maintaining these emotionally distorted misconstructions and *faulty evaluations of* the situation Under good psychiatric study and treatment such distortions will often be found to diminish as more satisfactory interpersonal attitudes are regained or developed

Constitutional and Temperamental Factors.—Constitutional factors are given prominence in the general discussion of psychiatric conditions usually with the implication of hereditary determination through chromosomes Certainly personality functions are strongly influenced by native endowment, but it is hard to say just how Human potentialities are seldom developed to the full whether for good or ill There is considerable evidence of a tendency toward much personality disorder in some families but the interrelated influences of hereditary, social and developmental mechanisms have not been elucidated The best chances for clarification seem to lie in the study of identical twins brought up separately Intellectual capacity, or its converse mental defect, appears in the main to be constitutionally determined Constitutional psychopathic personalities are recognized by one label or another in most clinics but the criteria for such diagnoses and the conceptions of such conditions are not generally agreed upon The diagnostic labels constitutional" or psychopathic form a scrapbasket for a number of types of long term (maybe life long) severe social maladjustments or personal inadequacies So called manic-depressive and schizophrenic psychoses have received a considerable amount of study from the standpoint of heredity but the evidence does not yield unequivocal conclusions A belief in constitutional determinism is a convenient balm to the frustrated therapist

The concepts of constitution and temperament have fostered much psychiatric interest in body build as one of the most obvious indices of individual differences The affective schizophrenic contrast in clinical pictures is paralleled in some measure by a statistical tendency toward *pyknic physique* in those patients with predominantly affective symptomatology and *dysplastic* or *leptosomic physique* in the schizophrenic patients This statistical correlation is of considerable theoretical interest but not sharp enough to have much diagnostic value

Temperament, like constitution, is a tricky term in psychiatric formulations The literature on this topic provides a big catalogue of epithets Endocrinology from which much was expected in the understanding of temperament has not fulfilled those high hopes but it has already brought some specific therapeutic aid in the control of menopausal symptoms and other endocrine disturbances which in certain instances are significant factors in personal maladjustment and even at times in psychotic reactions

As Bleuler has pointed out, it is possible to construct a very elegant conceptual scheme for the formulation of two large groups of psychotic conditions—the manic-depressive and schizophrenic types and certain related disorders—in terms of temperament. This classificatory scheme is based on the postulation of two reaction types the syntonic and the schizoid According to this theory one finds even among normal people a *syntonic* type in which all functions of the personality are characteristically integrated about a definite and relatively vivid affect suitable for the situation of the moment the emotional tone of an experience bringing thought speech gesture autonomic functions and other expressions of the personality into conformity therewith Manic depressive psychosis and chronic depressive and manic moods appear as exaggerations of this normal syntonic reaction type In another group of normal persons those of the *schizoid* reaction type there is a lack of uniformity in the expressions of the personality about a definite affect different and even contrasting strivings coexist Schizophrenic manifestations are interpreted as exaggerations or caricatures of this schizoid type These hypothetical parallelisms between syntonic temperament and manic depressive disorder and between schizoid temperament and schizophrenic disorder

may be employed even in the interpretation of personality disorders resulting from cerebral injuries or intoxications, in which the temperament still shows its influence Bleuler has also assumed that every man has a syntonic and a schizoid component of certain relative strengths determined by heredity Thus one can analyze mixed clinical pictures, and work out discriminating individual prognoses

Clinical Application —Even though one refrains from a rigid faith in constitutional or temperamental determinism clinical experience enforces the recognition that individual persons do show very durable dispositions toward a certain form of reaction The term *personality trend* serves to crystallize in a practically useful way and with appropriate flexibility the general idea that each person shapes up situations or events and reacts to them in a manner which expresses a tendency fairly fixed in his personality Paranoid trends, self-depreciatory and self assertive trends and obsessive and depersonalizing trends are fairly common The expression of these trends becomes extreme in psychotic and neurotic reactions this extreme expression may be moderated, but the underlying trend is not likely to be extirpated from the personality organization This persistence of personality trends can be considered fortunate for society in some ways for such trends in mildly exaggerated forms may constitute the foundation for personal careers of great social value Scholarly and scientific careers might be much less effective without the extreme preoccupation with detail which so often seems to others pedantically obsessive Even paranoid trends may serve in precipitating social reforms and political revolutions The aloof individual with the tendency to shut himself in or withdraw from what is for him a somewhat painful experience of free and easy sociability and with his tendency to depersonalize his impulse life does run grave risks of mental ill health and particularly has a grave handicap in recovering from a mental illness, but he may nevertheless when sufficiently well poised and stable, make a significant social or scientific contribution by developing a new and different point of view and helping thereby to liberate others from the inherent conservatism and stodginess of mere common sense Biographically, it is often possible and useful to trace the development of personality trends first as early modes of reaction in intrafamilial situations, and in other interpersonal situations and then as favored modes of allaying anxiety arising from intrapersonal conflicts A person may thus become more and more disposed to find certain personally predetermined issues whenever tense situations arise

Clinical experience may enable the psychiatrist to recognize frequently recurring *personal issues* about which certain patients are vaguely and indecisively preoccupied He may be able to establish promptly a mutual basis of understanding thereof between himself and the patient which may be of enormous importance for management and therapy Patients also may promptly perceive this recognition of issues sometimes with relief and sometimes with anxiety They frequently misinterpret it as mind reading' and exaggerate its extent

One of the principal differences between the highly skilled and the less skilled psychiatrist lies in the greater ability of the former to sense the nature of the personal issues with which the patient is preoccupied, and in the correlated ability to utilize the patient s own words in clarifying these issues acceptably Conflicting impulses of repentance and resentment or of gratitude and defiance may offer behavioral clues more readily perceived and understood by psychiatrist than by patient particularly by those patients who have a marked syntonic component in their temperament for they tend to throw themselves toward one or the other pole of such issues and so tend to remain unaware of the opposing impulses In a roughly approximate fashion one may say that the patient showing predominantly manic or depressive symptomatology is preoccupied over issues involving respect—self respect and respect to and from others Schizophrenic patients are more typically concerned about affection than about respect. When simple personal affection is brought into question—when one is preoccupied over the lack of this most elementary basis of acceptance by others and feels fundamentally rejected—then the most elemen

tary incentive to social conformity is dissolving The lack of this basic incentive to social living leaves the personality structure prone to dilapidation An awareness of this deep issue may help greatly in the difficult task of establishing tactful contact with schizophrenic patients whose illness is being used as a refuge from potentially bruising *emotional entanglements* In actual practical psychiatric work this sort of diagnosis of personal issues is probably more significant than the diagnosis of formal type of psychosis

Attention to personal issues personality trends temperament and constitution defense mechanisms and emotional immaturity *as shown in the modes of interpersonal relationship*—all such considerations and others of like import, tend to broaden somewhat the borderline between normal and pathologic personality functioning To express it more accurately these considerations enable one to recognize realistically that no sharp line of separation exists and also help one *to give systematic attention to significant* differences between individual patients and to whatever makes a difference Such considerations represent the modern trend to understand and utilize so far as possible the general principles of normal personality functioning in dealing with patients as the *internist utilizes physiologic principles in* clinical evaluation and care

Central Nervous System Factors—Another set of factors of fundamental importance for personality *functioning is* concerned with the *organic soundness* and *physiologic condition* of the central nervous system which is the prime integrating system of the organism An amazing amount of destruction of the brain can in some instances be tolerated without serious psychiatric disorder In general diffuse lesions are more *likely to disturb the personality* The classical example is general paresis (syphilitic meningo encephalitis) victims of *which formerly constituted about 10 per* cent of the admissions to mental hospitals it is now gradually being reduced principally by dealing more effectively with early syphilis Epidemic encephalitis and lead encephalitis are rarer determinants of psychosis Prolonged vitamin deficiencies (often associated with chronic addiction to alcohol) may produce irreversible cerebral damage as in Wernicke s syndrome A large, and increasingly larger number of psychotic conditions *are classified as due to various* types of senile and presenile degenerative changes in the cerebrum, particularly arteriosclerosis The increase is only in part attributable to the increased proportion of aged persons in the population Urbanization and inert economic dependence are statistically important determinants In urban areas about one third of all patients admitted to mental hospitals are more than sixty years of age Many of them show evidences of cerebral damage Lower admission rates in rural areas for these ages are probably to be explained by the greater tolerance for moderately incapacitated persons in farm and village households than in city conditions Probably also some help in preserving a relatively healthier social personality in grandfather' and old Uncle Joe' is provided by the better opportunities in the rural social milieu for some useful and gratifying activities even for those whose brains may be considerably impaired

The *neurologic examination* and the *medical history* provide the most reliable guide to the recognition of all the types of psychotic conditions determined by cerebral lesions Sudden and marked difficulties in *language memory and intellectual* capacity may also be characteristic of cerebral damage Serologic reactions of blood serum and cerebrospinal fluid are of primary diagnostic value *in general paresis It is wise to distinguish*, however the more actively *psychotic* features in the organically disabled patients —*e g* paranoid trends agitated depressive reactions sexual delinquencies or perversions grandiose delusions and so on as distinct from mere incapacitation The crippled personality still has much in common with the same *person s precrippled person*ality and the patient s personal functioning involves as in any other psychosis the psy*chological distortion* of situations by unhealthy interpersonal attitudes and the self defensive and self assertive struggling with such personal issues All this may be aggravated in individually significant ways by the personal meaning of the incapacitation and frustation resulting from the lesions

Fever toxins drugs vitamin deficiencies

dehydration and other noxious influences may produce delirium and other disturbances of personality functions through a temporary impairment of the nervous system although that is not the only way in which illness or incapacitation may elicit mental disorders Some persons can endure incapacitation by illness with more equanimity than others Some even seem to welcome illness as an escape or vacation from something worse Certain operations—e g hysterectomy, hemorrhoidectomy, breast amputation and so on—may involve personal meanings in disturbing ways and so elicit anxious or depressive or paranoid reactions or give such "color" to delirious reactions Preexisting anxieties or unconscious trends may be activated by special examination procedures or treatment measures for example, prostatic massage cystoscopy tube feeding testing for patency of Fallopian tubes, homatropine eye drops and others Obviously a mere medical incident of such kind can scarcely be considered of itself an adequate causal explanation of a psychosis An incident cannot be considered of serious etiologic significance in the individual patient's psychotic reaction without a fair amount of evidence that it is related to vital issues on which the patient has already developed a significant personal vulnerability Interesting examples of the multiplicity of individual factors are encountered in studying postpartum psychoses A brief delirium at such a time may be attributable on the evidence to exhaustion or drugs, but one may have to deal with a special terror of maternal responsibilities or a conflict which hinders the resolution of an old childhood jealousy of baby sister, or an unacknowledged resistance against resuming unacceptable marital relationships, or a panicky way of escape from intimate contact with an obstetrician or nurse toward whom the patient feels shamefully erotic or an autistic delusional intimacy with such a person Speaking rather generally in the psychotic reactions related to acute bodily ills some rough indication of the relative importance of impersonal factors may often be gained from the prominence of delirium or confusion and disorientation in the clinical picture

JOHN C WHITEHORN

STATISTICAL DIAGNOSTIC CLASSIFICATION

For purposes of hospital records and statistical reporting the American Psychiatric Association has agreed upon a classification which has been incorporated into the Standard Nomenclature of Disease, now widely adopted The Standard Nomenclature is codified primarily by topographic and etiologic considerations As far as possible, psychiatric conditions are classified as due to prenatal influence or to infectious or toxic or traumatic causes Other etiologic factors are considered also, such as circulatory disturbances and new growths Psychogenic' and "unknown' etiology are lumped together In large part the classification remains descriptive in terms of clinical pictures or syndromes Naturally the scheme does not succeed in being completely logical In order to be complete and inclusive it subdivides conditions to a rather artificial degree, yet the fundamental psychodynamic considerations have not been explicitly recognized because of the difficulties in codifying the multiplicity of factors that shape one s personal destiny and so contribute to determining the fact and the style of psychotic reaction

In the list given here from the Standard Classification, a parenthetical notation has been added in certain places The percentage figures given only for broad classes and only the more common classes, indicate the relative frequency of the class of disorder noted, expressed as the percentage of the total admissions to representative mental hospitals

Mental Disorders
- *Psychoses due to or associated with infection*
  - Psychoses with syphilis of the central nervous system
    - Meningoencephalitic type (general paresis) (5-10%)
    - Meningovascular type (cerebral syphilis)
    - Psychosis with intracranial gumma
    - Other types
  - Psychoses with tuberculous meningitis
  - Psychoses with meningitis (unspecified)
  - Psychoses with epidemic encephalitis
  - Psychoses with acute chorea (Sydenham s)
  - Psychoses with other infectious disease
  - Postinfectious psychoses
- *Psychoses due to intoxication*
  - Psychoses due to alcohol (5-11%)
    - Pathologic intoxication
    - Delirium tremens
    - Korsakoff s psychosis
    - Acute hallucinosis
    - Other types

Psychoses due to a drug or other exogenous poison
Psychoses due to a metal
Psychoses due to a gas
Psychoses due to opium or a derivative
Psychoses due to another drug
Psychoses due to trauma (Traumatic Psychoses)
Delirium due to trauma
Personality disorders due to trauma
Mental deterioration due to trauma
Other types
Psychoses due to disturbance of circulation
Psychoses with cerebral embolism
Psychoses with cerebral arteriosclerosis (16-32%)
Psychoses with cardiorenal disease
Other types
Psychoses due to convulsive disorder (*Epilepsy*)
Epileptic deterioration
Epileptic clouded states
Other epileptic types
Psychoses due to disturbance of metabolism, growth nutrition or endocrine function
Senile psychoses (1-15%)
Simple deterioration
Presbyophrenic type
Delirious and confused types
Depressed and agitated types
Paranoid types
Presenile sclerosis (Alzheimer's disease)
Involutional psychoses (2%)
Melancholia
Paranoid types
Other types
Psychoses with glandular disorder
Exhaustion delirium
Psychoses with pellagra
Psychoses with other somatic disease
Psychoses due to new growth
Psychoses with intracranial neoplasm
Psychoses with other neoplasm
Psychoses due to unknown or hereditary cause but associated with organic change
Psychoses with multiple sclerosis
Psychoses with paralysis agitans
Psychoses with Huntington's chorea
Psychoses with other disease of the brain or nervous system
Disorders of psychogenic origin or without clearly defined tangible cause or structural change
Manic-depressive psychoses (6-24%)
Manic type
Depressive type
Circular type
Mixed type
Perplexed type
Stuporous type
Other types
Dementia praecox (schizophrenia) (3-35%)
Simple type
Hebephrenic type
Catatonic type
Paranoid type
Other types
Paranoia
Paranoid conditions (2%)
Psychoses with psychopathic personality
Psychoses with mental deficiency
Psychoneuroses (2%)
Hysteria
Anxiety hysteria
Conversion hysteria
Anesthetic type
Paralytic type
Hyperkinetic type
Paresthetic type
Autonomic type
Amnesic type
Mixed hysterical psychoneurosis
Psychasthenia or compulsive states
Obsession
Compulsive tics and spasms
Phobia
Mixed compulsive states
Neurasthenia
Hypochondriasis
Reactive depression (simple situational reaction or other type)
Anxiety state
Anorexia nervosa
Mixed psychoneurosis
Undiagnosed psychoses
Without psychosis (0-15%)
Epilepsy
Alcoholism
Drug addiction
Mental deficiency
Disorders of personality due to epidemic encephalitis
Psychopathic personality
With pathologic sexuality
With pathologic emotionality
With asocial or amoral trends
Mixed types
Other nonpsychotic diseases or conditions
Primary behavior disorders
Simple adult maladjustment
Primary behavior disorders in children
Habit disturbance
Conduct disturbance
Neurotic traits
Mental deficiency (various types and causes)

SPECIAL PSYCHIATRIC CONDITIONS

Many of the psychiatric conditions listed in the Standard Nomenclature do not require special discussion here since they are considered in other sections of this textbook in the discussion of the specific etiologic agent, e g general paresis epidemic encephalitis lead poisoning pellagra and so on Because of the great practical importance of the individual personality in determining modes of reaction it is wise in every case to review the possible pertinence of the *General Considerations* discussed above. Special consideration is necessary, however for a few topics

Alcoholism —About 10 per cent of the admissions to mental hospitals are officially reported as due to alcoholism and another 10 per cent have alcoholism of considerable degree noted as an important contributing cause In addition general hospitals take care of many of the acutely disturbed alcoholics and there are an unknown but large number of persons not yet definitely psychotic and perhaps never going to be psy-

chotic, but who are ruining their careers and undergoing a sort of gradual personality-suicide through addiction to alcohol Of course ethyl alcohol is not the only noxious factor operating in this mass of cases Attempts to escape the distress of personal maladjustments often leads the way in alcoholism and even without alcohol many of these persons would doubtless develop other futile types of defiant dependent relationship Psychiatric assistance aimed at the resolution of inner sources of anxiety and the improvement of personal relationships may in some instances help to free one from the alcohol habit It is usually futile to attempt such treatment without hospitalization for several months Anxiety is dissolved by alcohol more easily than it is resolved by effort and understanding Nonalcoholic sociability is a primary concern in treatment and adjustment

Those interested in vitamin deficiencies have found many instances of pellagra and beriberi among heavy drinkers There is usually a deficiency in several vitamins in varying proportions the commonest lack being in the B group—thiamine, nicotinic acid (niacine) and riboflavin

The clinical pictures resulting from long continued alcoholism are quite variable but may be classified fairly sharply into three types delirium tremens Korsakoff psychosis and so called acute alcoholic hallucinosis

Delirium tremens is an acute illness of a few days duration occurring in chronic heavy drinkers and characterized by marked gross tremor and delirium with vivid hallucinations It is often precipitated by a sudden infectious illness or accident or an attack may be ushered in by a period of restlessness insomnia and anorexia Improved treatment has reduced the death rate markedly, to about 4 per cent Probably many such patients were formerly fatally exhausted by struggling against mechanical restraint and harmed by the administration of whiskey and opiates Rest, vitamins nourishment and tactful management are the main items in treatment Paraldehyde in half ounce doses is helpful in securing rest

Korsakoff Psychosis—After a prolonged attack of delirium tremens the memory may remain impaired or, even without such dramatic onset there may develop in chronic alcoholics (or also apparently, in other thiamine deficient persons) a condition of amnesia disorientation, and confabulation usually with an accompanying peripheral neuritis The condition tends to persist for weeks months or years The prognosis in cases of acute and recent onset has been improved in recent years through the administration of thiamine chloride (up to 200 mg per day) and other nutrients

Acute Alcoholic Hallucinosis Alcoholic Paranoia, and Pathologic Intoxication—In predisposed persons alcoholism may precipitate psychotic preoccupations over sexual problems Commonly there occur hallucinatory accusations of homosexual offenses or of sexual guilt to which the patient reacts more with fear than with depression Other alcoholics of more paranoid trend may make accusations of sexual infidelity against the spouse or express more vaguely a somewhat pointless disgruntlement and suspiciousness It seems probable that these hallucinatory and paranoid reactions of alcoholics are modified examples of schizophrenic disorder In some epileptics or in post traumatic personality disorders or in very unstable persons there may occur episodes of marked excitement and violence after slight alcoholic indulgence followed by amnesia This reaction is called pathologic intoxication

Mental Deficiency—The development of intelligence scales (the Binet and various others) has permitted a quantitative or pseudoquantitative measurement of large population groups from which it is apparent that the intelligence' whatever that may be which is measured by such scales has a unimodal distribution The incidence of feeblemindedness is not a definite quantity but a variable dependent upon the arbitrary selection of the dividing point The limitation of facilities for the care and training of those less well endowed in this respect has tended to overload institutions with just those feebleminded persons whose asocial and troublemaking tendencies cannot be tolerated in the community so that the institutionalized feebleminded are a rather bad lot Included among them are many mentally crippled by antenatal in

juries or anomalies and a few crippled by postnatal injuries to the brain

Much of the work of the world can be done without much intelligence, and many persons of limited intelligence have excellent personal dispositions and never become problems for school courts or psychiatrists A low level of intelligence sets a handicap in the psychiatric treatment of personality disorder when it does occur but so do the self sufficient rationalizations of the intelligentsia Sometimes the person of dull intelligence can be helped more than the bishop or the university professor

It is customary to record mathematically the results of mental tests and to classify degrees of defect thereby the scale consisting of a mental age rating standardized on "normals of comparable experience and opportunity for education Such measurements require that caution must be exercised to insure full cooperation and the absence of serious emotional disturbance or attention disorder at the time of testing as well as a reasonably comparable background of experience and incentive A good report will also state the basal mental age and the scatter, and will note special features of performance as aids to evaluating the person. It is notable that performance tests (*e g* the Kohs block test) may suffer markedly after organic brain injuries in late life while the same patient s vocabulary may remain at a high level Idiots those with the greatest defect have a mental age less than three years or if a child an intelligence quotient less than 20 (Intelligence quotient = 100 × mental age/chronologic age up to sixteen years of chronologic age) Imbeciles rate three to seven years or an IQ of 20 to 49 Morons rate eight years or more or an IQ of 50 or more

It is among the idiots that one finds the well characterized physical abnormalities—microcephaly mongolism cretinism Other special clinical varieties of feeblemindedness are those associated with tuberous sclerosis amaurotic family idiocy progressive lenticular degeneration hydrocephalus diffuse periaxial encephalitis and a recently-discovered metabolic anomaly phenylpyruvicaciduria

Schizophrenic and Affective Disorders — A great number and variety of psychotic reactions occur in early adult and middle life with no convincing evidence or slight evidence of any relationship between the type of disorder and any physical infectious or toxic cause Kraepelin made a magnificent effort to bring clinical order into this heterogenous group Operating ideologically with the concept of disease entities with characteristic course and outcome he found himself obliged in time to set up a considerable series of assumed diseases to accommodate his accumulated case studies but his best remembered contribution was the outstanding dichotomy between the so-called manic-depressive insanity (tending toward recovery and recurrence) and dementia praecox (now frequently called schizophrenia) tending toward a characteristic type of deterioration These two diagnostic terms as now employed cover between them the main bulk of psychoses without clearly defined tangible cause or structural change and together constitute about 35 per cent of admissions to mental hospitals * This sum is fairly consistent within a range of about 10 per cent up or down from year to year from hospital to hospital and in different regions but the separation into manic depressive psychoses and dementia praecox varies enormously Much of the variation is an ideological artefact reflecting different and fluctuating conceptions of what constitutes the condition called dementia praecox or schizophrenia

For example in Dayton s data for 1933 in six of the state hospitals of Massachusetts the sum of these two diagnoses ran for Boston State 27 per cent of new admissions for Danvers 38 per cent for Northampton 42 per cent for Taunton 27 per cent for Westboro 47 per cent for Worcester 24 per cent Yet there was a remarkable variance in the separation into manic depressive psychosis and schizophrenia (or dementia praecox as it is called in official reports) Boston State Hospital reported only 3 per cent as dementia praecox and 24 per cent as manic depressive psychosis, whereas Danvers was reporting almost the

* Involution melancholia, constituting about 2 per cent of first admissions is closely allied to manic-depressive psychosis and paranoid condition also constituting about 2 per cent of first admissions, is closely allied to schizophrenia and to the agitated depressions of the middle period of life.

reverse distribution, 31 per cent dementia praecox and 7 per cent manic depressive psychosis, and Northampton, 35 per cent dementia praecox and 7 per cent manic depressive psychosis There are no special reasons for thinking that there is any real difference corresponding to these differences in classification There is some reason to think that the deteriorated areas in large cities contribute unduly large numbers of dementia praecox cases but if this were happening in Boston in 1933 it should have changed the statistics in the opposite direction

It is probable that those responsible for the diagnostic classification at Danvers and Northampton were interpreting rather *strictly the criteria for a manic* depressive diagnosis and that the criteria for dementia praecox were being strictly interpreted at Boston State Hospital Comparable strictness for each group would leave the greater number of the cases (some 12 per cent to 35 per cent of all first admissions) as of undetermined diagnosis

Another view is that we deal here not with two distinct diseases or more, but with two somewhat contrasting reaction tendencies often simultaneously at work in the same patient the relative strength of these tendencies determining the preponderance of trend in the specific illness of a specific patient This method of dividing the case material splits it in three groups (1) preponderantly manic depressive types of reaction, (2) preponderantly schizophrenic types of reaction and (3) about equally balanced schizo affective or mixed types of reaction This seems to the writer the most reasonable view *and it is also his opinion* that the mixed or intermediate types outnumber the extreme types on first admissions and later become more clearly schizophrenic" or 'affective or without psychosis depending in part upon the working out of inner predetermined personality dynamics (which might theoretically be early recognized and their outcome predicted) but in part also upon unpredictable events including the quality of psychiatric treatment received The whole matter of differential diagnosis' in this field is more significantly an individual affair of personality dynamics personality structure *and* specific situation than it is one of specific ' disease or fixed 'reaction pattern" (See General Considerations) Probably space should be left in the diagnostic scheme for a few cases of 'true manic depressive psychosis" and "true dementia praecox' just as there is a space for ' true *paranoia"—just to have some nouns* to give substance to the useful adjectival terms, 'affective" and ' schizophrenic" tendencies This point of view can be reconciled with the use of the *Standard Nomenclature* by regarding these two main divisions and their numerous subheadings as merely cross sectional descriptions of phases in a potentially variable clinical *course*

There is in the state hospitals a vast and increasing accumulation of patients showing *mainly* schizophrenic tendencies, and there are excellent recovery rates for those showing mainly affective tendencies The practical importance of the results of these trends may be exemplified by the fact that nearly one quarter of all hospital beds in existence are used for schizophrenic patients Since recovery is much more probable in *the first year of illness than thereafter,* many state hospitals now have admission services to focus their best therapeutic resources and efforts on those newly admitted Some alarm has been expressed lest the human race be swamped by a rising tide of schizophrenia, but the most careful studies indicate that the incidence is not increasing

Kraepelin saw the unifying clinical principle of the dementia praecox group in an assumed uniformity of outcome in a characteristic deterioration with lack of emotional responsiveness and looked for evidences of some endogenous intoxication *Many abnormalities of an* anatomic or physiologic sort have been found—dysplastic build low basal metabolic rate low glucose tolerance *subnormal body temperature* slow circulation time impaired homeostasis and so on but these abnormalities do not statistically combine to separate out *a clear* physiologically characterized group Some have one abnormality some another and with little if any relation to the clinical picture *Rather it seems* that the candidates for schizophrenia are drawn in a significantly large proportion from among the *biologically* handicapped and the biological handicaps may be of the most diverse sort There are also some persons having schizophrenic re-

actions who seem to be fine anatomic and physiologic specimens

Bleuler, in proposing the term "schizophrenia" proposed also what he considered a more apt descriptive characterization of the primary unifying abnormality of this group—a rupture or loosening of associations (presumably by reason of neurohistologic lesions although this was later attributed by him to the schizoid temperament) The detailed features of the clinical picture were considered as brought about in a psychologic manner in the association loosened brain Perhaps the most striking and significant feature pointed out by Bleuler *in schizophrenia was ambivalence—coexistence* of contrary feelings toward the same person and the patient's awareness of these contrary feelings Perhaps all persons have some degree of ambivalence toward the more significant figures in their lives but most people are seldom aware of it feeling in general all one way at one time and all another way at another time The schizophrenic seems therefore not bound together in the same univalent (perhaps artificially univalent) emotional experience that "makes sense to the ordinary person The appearance of disorganization and disintegration is heightened by the occurrence of absurd behavior and bizarre delusions and hallucinations Indeed the very occurrence of delusions and hallucinations in the presence of good orientation seems absurd and bizarre The apparently disintegrated schizophrenic may however be highly integrated in his own peculiar way and inwardly consistent

The 'shut in' type of preschizophrenic personality was pointed out by Hoch and Meyer and Meyer postulated that bad mental habits might lead to the dementia praecox type of behavior a concept later expressed by the term parergasia"

Considered as phases in the dynamic functional adjustment to life the different styles of schizophrenic reaction can be partially understood as tentative attempts to reach a psychotic adjustment in life through accepting passive dependence not usually in a frank and outspoken way but by way of delusional distortions and disparagements which may give to the ultimate dependence an air of independence Some attain such I don't care anyway' adjustments as the Empress in prison or silly idolatry, or offensively punctilious obedience To reach such an adjustment is not easy for most of those who try that route into passivity and in the writer's opinion most of the more active schizophrenic symptomatology represents the antischizophrenic struggling so to speak, of the patient's own more active normal impulses and feelings of obligation

The formulation of the conditions called "manic depressive psychosis or allied disorders (affective disorders) has suffered much distortion from the very natural tendency of writers to set up somewhat artificial *dichotomies and antitheses Neat diagrams* portray (and exaggerate) the antithesis between elated and depressed moods Tradition sets up a contrast between these affective disorders and schizophrenia. Actually the schizophrenic and affective types of patients have more resemblances than differences There are no pathognomonic signs for one or the other condition Both groups show prepsychotic trends toward moodiness and seclusiveness Indeed one may say that any psychotic patient is somewhat schizophrenic—a bit cracked" or crazed"—terms which have the same primitive meaning as schizo phrenia' So too there is much empirical justification for the old fashioned view which set melancholia as a sort of common denominator of all psychotic reactions for most psychotic patients do have decidedly melancholy period at some time.

One of the grave dangers in the schizophrenic and affective types of reaction is the risk of suicide To prevent suicide close supervision may be needed but nagging reminders should be avoided Trained personnel and systematic routine can unobtrusively avoid many of the risks Risks may have to be taken at times to maintain reasonable opportunities for activity and recovery but it is wise to share the responsibility of such decisions with responsible relatives Two sources of error in practical judgment about affective disorders are so common and so serious as to call for special warning First, the shift from a depressed to a manic phase does not eliminate the danger of suicide it may increase that danger Second violent crimes against others

reverse distribution, 31 per cent dementia praecox and 7 per cent manic depressive *psychosis, and* Northampton, 35 per cent *dementia praecox and* 7 per cent manic depressive *psychosis There* are no special reasons for thinking that there is any real difference corresponding to these differences in classification There is some reason to think *that* the deteriorated areas in large cities *contribute unduly* large numbers of dementia praecox cases but if this were happening in Boston in 1933 it should have changed *the statistics* in the opposite direction

It is probable that those responsible for the diagnostic classification at Danvers and Northampton were interpreting rather strictly the criteria for a manic depressive diagnosis and that the criteria for dementia praecox were being strictly interpreted at Boston State Hospital Comparable strictness for each group would leave the greater number of the cases (some 12 per cent to 35 per cent of all first admissions) as of undetermined diagnosis

Another view is that we deal here not with two distinct diseases or more but with two somewhat contrasting reaction tendencies, often simultaneously at work in the same patient the relative strength of these tendencies determining the preponderance of trend in the specific illness of a specific patient This method of dividing the case material splits it in three groups (1) preponderantly manic depressive types of reaction *(2) preponderantly schizophrenic* types of reaction and (3) about equally balanced schizo affective or mixed types of reaction This seems to the writer the most reasonable view, and it is also his opinion that the mixed or intermediate types outnumber the extreme types on first admissions and later become more clearly 'schizophrenic' or 'affective or without psychosis' depending in part upon the working out of inner predetermined personality dynamics (which might theoretically be early recognized and their outcome predicted) but in part also upon unpredictable events including the quality of psychiatric treatment received The whole matter of differential diagnosis in this field is more significantly an individual affair of personality dynamics personality structure and specific situation, than it is one of specific disease' or fixed "*reaction pattern*" (See General Considerations) Probably space should be left in the diagnostic scheme for a few cases of 'true manic depressive psychosis" and 'true dementia praecox' just as there is a space for 'true *paranoia*"—*just to* have some nouns to give *substance to the useful* adjectival terms "affective" and 'schizophrenic" tendencies This point of view can be reconciled with the use of the Standard Nomenclature by *regarding these two* main divisions and their numerous subheadings as merely cross sectional descriptions of phases in a potentially variable clinical course

There is in the state hospitals a vast and increasing accumulation of patients showing mainly schizophrenic tendencies and there are excellent recovery rates for those showing mainly affective tendencies The practical importance of *the results of these* trends may be exemplified by the fact that nearly one quarter of all hospital beds in existence are used for schizophrenic patients Since recovery is much more probable in the first year of illness than *thereafter many* state hospitals now have admission services to focus their best therapeutic resources and efforts on those newly admitted Some alarm has been expressed lest the human race be swamped by a rising tide of schizophrenia but the most careful studies indicate that the incidence is not increasing

Kraepelin saw the unifying clinical principle of the dementia praecox group in an *assumed uniformity of outcome in a* characteristic deterioration with lack of emotional responsiveness and looked for evidences of some endogenous intoxication Many abnormalities of an anatomic or physiologic sort have been found—dysplastic build low basal metabolic rate low glucose tolerance subnormal body temperature slow circulation time, impaired homeostasis and so on but these abnormalities do not statistically combine to separate out a clear physiologically characterized group Some have one abnormality some another and with little if any relation to the clinical picture Rather it seems that the candidates for schizophrenia are drawn in a significantly large proportion from among the biologically handicapped and the biological handicaps may be of the most diverse sort There are also some persons having schizophrenic re-

actions who seem to be fine anatomic and physiologic specimens

Bleuler in proposing the term 'schizophrenia, proposed also what he considered a more apt descriptive characterization of the *primary unifying* abnormality of this group—a rupture or loosening of associations (presumably by reason of neurohistologic lesions although this was later attributed by him to the schizoid temperament) The detailed features of the clinical picture were considered as brought about in a psychologic manner in the association-loosened brain Perhaps the most striking and significant feature pointed out by Bleuler in schizophrenia was ambivalence—coexistence of contrary feelings toward the same person and the patient s awareness of these contrary feelings Perhaps all persons have some degree of ambivalence toward the more significant figures in their lives but most people are seldom aware of it, feeling in general all one way at one time and all another way at another time The schizophrenic seems therefore not bound together in the same univalent (perhaps artificially univalent) emotional experience that makes sense' to the ordinary person The appearance of disorganization and disintegration is heightened by the occurrence of absurd behavior and bizarre delusions and hallucinations Indeed the very occurrence of delusions and hallucinations in the presence of good orientation seems absurd and bizarre The apparently disintegrated schizophrenic may however be highly integrated in his own peculiar way and inwardly consistent

The shut in type of preschizophrenic personality was pointed out by Hoch and Meyer and Meyer postulated that bad mental habits might lead to the dementia praecox type of behavior a concept later expressed by the term parergasia

Considered as phases in the dynamic functional adjustment to life the different styles of schizophrenic reaction can be partially understood as tentative attempts to reach a psychotic adjustment in life through accepting passive dependence not usually in a frank and outspoken way but by way of delusional distortions and disparagements which may give to the ultimate dependence an air of independence Some attain such I don t care anyway' adjustments as the Empress in prison, or silly idolatry or offensively punctilious obedience To reach such an adjustment is not easy for most of those who try that route into passivity and in the writer s opinion most of the more active schizophrenic symptomatology represents the antischizophrenic struggling so to speak, of the patient's own more active normal impulses and feelings of obligation

The formulation of the conditions called "manic depressive psychosis or allied disorders (affective disorders) has suffered much distortion from the very natural tendency of writers to set up somewhat artificial dichotomies and antitheses Neat diagrams portray (and exaggerate) the antithesis between elated and depressed moods Tradition sets up a contrast between these affective disorders and schizophrenia Actually the schizophrenic and affective types of patients have more resemblances than differences There are no pathognomonic signs for one or the other condition Both groups show prepsychotic trends toward moodiness and seclusiveness Indeed one may say that any psychotic patient is somewhat schizophrenic—a bit cracked or crazed"—terms which have the same primitive meaning as schizo phrenia So too there is much empirical justification for the old fashioned view which set melancholia as a sort of common denominator of all psychotic reactions for most psychotic patients do have decidedly melancholy period at some time.

One of the grave dangers in the schizophrenic and affective types of reaction is the risk of suicide To prevent suicide close supervision may be needed but nagging reminders should be avoided Trained personnel and systematic routine can unobtrusively avoid many of the risks Risks may have to be taken at times to maintain reasonable opportunities for activity and recovery but it is wise to share the responsibility of such decisions with responsible relatives Two sources of error in practical judgment about affective disorders are so common and so serious as to call for special warning First the shift from a depressed to a manic phase does not eliminate the danger of suicide it may increase that danger Second violent crimes against others

reverse distribution 31 per cent dementia praecox and 7 per cent manic depressive psychosis and Northampton, 35 per cent dementia praecox and 7 per cent manic depressive psychosis There are no special reasons for thinking that there is any real difference corresponding to these differences in classification There is some reason to think that the deteriorated areas in large cities contribute unduly large numbers of demen tia praecox cases but if this were happening in Boston in 1933 it should have changed the statistics in the opposite direction

It is probable that those responsible for the diagnostic classification at Danvers and Northampton were interpreting rather strictly the criteria for a manic depressive diagnosis and that the criteria for dementia praecox were being strictly interpreted at Boston State Hospital Comparable strictness for each group would leave the greater number of the cases (some 12 per cent to 35 per cent of all first admissions) as of un determined diagnosis

Another view is that we deal here not with two distinct diseases or more but with two somewhat contrasting reaction tend encies often simultaneously at work in the *same* patient the relative strength of these *tendencies* determining the preponderance of *trend in the specific illness* of a specific patient *This method of* dividing the case material splits it in three groups (1) preponderantly manic depressive types of re action, (2) preponderantly schizophrenic types of reaction and (3) about equally balanced schizo affective or mixed types of reaction This seems to the writer the most reasonable view and it is also his opinion that the mixed or intermediate types outnumber the extreme types on first admissions and later become more clearly schizophrenic or affective or without psychosis' depending in part upon the working out of inner predetermined personality dynamics (which might theoretically be early recognized and their outcome predicted) but in part also upon unpredictable events including the quality of psychiatric treatment received The whole matter of differential diagnosis' in this field is more significantly an individual affair of personality dynamics personality structure and specific situation than it is one of specific disease or fixed reaction pattern" (See *General Considerations*) *Probably* space should be left in the *diagnostic scheme* for a few cases of "true manic depressive *psychosis*" and true de *mentia praecox*" just as there is a space for 'true *paranoia*"—just to have some nouns to give substance to the useful adjectival terms, "*affective*' and 'schizophrenic" tend *encies This* point of view can be reconciled with the use of the Standard Nomenclature by *regarding* these two main divisions and *their numerous* subheadings as merely cross *sectional descriptions* of phases in a poten tially variable clinical *course*

There is in the state hospitals *a vast and* increasing accumulation of patients *showing* mainly schizophrenic tendencies *and there* are excellent recovery rates for *those show* ing mainly affective tendencies The practical importance of the results of these trends may be exemplified by the fact that nearly one quarter of all hospital beds in existence are used for schizophrenic patients Since recovery is much more probable in the first year of illness than thereafter many state hospitals now have admission services to focus their best therapeutic resources and efforts on those newly admitted Some alarm has been expressed lest the human race be swamped by a rising tide of schizo phrenia but the most careful studies indi cate that the incidence is not increasing

Kraepelin *saw* the *unifying clinical* prin ciple of the dementia praecox group in an assumed uniformity of outcome in a char acteristic deterioration with lack of emo tional responsiveness and looked for evi dences of some endogenous intoxication Many abnormalities of an anatomic or physiologic sort have been found—dysplas tic build low basal metabolic rate low glu cose tolerance subnormal body temperature slow circulation time impaired homeostasis and so on but these abnormalities do not statistically combine to separate out a clear physiologically characterized group Some have one abnormality some another and with little if any relation to the clinical pic ture Rather it seems that the candidates for schizophrenia are drawn in a significantly large proportion from among the biologically handicapped and the biological handicaps may be of the most diverse sort There are also some persons having schizophrenic re

complacently convinced of his or her transcendent importance Commonly there are also hallucinations concordant with the delusions but the hallucinations may be long delayed in their appearance The more intelligent among the paranoid schizophrenics are likely to evolve elaborate systematized delusions of persecution or grandeur, or both (This diagnostic group shades off gradually through a less definitely schizophrenic group called *paranoid condition* toward a very rare and rather idealized diagnosis of *true paranoia* meaning without deterioration or hallucinations)

SIMPLE —The patient without much delusional or hallucinatory embroidery to the theme of his or her preoccupations insidiously loses interest in an active career and drifts into irresponsible vagrancy prostitution or hospitalized inertia

Personal Diagnostic Formulation.—The psychiatric diagnosis for statistical purposes in terms of the Standard Classification is seldom if ever adequate for the purpose of guiding care and treatment because a due regard for personalities and situations requires a more specific consideration of personal attitudes and their pertinence For these purposes it has become the custom in many psychiatric clinics to work out for each patient a personal diagnostic summary No uniform system has yet become standard Of several plans which have been found useful by the author the following outline is the one which includes the most definite suggestions

A *Organic Lesions Toxic Effects in the Central Nervous System and Other Somatic Factors*
(Give a brief summary of *deficits disabilities* and *handicaps* due to any of these three classes of causes as justified by clinical and laboratory evidence)

1 BRAIN LESIONS
(State nature, location extent and cause)

2 TOXIC FACTORS
(Include broadly any and all significant harmful effects from infections drugs, poisons alcohol exhaustion metabolic and endocrine disorders vitamin deficiencies uremia, anemia, momentary circulatory or respiratory failure starvation dehydration etc., which on the evidence seem to be exerting a deleterious influence on the central nervous system)

3 OTHER SOMATIC DISEASE, ACUTE OR CHRONIC
(How does it limit or hinder the person?)

B *The Personality*

1 THE CLINICAL PICTURE OR PATTERN OF PRESENT PERSONAL REACTION

(a) Adjectival Characterization
(A brief characterization as delirious confused amnesic panicky hypomanic, manic, agitated-depressive retarded-depressive anxious neurasthenic, obsessive catatonic hebephrenic paranoid hypochondriacal dissociative asocial self blaming self praising etc., or combinations thereof N.B *Destructive trends* whether suicidal, homicidal assaultive, mutilative or surgery seeking should be specially noted and evaluated, and *underlined*)

(b) Sentiment-Organization Now Dominant
(In what patterns of personal relationship does the patient now bring about, or permit, personal contact and relationship with others?)

2 BIOGRAPHICALLY ESTABLISHED CHARACTERIZATION of the patient's constitutional and temperamental assets and liabilities, personality trends and special emotional needs and vulnerabilities as developed in familial setting and exhibited in pre-psychotic life

3 ANALYSIS OF CURRENT PERSONAL ISSUE AND LIFE SITUATION

(a) The "complaint *problem*" and the patient's *attitudes* about the complaint about the life-situation and about the responsibilities involved

(b) The potential *advantages* and *disadvantages* in the present life-situation *for* the satisfaction of the patient's *emotional needs* by the type of reaction shown

4 ALTERNATIVE POSSIBILITIES by which *this* patient may resolve *this* situation more satisfactorily for *this patient's needs* with due consideration for the welfare of others

JOHN C WHITEHORN

PSYCHIATRIC THERAPY

The personal diagnostic formulation is designed primarily to provide a grasp of the considerations necessary to guide the therapy It is of primary importance to provide appropriate surgical and medical measures for conditions remediable thereby

Medical Treatment —*Placebo medication* has a legitimate diagnostic purpose but the use of placebos as a regular therapy is of dubious propriety and is unjustified when good psychotherapy is available Generous provision of vitamins is empirically and rationally justified even when no specific deficiency state is clinically demonstrable Sex hormone treatment if utilized should be cautiously integrated into the general therapeutic strategy lest conflicts be unduly aggravated

Sedative and *hypnotic medication* is widely (too widely) and intensively (too

are more commonly committed by depressed than by manic patients These practical points are also of much theoretical interest as indicating needed corrections to oversimplified formulations

As psychobiological modes of reaction the manic and depressive phases are in our culture expressive of more conventional patterns of personality integration than are the schizophrenic tendencies These patients are quite likely to have established some consistent loyalties and also to have harbored submerged resentments and frustrated ambitions without insight into this ambivalence The manic reactions may represent a sort of 'generalized rehearsal with triumph" of an opportunity previously lost through failure of self assertion The precipitating situation may be found on close scrutiny, to have seemed to offer a startling success *if only* one seized it with supreme confidence The manic assertiveness is not to be construed as a practical striving toward a particular success but as a kind of generalized demonstration of adequacy not quite convincing to the patient himself It is much more difficult to formulate a generalized functional significance in the great diversity of depressive reactions There is the common paradox of the self derogatory or self-accusatory patient who shows an amazing resistance to advice or guidance from others Some of these depressed patients seem to be driven by a sense of guilt to absurdly extreme self accusation and yet to be inwardly blocked by some self justifying resentment from that very relief which they seek through overdone repentance Other depressed patients seem more simply defeated for a time through lack of self confidence

Appropriate descriptive terms may be very briefly defined as follows

In the *retarded depressive* type or phase of reaction the patient who has been growing increasingly indecisive and feeling inadequate complains of inability to carry through any task and becomes extremely slow and groping in response

In the *agitated depressive* type or phase of reaction the patient appears harried and perplexed paces about wrings hands mutters and laments in lugubrious but insistent voice *frequently talks* in a self accusatory or self derogatory way but vaguely implies misunderstanding or *self justification* and sometimes hints at or expresses definitely paranoid delusions of persecution (Symptomatically this condition shades in one direction into that called involution melancholia in which there may be more marked somatic delusions and a more marked routinization of complaint and in the other direction into paranoid condition')

In these depressive states physiologic rhythms and functions are commonly altered Constipation is practically universal sleep is broken and the early morning *is likely to be a period of special distress* Women become indifferent or antagonistic to sex and men become impotent, appetite for food diminishes and troublesome food delusions may be expressed

In the *manic* phase of reaction the patient appears elated (or, more accurately inflated) in mood rushes with apparent assurance from one thought or action to another overflows with suggestions, criticisms and advice and is demanding and assertive toward others The underlying uneasiness and self distrust which bear witness to preoccupations identical with those of the depressed patient are only manifested in irritability, in a quickness in sensing slights and in momentary lapses into tears or dejection *Hypomanic* means mildly manic

A '*benign stupor* has been described as part of the manic depressive picture but it usually turns out to be not so benign—a tentative step toward the schizophrenic style of psychotic dependence

In *clinical symptomatology* the *schizophrenic* patient is likely to appear in one of four types of clinical picture

HEBEPHRENIC—The patient appears silly childish giggling or ecstatic *frequently* carrying on hallucinatory conversations with apparent pleasure or amusement

CATATONIC—The patient appears tense stiff manneristic antagonistic or absurdly obedient subject to long periods of motionless rigidity or outbreaks of apparently aimless excitement and activity

PARANOID—The patient appears suspicious or frightened about threatened danger or accusation or concerned about some impending greatness or special mission or

same time these hospital situations may be utilized for the mutual gain in insight of the patient and his personal associates

The Psychiatrist —The personal role of the psychiatrist and of his special nursing, social and occupational aides, in the treatment of the psychoses has been the subject of numerous special treatises which should be consulted for detailed guidance and frequent review Like all other arts psychotherapy is hard to learn from books To a certain extent it can be the subject of scientific investigation and report, but psychotherapy which has been systematized and learned by rote is likely to become excessively rationalistic and ritualistic, and fails to meet many patients' needs It also tends to shift certain susceptible patients towards an obsessive or compulsive type of neurotic adjustment.

Many patients lack *incentive to normal living* In a certain sense the psychiatrist may be said to function as a sort of ambassador between the practical common sense world and the alienated patient In the main, it is through reliability considerateness, and his special acquaintance with human problems and his skill in recognizing them that the psychiatrist assists the patient toward a more effective and gratifying personal reorientation of attitudes He seeks to aid the patient both in the better understanding of personal issues and situations, *and in the more spontaneous participation* in life

Whereas the neurotic patient may, in general in this analytic process be prepared to gain much through a fairly direct analysis of his personal attitudes it is usually better with the psychotic patient to *begin* such efforts in terms of an analysis of *situations* often most usefully the trivial situations of the moment rather than the more vital ones which the patient is likely to face only with a protective rigidity A very valuable therapeutic ability is that of perceiving the *larger issues within the trivial incidents* and of dealing with them by a kind of *double entendre* This is the main constituent of the psychiatrist's so-called intuition'

JOHN C WHITEHORN

intensively) employed in the management of restless and disturbed patients This practice is more common in general hospitals, outpatient departments and private practice than in psychiatric institutions where better organized work and recreation, warm baths and wet packs, under well trained supervision, provide more adequate and less harmful relief For the stuporous restlessness of acute exhaustion states seen in war conditions or other prolonged emergencies a special regimen of a few days of barbiturate narcosis has been found very helpful combined with generous fluids and nourishment, followed when necessary by prompt and vigorous explanation and encouragement

Amphetamine sulfate (*Benzedrine*) which came into clinical use for the treatment of narcolepsy has been found useful in overcoming mild depression Its use may precipitate paranoid reactions, or increase the agitation in agitated depressions

In recent years several types of *shock treatment* for psychotic conditions have received extensive trial hypoglycemic shock induced by insulin and epileptiform convulsions induced by metrazol or other drugs or by faradic electrical stimulation applied to the forehead Sudden and dramatic improvement in behavior or recovery from psychosis may be thereby induced in a considerable percentage of patients but the psychosis may recur Deaths from such forms of treatment are rare Postmortem examinations show in some cases diffuse cerebral injuries Fractures especially compression fractures of the bodies of vertebrae, were common in earlier procedures but have become rare with improved technic of administration Curare has been used to 'soften the convulsion The earlier shock treatments were given to schizophrenic patients who were thought to be otherwise unlikely to recover More recently the enthusiasm has shifted to the use of electro shock in depressed patients to shorten the illness It is not known by what mechanisms the shock experience may induce improvement when it occurs Final evaluations must be based on more prolonged case studies than there has yet been time to report

Surgery—There may be special psychiatric indications for surgery The surgical removal of a pulmonary abscess for example, may be good mental hygiene in certain cases for this removes an olfactory barrier to social adjustment, but plastic facial surgery or the operative correction of strabismus or other quasicosmetic surgical procedures should not be used for psychotherapeutic effect without good psychiatric teamwork to deal with the potentialities of severe anxiety reactions or paranoid developments in case the operation does not bring the desired ' popularity " Unnecessary appendectomies or exploratory operations or sham operations are not usually psychotherapeutically effective for the relief of psychiatric conditions and when tried for that purpose commonly create more trouble and enormously increase the difficulties of subsequent attempts at therapy *Leucotomy* of the frontal lobes may relieve anxiety in chronic agitated patients and the sacrifice of some measure of intelligence judgment and self control may not be too high a price to pay for this possibility of relief Eugenic considerations may justify *sterilization* In regard to sterilization as also in regard to abortion for the prevention of a psychosis it is necessary to get the concurring judgment of colleagues, and one must consider prevailing sentiments and laws Special sensitivity or emotional vulnerability such, for example as may be involved in gynecologic rectal or breast operations, may lead one to delay the operation if delay is permissible until the patient s attitude about it has been clarified or fortified

Institutional Care.—Among the more specialized psychiatric procedures *resident institutional care* is very important Protective custody of this sort may be made necessary by destructive trends in the patient, or to avoid the effect of extravagant or dangerous errors of judgment Institutional care may help greatly by providing a simplified yet active regime free from the fretting responsibilities, advice and importunities of family friends and work associates A well organized institution provides rest but it also provides appropriate and graduated work recreation and less demanding personal relationships There is usually enough variety or flexibility in hospital situations so that they can be adjusted to the changing needs of the patient and to his increasing responsibility in convalescence and at the

	mg./100 ml.
Phosphorus, inorganic, serum, adults	3-4
children	5
lipoid serum	12-14
total acid soluble serum	18-25
total serum	35-45
Potassium, blood	1.0-2.0
serum (4.1-5.6 milliequiv. per liter)	16-22
Protein total serum	6.0-8.2%
Prothrombin concentration (Warner Brinkhous and Smith)	70-100%
(Quick)	50-100%
Prothrombin time (Quick)	12-16 sec.
Sodium, blood	200
serum (139-152 milliequiv. per liter)	315-340
Solids, total	19-23%

Water content	77-81%

CLINICAL EXAMINATIONS

Bleeding time		1-3 min.
Cells, Differential count.		
Lymphocytes	1250-3500 per cu. mm.	25-35%
Monocytes	200-1000 per cu. mm.	4-10%
Neutrophils		
Young (non filament)	150-1500 per cu. mm.	3-15%
Adult (filament)	2500-6000 per cu. mm.	50-65%
Eosinophils	25-400 per cu. mm.	0.5-4%
Basophils	0-200 per cu. mm.	0-2%
Erythrocytes	per cu. mm.	4.2-5.5 million
Leukocytes	per cu. mm.	5-10 thousand
Platelets	per cu. mm.	200-500 thousand
Reticulocytes	per cu. mm.	0.5-2.0% red cells
Clot retraction time		1-3 hrs.
Coagulation time, capillary blood		3-6 min.
venous blood		5-20 min.
Congo red test. Disappearance in 1 hr. of less than 40% dye from the blood and no dye in urine		
Erythrocyte diameter average		7.5 microns
"Fragility" of erythrocytes maximal resistance		0.32% NaCl
minimal resistance		0.42% NaCl
Hematocrit (vol. % of cells)		42-50%
Hemoglobin adults females	Gm. per 100 ml	12.8-15.2
males	Gm. per 100 ml	14-17
children varies with age	Gm. per 100 ml	10-18
Icterus index		4-6
Indexes of erythrocytes color saturation volume		0.9-1.1
Sedimentation rate Cutler men		2-8
women		2-10
Rourke & Ernstene	not more than	0.4 mm. per min.
Westergren	less than	20 mm. per hr.
Wintrob men		0-9 mm. per hr.
women		0-20 mm. per hr.
Viscosity blood		1.4 to 1.6
Volume, blood	per Kg. body weight	70-100 ml
	per sq. meter body surface	2800-3800 ml

FUNCTIONAL TESTS

Bromsulfalein	No dye remaining in serum 20 min. after injecting 2 mg. per Kg. body weight
Or	No dye remaining in serum 45 min. after injecting 5 mg. per Kg. body weight.
Cephalin flocculation	No precipitate
Concentration and dilution	Sp. gr. of urine after dry day 1.025 or more; after water day 1.003 or less.
Creatin tolerance	70% ingested creatin retained in adults

NORMAL VALUES FOR CLINICAL EXAMINATIONS

With the constant multiplication of clinical examinations, the results of which are expressed in figures it becomes increasingly difficult for the clinician to keep in his memory the values that are to be expected in the normal person It seemed worth while therefore, to assemble for ready reference some of the figures commonly regarded as being within normal limits No apology is made for using 'normal' in this connection

BLOOD

CHEMICAL CONSTITUENTS

(Values are given in mg per 100 ml [1 dl 100 cc.] unless otherwise stated)

		mg/100 ml
Acetone and aceto-acetic acid		0.3–2.0
Acetone bodies total		0.8–5.5
Albumin serum		4.6–6.7%
Albumin globulin ratio serum		1.5:1 to 3:1
Amino acid nitrogen blood		5–8
Amylase serum		80–150 mg glucose liberated from starch by 100 ml blood serum
Ascorbic acid reduced plasma		0.7–1.2
Base, total serum		145–160 ml N/10 base per 100 ml serum
Bilirubin		0.1–0.5
Bromine		0.2–0.6
Calcium serum (4.5–5.5 milliequiv per liter)		9–11
CO_2 combining power plasma, adults (44–52 milliequiv per liter)		55–75 vols %
children		45–65 vols %
CO content plasma arterial		45–55 vols %
venous		50–60 vols %
Chlorides as NaCl blood		450–500
plasma		570–620
serum (99–110 milliequiv per liter)		350–390
Cholesterol blood		150–230
plasma		160–200
Cholesterol esters plasma		100–150
Creatin		3–7
Creatinine blood		1–2
Fatty acids blood		290–420
Fibrinogen plasma, as fibrin		200–600
Globulin serum		1.2–2.3%
Glucose blood		70–110
Iodine total		0.004–0.01
Iron blood		45–55
serum		0.04–0.23
Lactic acid		5–20
Lecithin		200–250
Lipase serum		0.2–1.5 ml N/20 NaOH per ml serum
Lipoids total plasma		500–550
Magnesium blood		1.6
serum (1.6–2.5 milliequiv per liter)		2–3
Nitrogen nonprotein blood		15–40
total		3.0–3.7%
undetermined		4–18
urea blood		8–15
Oxygen capacity blood		18–24%
Oxygen content arterial		15–23%
venous		10–18%
pH arterial		7.3–7.35
venous		7.2–7.25
Phosphatase acid		3–4 units
alkaline, adults	(Bodansky)	1.5–4 units
	(King and Armstrong)	14 units
children	(Bodansky)	5–15 units

Gastric test meal, free acid	24–45 degrees (ml N/10 alkali per 100 ml gastric fluid)
total acidity	50–100 degrees
volume	5–150 ml fasting
	40–50 ml 1 hr after Ewald meal
Kidney threshold for glucose	160–180 mg per 100 ml blood
P R interval in electrocardiogram	0 1–0.2 sec
Q-R-S time in electrocardiogram	0 1 sec.
Respiratory quotient, for burning carbohydrate	1.00
fat	0 71
protein	0 80
under basal conditions	0.83
Venous pressure, peripheral vein	60–120 mm water
Vital capacity	3500–4,00 ml

Sodium cyanide	arm to carotid sinus	7 sec.	5–10 sec.

in the treatment of superficial wound infections and surface burns of limited extent

Administration.—For multiple intravenous or intramuscular injections the most convenient solution is one containing 5000 units per cc of sterile physiologic salt solution, but more dilute solutions may be used when indicated When a constant intravenous infusion is used a solution containing 25 to 50 units per cc of sterile saline or 5 per cent glucose solution is usually employed Solutions for injection into the various body cavities are ordinarily made up to a strength of 1000 units per cc of saline solution For topical application in the treatment of burns and superficial infections saline solutions with a concentration of 250 to 500 units per cc are satisfactory

Action.—The action of penicillin in clinical infections appears to be bacteriostatic rather than bactericidal so that it is essential to continue treatment until the infection is definitely controlled or eradicated Not infrequently relapses occur when treatment is discontinued too soon after the first signs of improvement have appeared

The antibacterial action of penicillin is selective It is very active against certain species and almost totally without action against others those susceptible are chiefly gram positive species Except for the gonococcus and the meningococcus gram negative bacteria are not significantly inhibited by it

The following list includes the more important pathogens that have been found to be sensitive to the action of penicillin

Gonococcus	*Streptococcus viridans* (most strains)
Meningococcus	*Clostridium tetani*
Hemolytic streptococcus	*Clostridium welchii*
Pneumococcus	*Corynebacterium diphtheriae*
Staphylococcus	*Actinomyces bovis*
Nonhemolytic streptococci (most strains)	*Treponema pallidum*

Occasional strains of susceptible bacteria are encountered that are resistant to the action of penicillin Likewise in a few cases susceptible organisms have been observed to develop resistance to penicillin during the treatment of clinical infections

The following list includes some of the more important pathogens that have been found to be insensitive to the action of penicillin It can be seen that it has no effect against the whole group of gram negative bacilli

Enterococcus	*Vibrio cholerae*
Escherichia coli	*Bacillus proteus*
Bacillus typhosus	*Pseudomonas aeruginosa*
Bacillus paratyphosus	Friedlander s bacillus
Bacillus dysenteriae	Brucella group
Hemophilus influenzae	*Mycobacterium tuberculosis*
Hemophilus pertussis	*Pasteurella pestis*
Hemophilus ducreyi	*Pasteurella tularensis*
	Yeasts
	Molds

Preliminary studies have indicated that penicillin has no effective action against rickettsiae or the viruses

Indications.—While the full range of penicillin s usefulness remains to be determined clinical experience has already established the fact that it is the best therapeutic agent available for the treatment of several important groups of infections These are

All staphylococcic infections with or without bacteremia respond better to penicillin than to any other chemotherapeutic agent More than 500 cases of staphylococcic bacteremia have been treated with penicillin with 80 per cent of the patients surviving—a low mortality rate that no other form of therapy in this disease has ever achieved Of the patients with acute osteomyelitis who have been treated 90 per cent have recovered Of patients with lateral or cavernous sinus thrombosis recovery has taken place in 75 per cent

In serious localized staphylococcic infections without bacteremia improvement or recovery has occurred in more than 80 per cent of cases It should be emphasized that in this type of infection prolonged and intensive treatment is usually necessary and that recurrence of the active infection after a period of latency must be guarded against

Frequently adequate surgical management as well as the use of penicillin is nec

TREATMENT OF INFECTIONS WITH PENICILLIN*

Penicillin was discovered in 1928 by Dr Alexander Fleming who showed that filtrates of the culture liquor of the mold *Penicillium notatum* exert a potent antibacterial action on a number of bacterial species The application of Fleming s important discovery to the problem of the treatment of infections was postponed for more than a decade until Florey and his colleagues demonstrated that stable nontoxic preparations of penicillin could be produced in sufficient quantity to permit the effective treatment of infections in man The value of *penicillin as a therapeutic agent in a wide* variety of infections has now been well established by extensive clinical investigations both in England and in the United States

Penicillin possesses certain advantages that render it definitely superior to the sulfonamides Against susceptible organisms its antibacterial action is many times more potent than that of the sulfonamides At the same time even when it is administered in full therapeutic doses penicillin is entirely free of significant toxicity for the host Unlike the sulfonamides it is not inhibited by pus or the breakdown products of tissue autolysis

Description —Penicillin itself is an unstable acid For clinical use various salts of the acid are employed the sodium salt being the preparation that has been most extensively studied Recent work has indicated that the calcium salt which is less hygroscopic and somewhat more stable than the sodium salt does not differ from the latter either in effectiveness or in toxicity

The salts of penicillin are readily soluble in physiologic salt solution distilled water and 5 per cent glucose solution Since solutions of penicillin are less stable than the dried powder they should be freshly prepared every twenty four or forty eight hours Both the solutions and the dried powder may become inactivated by exposure to room temperatures for prolonged periods, hence to avoid deterioration they should be stored at a temperature below 10° C

The exact chemical structure of penicillin is not yet known, and the drug has not been prepared synthetically The preparations in use today are still obtained by extraction from the culture liquor in which *Penicillium notatum* has been grown The extracts that were first employed clinically had a very low potency and the final preparations contained 85 to 90 per cent of impurities, but recent improvements in the technics of ex*traction have produced preparations con*taining less than 50 per cent of impurities Such material possesses an activity of 500 to 800 Oxford units per milligram Pure crystalline penicillin has been found to assay about 1600 units per milligram

Pharmacology —An understanding of the pharmacologic properties of penicillin is essential if one is to achieve a maximal therapeutic effect Penicillin is inactivated by the hydrochloric acid of the gastric juice following oral administration and by the action of certain intestinal bacteria notably *Escherichia coli* after rectal instillation Its enteral administration is therefore not effective

Penicillin is readily absorbed following either intramuscular or intravenous injection but in persons with normal renal function it is rapidly excreted in the urine Consequently injections must be repeated at intervals of not more than three hours if an effective concentration is to be maintained in the tissues throughout the course of treatment Continuous intravenous drip is another satisfactory method of ensuring a constant level of penicillin in the tissues

After intramuscular or intravenous injection penicillin does not pass into the cerebrospinal fluid or the various serous spaces of the body in significant concentrations It is essential therefore that penicillin be introduced directly into the infected cavity in the treatment of meningitis empyema and infections of the joints Absorption from these sites is slow so that penicillin need be introduced locally in this manner only once or twice daily

The local use of penicillin is also of value

* The penicillin was provided by the Office of Scientific Research and Development from supplies assigned by the Committee on Medical Research for clinical investigations recommended by the Committee on Chemotherapeutics and Other Agents of the National Research Council

come negative within three to six weeks In late syphilis with cutaneous or central nervous system manifestations dramatic resolution of the signs of the local infection have been observed after treatment with penicillin It should be emphasized that the use of penicillin in the treatment of syphilis is still in the stage of preliminary investigation and that no information is yet available as to the permanency of the improvement thus effected the optimal schedule of treatment or the possible hazards of penicillin therapy especially in patients with syphilitic aortitis

Bacterial endocarditis is a disease notoriously resistant to all forms of therapy Early experiences with the use of relatively small doses of penicillin were almost uniformly discouraging More recently the administration of 200 000 to 300 000 units a day for periods of two to three weeks has produced improvement in a considerable percentage of cases However a marked tendency to relapse within a few days to a few weeks after the discontinuation of treatment has been observed in the cases that have shown temporary improvement Observations conducted over a long period of time will be necessary before any final conclusions can be drawn regarding the possibility of permanently arresting this infection

Of the forms of bacterial endocarditis that have been treated that caused by *Streptococcus viridans* has responded best Staphylococcic bacterial endocarditis with a few striking exceptions has not responded well to even massive doses of penicillin Bacterial endocarditis caused by the pneumococcus appears to occupy an intermediate position

In a few cases patients with *actinomycosis* have shown marked improvement after the administration of penicillin Relapses are frequent and several strains of actinomyces have been encountered that show a marked resistance to the action of penicillin

In mixed infections in which the predominating organism is of the gram negative flora penicillin has proved to be of questionable value In this group are included the complications following ruptured appendix liver abscesses and urinary tract infections

Penicillin has been found totally ineffective in a large group of miscellaneous diseases of known and unknown etiology, so that its use in these conditions is unjustified These conditions are listed below

1 *All gram-negative bacillary infections* typhoid and paratyphoid fever dysentery *Escherichia coli* infections *Hemophilus influenzae* infections *Bacillus proteus* infections *Bacillus pyocyaneus* infections *Brucella melitensis* (undulant fever) tularemia *Friedlander bacillus* infections
2 Tuberculosis
3 Toxoplasmosis
4 Histoplasmosis
5 Acute rheumatic fever
6 Lupus erythematosus diffuse
7 Infectious mononucleosis
8 Pemphigus
9 Hodgkin s disease
10 Acute and chronic leukemia
11 Ulcerative colitis
12 Coccidioidomycosis
13 Malaria
14 Poliomyelitis
15 Blastomycosis
16 Nonspecific iritis and uveitis
17 Moniliasis

Dosage —The dosage of penicillin varies from one patient to another depending on the type and severity of the infection Experience has shown that recovery has occurred in many serious infections following the administration of 40 000 to 50 000 Oxford units a day In other cases 100 000 to 200 000 units or even larger doses are necessary The objective in every case is to bring the infection under control as quickly as possible The following recommendations are made at the present time with a full realization that revisions may be necessary as experience accumulates

1 *In serious infections with or without bacteremia* an initial dose of 15 000 or 20 000 Oxford units intravenously or intramuscularly with continuing dosage as follows

a) A constant intravenous infusion of penicillin in normal saline or 5 per cent glucose solution at a rate of 2000 to 5000 Oxford units an hour Occasionally the dosage may have to be increased to 10 000 units an hour for the first few days
b) When a constant intravenous infusion is not desirable 10 000 to 25 000 units injected intramuscularly every three hours
c) After the temperature has been normal for two to five days omission of penicillin and careful following of the course of the disease

essary to effect recovery In many situations this agent must be considered only as an adjunct to surgery and not as a substitute for surgical procedures of established value Experience has shown however that penicillin frequently renders the surgeon s task easier by improving the patient's general condition allowing the surgeon to select the optimum time for operation, decreasing the extent of the surgery necessary and greatly shortening the recovery period

Clostridia infections such as gas gangrene and malignant edema are favorably influenced by penicillin, but large doses are necessary The urgent necessity for the administration of antitoxin and for the surgical removal of necrotic and devitalized tissue is not lessened by the use of penicillin

Hemolytic streptococcic infections with bacteremia and all serious local infections caused by the hemolytic streptococcus are best treated with penicillin The response to treatment in acute invasive infections such as cellulitis, erysipelas and puerperal sepsis is frequently dramatic Cases in which the infection has become localized with destruction of tissues and impairment of the blood supply as in empyema peritonitis and meningitis may require more prolonged treatment before recovery is assured

Anaerobic streptococcic infections respond irregularly to the use of penicillin In several cases a striking therapeutic response has been observed, in others penicillin appears to have had no effect on the course of the disease Since it may be effective and since it is known that the sulfonamides are never effective the use of penicillin in all cases of anaerobic streptococcic infections appears to be indicated

Pneumococcic infections of all types are definitely susceptible to penicillin and its use is frequently advisable This is true in all pneumococcic infections in which for any reason the sulfonamides are contraindicated or in which their use would be hazardous It is also true of cases of pneumococcic pneumonia in which there is definite or strongly suggestive evidence that the infecting strain is resistant to the sulfonamides

In *three types* of pneumococcic infections penicillin is definitely the *drug of choice* Before the advent of penicillin pneumococcic bacterial endocarditis was inevitably fatal With its use an occasional recovery has been observed, although in the great majority of cases the outlook is still unfavorable

About 45 per cent of the patients with pneumococcic meningitis treated with penicillin have recovered a result somewhat better than that generally obtained with the sulfonamides In this disease penicillin should be given both intrathecally and intramuscularly or intravenously for ten to fourteen days It also appears advisable to administer the sulfonamides concomitantly, since penicillin injected intrathecally may not reach all regions of the subarachnoid space and the ventricular system in adequate concentration

In pneumococcic empyema it is frequently possible to sterilize the pleural cavity by three or four injections of penicillin directly into the empyema cavity at intervals of twenty four to forty eight hours In about 50 per cent of cases the fluid is resorbed without recourse to surgical drainage

Gonococcic urethritis or cervicitis resistant to the sulfonamides can be effectively treated with penicillin in 98 per cent of cases In addition it seems advisable to treat with penicillin all cases of gonococcic infections complicated by arthritis ophthalmia peritonitis salpingitis, epididymitis and endocarditis Cases in which such complications are present require more prolonged treatment than do those presenting only a simple urethritis or cervicitis

Meningococcic meningitis is best treated by the sulfonamides In cases in which the infection fails to respond to adequate sulfonamide therapy the use of penicillin may effect recovery

There are three important diseases in which penicillin s an effective agent but in which there has not been sufficient time as yet to define its position These are syphilis bacterial endocarditis and actinomycosis

In both *early* and *late syphilis* the use of penicillin is followed by striking changes In primary and secondary syphilis spirochetes disappear as rapidly from the local lesions as they do after the use of the arsenicals while the serologic tests for syphilis usually be-

INDEX

NOTE In this index the expression *vs* has been used to denote differential diagnosis Thus Abscess subphrenic *vs* pleurisy with effusion is the equivalent of Abscess subphrenic, differential diagnosis with pleurisy with effusion

2 *In chronic localized infections* such as osteomyelitis a dosage schedule of 10 000 to 15,000 units injected intramuscularly every three hours is usually effective Treatment should be continued until cultures from the local lesions have been sterile for five to seven days

3 *Sulfonamide resistant gonococcic infections*

a) In uncomplicated urethritis or cervicitis 10 000 units given every three hours intramuscularly or intravenously for ten doses has proved effective It is likely that the same effect can be obtained with the administration of 20 000 units every three hours for five doses The results of treatment should be controlled by culture of the exudate

b) When complications are present treatment for three to five days may be necessary

4 *Empyema* —30 000 to 40 000 units of penicillin dissolved in normal physiologic saline solution should be injected directly into the empyema cavity once or twice daily after the aspiration of whatever pus or fluid is present Treatment should be continued until no organisms can be found on either smear or culture of the exudate

5 *Meningitis* —Penicillin must be administered intrathecally since it does not penetrate the subarachnoid space in appreciable amounts Ten thousand to 15 000 units diluted in physiologic saline solution to a concentration of 5000 units per cc should be injected into the lumbar sac or the cisterna magna once or twice a day Intramuscular or intravenous therapy should be given concomitantly Both parenteral and intrathecal therapy should be continued for several days after apparent recovery

Toxic Reactions —Penicillin has been administered to several thousand patients without causing any serious toxic reactions No deleterious effects on the kidneys liver or hematopoietic system have been observed The reactions that have been observed include pain at the site of intramuscular injection thrombophlebitis at the site of intravenous injection occasionally accompanied by chills and fever and in a few cases diarrhea with or without abdominal cramps One reaction deserves special mention From 2 to 5 per cent of the patients receiving penicillin develop urticaria This phenomenon may occur on the first day of therapy or may not occur until several days after therapy has stopped More commonly, however, it appears between the seventh and fourteenth day of treatment Aside from the discomfort that it causes the patient it does not appear to be serious Frequently it has disappeared after a few days while therapy has been continued Readministration of penicillin at a later time may or may not evoke urticaria

At present there are no known *contraindications* to the use of penicillin in the treatment of susceptible infections
